Preface

This Companion to the Mind has been companion to my mind, throughout her ten years of gestation. I am grateful for her friendship; and honoured by the trust accorded me by the Oxford University Press, without whose generous help and advice through this long time she would not have been born.

Her inception followed a gleam in the farseeing eyes of Michael Rodgers, who was then an Oxford University Press editor. He approached me to take on the task of editing a Companion to the Mind, following a perhaps tooambitious scheme that I had submitted a year or two before for an Encyclopaedia of Concepts, or ideas, to cover the whole of science and even more as it would extend into philosophy and perhaps the arts. This scheme unfortunately foundered in the planning stage, as it was deemed impracticable; but somehow this proposal must have led to the notion of a Companion to the Mind—to be written by a wide range of authorities on as many aspects of Mind as possible: to be interesting, useful, and understandable not only to experts but to anyone interested in normal or abnormal behaviour, human potentials that might be enhanced, the biological origins and evolution of man, the deeply difficult philosophical questions of relations between Mind and matter (both in brains and computers), and those perpetually puzzling questions of free will, and what is perhaps the main mark of Mind—intentionality. Some of this is necessarily technical, and much depends on certain key concepts which (and this is a criticism) are not familiar to us from our schooldays.

In particular, the structure and function of the nervous system is important for considering perception, behaviour, skill, arousal and attention, thinking, effects of drugs and of brain damage, and a great deal more. For, in a physical sense, the structure and function of the nervous system are what we are. It was, also, deafly desirable to avoid the need to define technical terms (such as 'neurone', 'synapse', and so on) in each entry where they may occur. So early on it was decided to include (for the first time in an Oxford Companion) a *tutorial*, on the basic plan and function of the human nervous system, together with useful definitions of oftenoccurring technical terms which might be unfamiliar. This tutorial (' *Nervous System*') is written by the distinguished neurologist Peter Nathan, from the National Hospital for Nervous Diseases, Queen's Square, London. All the entries, including this introduction to the physical basis of mind, are specially written for this book.

The range is wide, as the concept of Mind accepted here is far broader than what may (at least at first) come to mind, as one thinks of Mind: especially thinking and consciousness. We do not, however, limit 'Mind' to consciousness, or awareness, for even long before Freud it was clear that a great deal goes on 'mentally' that is beyond (or beneath, or at least outside) our awareness. Here we present contributions from over a hundred experts on Page vi

many aspects of the nervous system and its functionings—and all manner of malfunctions. These focus not only on such diverse and clearly very important topics as education; human, animal, and computer intelligence; sex; subnormalities; genius; learning; language; diminished responsibility in law; drugs; art; a great variety of philosophical accounts, and puzzles of Mind that can intrigue all of us; but also on more way-out topics (which some may reject out of hand but which we feel should be presented for discussion) such as parapsychology, and various widely held beliefs which are frankly outside science, such as blood myths and the origins of powerful fantasies such as Dracula and Frankenstein. Then there are state-of-the-art technical, and specifically medical, contributions on matters of concern for many people and indeed ultimately for all of us. All these, and much more, are presented and discussed here, as Mind is widely (and we hope in some depth) considered in this book.

A problem throughout has been the inclusion—or not—of biographies of the many philosophers, scientists, educators, doctors, and writers of all kinds who have contributed knowledge and advanced ideas over the centuries. As it has turned out, the selection of biographies is only partial, as this is not primarily a historical work and in any case makes no claim to completeness. Following misgivings, we finally decided against the inclusion of any biographies of living persons. This should at least protect us from some inevitable criticisms of omission! On the other hand, the *work* and *views* of very many people, both living and dead, are discussed in appropriate subject entries; their names can be found in the index (p. 821).

How were the contents planned? They were based on an initial list of topics of just about everything one could conceive of as relevant, having possible interest or use.

Appropriate lengths were estimated, and authors (at first mainly friends and colleagues from around the world) were selected and invited to contribute. Then the fun started—and went on and on for years and years. The correspondence files grew even faster than the piles of manuscripts, and many were the bribes, threats, promises, and shared jokes (which were especially effective and mutually rewarding), which were vital stimuli for action—but now lie silent in the dark, their work done.

Angela Sainsbury, then Kate Tiffin, spent many evenings not only typing letters and sorting and filing, but suggesting new entries and improvements. Their careful work and enthusiasm is greatly appreciated. Following the vital initial work at the press by Michael Rodgers—who was both soundingboard and his own voice, as we walked in the meadows in Oxford, lunching at the Trout, while building up the book in our minds—the responsibility devolved upon Bruce Phillips, Dorothy McCarthy, Nick Wilson, and Christopher Riches, then finally on Pam Coote who focused the enterprise to completion—undertaking with wonderful effectiveness the intimidating task of cutting entries down to size, and with her colleagues going through the proofs. It is very important (as by now I have learned several times) for an editor, or author, to have ready understanding and mutual trust

(which must, however, be based on Page vii

evidence!) with his publishers. However it be for Nature, a vacuum is abhorrent to inspiration.

Thanks are due to John Cottingham who read all of the philosophy entries, suggesting and making many improvements; to Professor F. A. Whitlock who provided valuable help with the psychiatry entries; and to many other advisers.

It is most pleasant to record that several of my teachers have made major contributions to this book. Here I particularly record that one of my Cambridge teachers, Derek Russell Davis (now Emeritus Professor of Mental Health at Bristol) proved (as I expected) singularly adept at writing lucidly and instantly on any topic requested. Several of my students also are represented here; though just a few it must be confessed have not improved over the years in getting their essay in on time!

Most of all, thanks and gratitude are due to my exboss at Cambridge, who succeeded my teacher Sir Frederic Bartlett in the Psychology Department: Professor Oliver Zangwill. Upon his retirement, Oliver Zangwill devoted a lot of his time and energy to going through the entire manuscript, pointing out inconsistencies, and suggesting and implementing many improvements and filling important gaps, often with his own writing. (These omissions were not like those a book reviewer once described: 'This book fills a much needed gap'.) Oliver Zangwill repaired inadequacies due to my lack of appreciation of several topics that he rightly saw to be significant and interesting.

Authorships are given for each entry, with initials to be identified from the list of contributors (p. ix). My own entries (which, when written, were often abandoned in favour of superior accounts as they came in) are left without initials; except for 'R.L.G.' on some for which I had no doubt unjustified pride, or (more often) regarded as controversial and so needing explicit authorship.

Some authors have, sadly, died since contributing. This includes the great Russian neuropsychologist, whom I had the pleasure of meeting at Cambridge and Moscow—Alexander Romanovich Luria—whose very last writings (which he tapped out on a portable typewriter on the shore of the Black Sea) now appear in this book. These he wrote in English, in which he was fluent. As he wrote with Russian sentence constructions, which can be quite hard to understand, Luria's last writings have been 'Englished', by a Russian scholar with a knowledge of psychology, Armorer Wason. By and large, editing has been light, as clearly each contributor should speak for him or herself; but occasionally I have cut sections I was perfectly certain were in error, and sometimes, in the cause of clarity, modified punctuation.

Occasionally, for various reasons, entries have been 'dropped' at the final stage of editing; here apologies are due to their authors, which will I hope be accepted, as inevitably overlaps occurred which could not be allowed to remain.

It is hoped that this book, as it falls hot from the press, will be interesting and useful. It could be, however, that in a hundred year's time it will be even more interesting to the specialist—to see who wrote what and to guess why we think about Mind as we do now. There is no one way of thinking or

writing about these many topics. I can only hope that encapsulated here—and not entirely

Page viii

limited to the Western tradition—there is a familiar sample of the facts and fancies, the perceptions and conceptions, of our past and present understanding of what we all recognize as deeply mysterious, though they are our reality— the many hidden faces of Mind.

Note to the Reader

Entries are arranged in strict alphabetical order of their headword, except that names beginning with Mc are ordered as if they were spelt Mac. Crossreferences between entries are indicated either by means of an asterisk (*) in front of the word to be looked up, or by the use of 'See' followed by the entry title in small capitals.

Crossreferences are given only when reference will provide further information relevant to the subject under discussion; they are not given automatically merely to indicate that a separate entry exists. The comprehensive index at the back of the book, includes not only the subjects discussed within entries but also the names of the contributors and the principal author of each bibliographical reference.

A

ABACUS. Ancient calculating instrument in which numbers and operations (especially adding) are represented by the numbers and positions of pebbles or (later) beads on strings or wooden rods; it may be regarded as an early form of*digital computer. Although it originated in prehistoric times, the abacus is still widely used especially in China and Japan. The fact that this 'mind tool' can vastly improve mental arithmetic might suggest that the unaided mind functions on very different principles (perhaps that thinking is analogical rather than a digital process). Just as, if fingers were like screwdrivers we would not need screwdrivers, so, if the brain worked like an abacus, beadcounters should not be so helpful. But perhaps the abacus serves as a memory.

Our language reflects the importance of the abacus throughout history. The word 'calculate' comes from the Latin word for a pebble, and the term 'Exchequer' derives from the chequered table on which counters or jettons were moved to reckon the nation's accounts (the abacus continued to be used for British governmental accounting into the eighteenth century). The mechanical calculating machine with geared wheels (invented by Blaise*Pascal in 1642) is a direct development of the abacus; and this in turn led to Charles*Babbage's programmable wheeled calculator and, eventually, to today's electronic computers.

Pullan, J. M. (1969). *The History of the Abacus*. New York.

ABNORMAL describes behaviour or an event that differs from the familiar or usual. Just how, bizarre, unusual, or even antisocial behaviour must be in order to be classified as 'abnormal' depends on many factors that change with knowledge and with social preconceptions. Thus, for example, classification might depend upon whether or not the behaviour was socially acceptable or whether there were symptoms, however minor, of an underlying problem or disease already regarded as abnormal. Such classification is helpful when it leads to useful treatment, therapy, or special education, but it can also be dangerous, for in extreme cases it can take an unusual or gifted person away from society.

The probability of an abnormal event occurring against chance can be predicted from statistical tests. In scientific research such tests are important in establishing whether an event is unusual enough to require special explanation. In clinical situations, however, applicable tests are difficult to establish, because classification of abnormal events depends on factors that are changeable.

ABRAHAM, KARL, German psychoanalyst. See FREUDIANISM: LATER DEVELOPMENTS.

ABREACTION. A recalling or reexperiencing of stressful or disturbing situations or events which appear to have precipitated a neurosis. During the recalling the patient is encouraged to give an uninhibited display of emotion and afterwards it is hoped that the neurosis will have vanished. Abreaction was used by Josef*Breuer in the treatment of patients with*hysteria; in a modified form, it still finds some applications in modern psychiatry, especially in the treatment of battle stress.

ACCELERATION. Acceleration of the body is sensed in the inner ear by the otoliths, small weights of calcium carbonate suspended on stalks. Accelerated movements of the head produce deflections of the stalks, since the otoliths do not respond immediately to movement because of their inertia. Unaccelerated motion cannot be sensed intrinsically by any sense or by any physical instrument, but only by reference to external objects that may themselves be moving. So there is ambiguity, such as occurs when a stationary train appears, to one who is in it, to move when a neighbouring train moves past it. Here the visual sense of movement dominates the sensing of acceleration—or rather the lack of acceleration—for the observer in the stationary train.

ACCIDENTAL PROPERTY. See CONTINGENT PROPERTY.

ACCIDENT PRONENESS is a deceptively easy term. We all know what it means but we do not all mean the same thing. Since the ambiguities arise partly because of the way we speak about accidents, it may be helpful to clarify this term.

An accident refers to the results of an action, generally to an unplanned, even an unexpected result. It has been described as 'an error with sad consequences', but the relationship between the preceding behaviour and the consequences is not at all simple. A timehonoured example of an accident is a person falling flat as he slips on a bananaskin—an act, incidentally, that few have ever witnessed and which conveys the impression that the world at one time must have been littered with bananaskins. In such an example the person who slips has the accident for which he was partly responsible. But we also speak of someone having an accident when something falls on him. *A* spills a cup of tea over *B* and we say that *B* has suffered an

accident. To add to the confusion, different kinds of action result in similar accidents, while the same act often has very different results. Hence, if we are to understand accidents we need to understand the preceding behaviour. But accident data are usually only records of the outcome of actions.

There is a further complication. It is a feature of accident statistics that the more severe the accident (particularly a fatal injury), the more accurate is the record. But the majority of accidents are relatively trivial, and in our society the greatest number occur in the home and often go unrecorded. The basis for extrapolation, therefore, is somewhat shaky. Nevertheless we can be confident that over the years the trend of incidence in different kinds of activities has shifted. Industrial accidents are no longer the major component; rather, the home and transport make up the bulk of the total. This shift is important, for a quick inspection of a nation's annual accident data shows such regularity from year to year that it might be concluded that accidents were an inevitable consequence of man's mobility. Closer scrutiny reveals that within the total of accidents the pattern has shifted from one class of accidents to another.

Within this general framework, it is accepted that the risks inherent in some activities are greater than in others and that the chances of accident also fluctuate with varying environmental conditions: changes in lighting, humidity, temperature, for example. The behaviour of the individual is the common factor, and inevitably explanation has been sought of the proneness to accident. The direct question has been asked: in the same circumstances, do individuals differ in their liability to

accident? In everyday thinking about skilled actions, some individuals would be more proficient than others; conversely, some individuals would be less so, and to that extent they would have more accidents. This straightforward and rather simple line of thought presumed that a single measure of overall performance provided a reliable index of the skill of a performer. But a performer's degree of skill is not necessarily an index to his liability to accident. A palpably poor driver of a car may be aware of his fallibility and drive more cautiously, with the result that he has fewer accidents than a skilful but overconfident driver. It is necessary to analyse the skill in some detail if it is to provide a guide to accident liability.

Even so, accepting for the moment that we may use an overall measure, it is easy enough to demonstrate in statistical data that some individuals over a limited timeperiod incur more accidents than others. It is tempting to infer that this identifies those who are more liable to have accidents—the accidentprone. But, of course, such an inference is not necessarily justified. In a normal distribution of random events over a sample timeperiod, some will occur more frequently than others.

Early research workers, such as Greenwood and Yule (1920), were well aware of these statistically attractive fallacies and, though their data indicated that some individuals had incurred a high proportion of the accidents in situations where other factors were equal, they stressed the need for caution. But in 1926 Farmer and Chambers suggested the term 'accident proneness' for this liability to incur accidents, and such is the power of an attractive label that it was universally accepted, not as a tentative guess to be examined by further research, as they proposed, but as an established fact. The concept of accident proneness was taken a stage further by Flanders Dunbar in America who claimed that a personality trait of accident proneness was proven fact. She gave psychodynamic interpretations which claimed that persons involved in repeated accidents had some unconscious need for physical trauma. Later she had to modify her original views about accident proneness being an enduring personality trait when it was pointed out that some of these so-called accidentprone personalities ceased to have accidents as they grew older.

The history is typical of what happens when scientific ideas are accepted on too little evidence. For a time accident proneness became the major explanatory concept in its field; then in the 1940s doubts began to creep in and by the 1950s careful assessments were pointing out that the evidence was insufficient. Soon opposition swung well beyond this point, as in the highly critical major review of Haddon, Suchman, and Klein (1964). During the 1960s, the fact that the statistical evidence failed to demonstrate the existence of accident proneness was interpreted as a refutation of all hypotheses relating to it. The pendulum had to swing back, and in 1971

Shaw published her comprehensive analysis of accident proneness. She avoided an extreme position. She conceded that many characteristics of behaviour change with age and that it is not true that most accidents are sustained by a small number of people. But she examined in detail earlier studies and demonstrated the importance of certain factors such as *attention (defined as the ability to choose quickly and perform a correct response to a sudden stimulus), the stability of behaviour, and the involuntary control of motor behaviour. She supported the study of car drivers—'a man drives as he lives'—and the finding that a bad civil record tends to indicate a bad accident risk.

Where does this leave accident proneness? In spite of, perhaps because of, much contentious writing the problem is still with us and becoming of increasing importance as accidents, the twentieth century disease, assume an ever greater significance in mortality rates. Now, if accident data are not recording behaviour directly but its consequences, then the less the probability of an accident following an action, the more insensitive the data as an index of behaviour. Little can be inferred about, say, the behaviour of pedestrians at railway level crossings from accident data for, fortunately, there is little data—but what if behaviour could be recorded directly? In general the

Page 3

problem would be lessened, given guidance on the kinds of behaviour that cause accidents, or if the number of situations that have to be studied were reduced. Some beginnings have been made with detailed examinations of the behaviour of drivers on the roads, and these should be extended into the home and to other everyday situations. An understanding is required of the basis of human skills, and fortunately advances have now been made in this field of study. When a human operator is carrying out a skill, he is receiving signals from several sensory modalities and initiating responses to them. The whole process is conceived as an information loop. The operator is in the centre and the information is measured statistically in terms of the probability of the signals. Though this concept may seem at first sight a little removed from everyday thinking, a moment's reflection will show that it is not. We expect to see certain things under certain conditions and we know how we shall respond. For example, it is no surprise to drive round a corner and see another car; it would be to see an elephant. And evidence shows we respond more quickly to the car than we would to the elephant, or, to put it another way, the more certain the signal, the less information in a statistical sense it carries. If, then, we conceive of a skill as processing information, one essential is for the operator to reduce the amount of information by anticipating the probability of different signals. It is a truism to say that accidents occur when the operator has too much information to process in too little time. One way to handle such situations is to know which events are likely to occur.

But although a sensitive analysis may be made of human skills, and insight gained into how a person's propensities vary with different tasks and at different stages of his life, knowledge of how performance is affected by the personality of the individual is still sketchy. Over and above the psychomotor skill itself, there is a further influence reflecting the personal qualities of the performer, and exactly how this affects accident proneness is not known. The influence differs according to the state of fatigue or the vigilance of the operator, to the difficulty or length of the task, to the importance of the occasion, and so forth. This area requires much more study, but we see its importance exemplified in the case of age. It is often said, 'Tell me a person's age and I will tell you what accidents he may have.' The under 25s contribute disproportionately to road accidents the world over (seen even when experience is held constant over different age groups). Similarly the over 65s contribute a large proportion of the psychomotor *accidents in the home*, which are generally due to falls as control deteriorates. It is a question of coming to terms with the varying skills we possess as life advances. Finally, there is the puzzling and recurring example of accidents that turn out to be anything but accidental. Investigation into the antecedent history of the individual in these cases suggests that the behaviour causing the accident was highly predictable and that the accident had the inevitability of Greek tragedy. It was fitting that Michael Ayrton added a new dimension to the

classical myth of Daedalus and his son Icarus; under his interpretation it was no mischance that Icarus flew too close to the sun god, Apollo, and thereby caused the wax of his wings to melt: it was his act of challenge and defiance.

ACCOMMODATION (OF THE EYE). The lens in the eye of landliving vertebrates focuses by changing the curvature of its surface, a process known as

'accommodation'. In fish the lens moves backwards and forwards as in a camera. Accommodation brings objects of interest, when fixated on the centre of the retinas in animals that have foveae, into sharp focus. This is achieved by 'hunting' for the sharpest image (or highest spatial frequency response of the eye), as there is no available signal indicating whether accommodation is set too *far* (insufficient curvature of the lens) or too *near* (too much curvature). Spectacles can correct for too great or too small a curvature of the lens, to give focused images when the eye's accommodation is incorrect or, as almost invariably happens in middle age, when the lens of the eye becomes too inflexible to change its shape to keep the image in focus for a wide range of distances of objects. Spectacles were invented in the thirteenth century in the West, and earlier in China. Several inventors have been suggested, especially Salvino d'Armato (d. 1312), and Roger Bacon (?121494), who also described the magnifying glass.

ACETYLCHOLINE (ACh). An important*neurotransmitter, liberated at nerve endings, that transmits nervous impulses to muscles or to other nerve cells. Once released, acetylcholine has a very short existence as it is quickly broken down by the enzyme cholinesterase. See NERVOUS SYSTEM.

ACTION POTENTIAL. See NERVOUS SYSTEM.

ACUPUNCTURE. See PAIN.

ADAPTATION OF THE EYES. See VISUAL ADAPTATION.

ADDICTION. For most people the concept of drug addiction is dominated by images of physical and

mental degradation brought about by the use of heroin and cocaine. It is generally forgotten that the most widely used*drugs are caffeine (in tea and coffee), nicotine, and alcohol; and that the most successful drug 'pushers' are tobacconists and publicans. Of course the great majority of those who enjoy these drugs are not necessarily addicted, if addiction means a tendency to excessive use of the drug, a craving for it when it is not available, and the development of a variety of physical and psychological symptoms when it is suddenly withdrawn.

Addiction is a difficult word to define, and a WHO expert committee in 1970 substituted the words 'drug dependence'. This is characterized by psychological symptoms such as craving and a compulsion to take the drug on a continuous or periodic basis, and physical effects developing when the drug is withheld or is unavailable. Although many drugs will meet these criteria, those of overriding concern are the opiates, alcohol, and the sedatives, particularly barbiturates, all of which cause both physical and psychological symptoms of dependence. Other drugs of significance are stimulants such as cocaine and the amphetamines, the hallucinogens, of which mescaline, and lysergic acid diethylamide (LSD) are examples, and cannabis. Most of these drugs do not induce the symptoms of physical dependence associated with abrupt discontinuance, and it is their psychological effects which are the main driving forces behind their continued use. Glue sniffing and the inhalation of volatile solvents by children are probably increased by publicity. None of these substances can be regarded as addictive; apart from the risk of liver damage from the solvents, the chief danger is from asphyxia, should the user place the glue in a plastic bag and pull it over his head. Glue sniffing is a form of behaviour which usually ceases with adolescence—and possibly with legal access to alcoholic drinks.

Although government concern centres principally on the illegal use of heroin, the number of known 'addicts' is relatively small in comparison with the very large number of people who have become dependent on alcohol. Precise figures are impossible to obtain but, as the purchase of alcoholic drinks has increased considerably over the past few decades, so has the number of alcoholics. A wellknown formula has related the estimated number of alcoholics in a community to the annual consumption of liquor calculated as pure ethanol per head of population. In Great Britain the overall consumption of alcohol between 1950 and 1976 increased by 87

per cent, and it was estimated that in 1979 there were at least 300,000 alcoholics in the country. Whereas in the past alcoholism and excessive drinking were mainly male attributes, over the past few decades there has been a sharp increase in the number of women damaged by intemperance, a phenomenon which is probably related to the ease of purchase of liquor from supermarkets and other retail outlets, and of its concealment.

The problem of addiction to alcohol is not peculiar to the twentieth century. The Romans passed laws to control drunken charioteers and Victorian philanthropy was well acquainted with the evils of drink. Now as then, excessive drinking results in medical and social damage. Research in Great Britain and Australia has shown that 1520 per cent of hospital beds are occupied by patients suffering from diseases or injuries directly or indirectly brought about by excessive indulgence in alcohol. As its consumption has increased, so have deaths from cirrhosis of the liver and the other diseases it causes, while psychiatric hospitals are familiar with the acute and chronic psychoses due to it. The social

damage is not always recognized or acknowledged. In Great Britain, Australia, and the USA, for example, some 50 per cent of deaths and injuries from car crashes and 2040 per cent of other accidental deaths such as falls, drowning, and incineration can be attributed to the effects of alcohol. It is impossible to obtain accurate figures on the role of alcohol in occupational accidents but there is a striking correlation between the numbers of patients admitted to hospital with alcoholism and those of patients undergoing treatment for injuries sustained at work. The contribution of alcohol to antisocial behaviour is well known: violence in the streets, at football matches, and in the home; the battering of wives and of babies are all familiar examples of the phenomenon. Criminal behaviour such as rape and homicide can often be attributed to intoxication of the aggressor and, in some cases, of the victim as well. Yet in the West it continues to be a widely advertised drug; from it in 1983 the British government reaped tax of £3,900 million. As to nicotine, in recent years much publicity has been given to the contribution of tobacco to diseases of the heart and lungs to whose aetiology heavy smoking is an important contributor. Following the introduction of tobacco into England in 1565, James I wrote his trenchant 'Counterblaste to Tobacco' (1604). Wiser than some other rulers, however, he did not attempt to ban its use but placed a tax on it; and governments ever since have found it a singularly lucrative source of revenue.

The reputation of heroin with its addictive properties may mislead some people into thinking that other drugs are relatively troublefree. But in the case of sedative drugs, the widespread use of barbiturates—predominantly by middleaged women—in the 1960s was an epidemic which caused considerable ill health and an increase in the rates of suicide and attempted suicide. For therapeutic use they have been largely superseded by the safer benzodiazepines (Valium, Mogadon, etc.—see PSYCHOPARMACOLOGY), though these are not so free from addictive potential as was believed initially. Sudden cessation of their regular use by an individual accustomed to them can cause a drugwithdrawal syndrome with both physical and psychological symptoms (Ashton, 1984). While their popularity for the control of anxiety,

Page 5

insomnia, and a variety of psychosomatic symptoms is testified to by Tyrer's estimate (1980) that some 40 billion doses were being consumed each day throughout the world, the publicity given to benzodiazepine dependence in recent years has probably influenced doctors towards greater caution in prescribing them for long periods of time. The greater the dose and duration of consumption, the greater is the risk of dependence developing.

Cannabis (also known as marijuana, pot, and hashish) grows wild as hemp in many parts of the world. It was used medicinally in China as long ago as 2737 BC, Herodotus (c.484/425 BC) mentions its being inhaled by Scythians as part of a funeral ritual, and the physician*Galen says that it was customary to give hemp to guests at feasts to promote hilarity and happiness. In recent times every kind of evil has been attributed to smokers of marijuana (see Schofield, 1971), but the evidence for these baneful effects is far from satisfactory and there are singularly few dangers to health that can be attributed to cannabis alone—though anyone driving while affected by cannabis is at risk, and even more so if alcohol has also been consumed. Few addicts confine their intake to a single substance,

and interactions are often more hazardous than the effects of single substances; even so, the cultivation and possession of hemp products are generally prohibited by law. Whether such laws should continue has become a matter for continued debate.

The control of drug trafficking and misuse is based on the United Nations Single Convention on Narcotic Drugs (1961) to which most countries are signatories. This instrument wholly restricts the use of a wide range of substances and requires governments to enforce by punishment its regulations on the cultivation, manufacture, and sale of the drugs listed. Unfortunately, total prohibition of the recreational use of drugs which users are determined to obtain appears to be a singularly unsuccessful policy, as the USA discovered when alcoholic drinks were forbidden for nearly fourteen years from 1919. Attempts by governments to prevent their citizens from smoking tobacco have been equally futile: suppliers were liable to decapitation in ancient China; smokers were tortured to death or exiled to Siberia in Tsarist Russia, and had molten lead poured down their throats in Persia; and the popes from time to time threatened excommunication. Similarly, with suppliers and users of opiates and cannabis, the draconian laws of some countries seem not to inhibit those who are prepared to risk apprehension.

In the United Kingdom great emphasis is placed on the control of opiates. In many cities heroin addicts can be treated in special centres, where the main task of the therapist is to wean the addict off the heroin by reducing his daily intake or else to substitute a longacting opiate, such as methadone, that will block the action of heroin if this continues to be used. In addition, much attention is paid to the addict's life circumstances, with counselling offered by social workers, psychologists, and other members of the centre's staff. Whereas withdrawal of the drug is comparatively easy, the task of ensuring continued abstinence is decidedly difficult, and relapses are commonplace. It is questionable whether young addicts 'mature out' of dependence on reaching an age even of 3035, yet it is possible that a change in circumstances coupled with a desire to be free from the constant need for opiates and money for their purchase may persuade a sufferer to find other satisfactions in life.

The treatment of alcoholism is scarcely easier, largely because of the ready availability of alcoholic drink: a person persuaded to give up the drink habit in the clinic may suffer immediate relapse on returning to former surroundings. Yet there is evidence to show that some alcoholics can abstain sufficiently to permit a return to

'normal social drinking', an elasticsided term that depends on the attitudes of a society to drinking behaviour.

ADLER, ALFRED (1870-1937). Adler, the founder of the School of Individual Psychology, was born in Vienna, and qualified in medicine in 1895. He spent his early years in medical practice, and became increasingly interested in the environmental and psychological aspects of physical disorders. In 1902, Sigmund*Freud invited Adler and three other colleagues to discuss the psychology of the neuroses. The group was later to become the Vienna Psychoanalytic Society, with Adler as a president and coeditor of its journal. During this period he developed the theory of organ inferiority and compensation, based on his observation of the effects of different environments on the outcome of developmentally retarded organs. The purpose of compensation, either organic or psychological, was seen to make up a deficiency by increasing development or function. Compensation, which could be favourable or unfavourable, might, for example, in good enough circumstances bring about normal speech in cases of retarded speech development; while overcompensation in particular cases might lead a stutterer like Demosthenes to brilliant oratory.

The theory led to the development of Adler's view that feelings of inferiority, determined by genetic, organic, or situational factors, were of fundamental importance in provoking the small, weak, and dependent child to conceive of weakness as analogous to both inferiority and femininity. The 'masculine protest' and the striving for power and superiority were thus the predictable outcome of compensation in a male-dominated society.

Page 6

In 1911 Adler's theoretical divergence from Freud's views was forcefully expressed in his papers given to the Psychoanalytic Congress at Weimar. He disagreed with Freud's view of the sex instinct as the preeminent motivational drive and pertinently questioned whether*ego drives did not have a libidinal character: a position which Freud was later to entertain, and one which Carl*Jung regarded as a 'rather poky corner' in Freud's psychology. Adler criticized Freud's concept of repression, replacing it by egodefensive safeguarding tendencies, and asserted that the neurotic's value system resulted from increased feelings of inferiority and the subsequent unfavourable overcompensation of the masculine protest, of which the*Oedipus complex represented a comparatively insignificant stage. Freud in his reply recognized this presentation as 'ego psychology deepened by knowledge of the unconscious', but saw it as an impediment to his development of an instinct and impulse psychology. Only one helmsman was required, and Adler left to form a society with the rebuking title of 'The Society of Free Analytic Research', which was, within the year, significantly renamed 'The Society of Individual Psychology'.

In 1911 Adler was profoundly influenced by Vaihinger's concept of 'fictions', i.e. mental constructs or early conceptions of what might now be called working models.

This led him, in his first and essentially most significant book, *The Neurotic Character* (1912), to insist that human character and actions must be explained teleologically; separate goals coming under

the dominance of, and oriented towards, the final purpose. This guiding fiction or purpose, developed by the age of five years, was to move feelings of inferiority to those of superiority—under the direction of the individual's unconscious but uniquely created self ideal—as a constellation of wishful thoughts and imaginings of being and becoming strong and powerful; or if overcompensation was present, in fantasies of godlike immutable supremacy.

'Counterfiction forces', Adler's name for the correcting factors of social and ethical demand on the self ideal, led to mental health if mutual compatibility with the self ideal was achieved. However, devaluation of corrective factors (later seen to be the patient's overt or covert mode of dealing with the therapist), when combined with a high level of unfavourable overcompensation, led to the development of the more extreme personality traits and psychological disorders.

A major period of expansion in the influence of Individual Psychology took place between 1920 and 1935. Adler, whose work had been restricted during his service as a physician in the Austrian army in the First World War, was to extend and consolidate both his theory and his practice. In 1927 he established twentytwo child guidance clinics in Austria, a number which increased to thirty before they were closed down in 1933. He became a regular visitor to, and frequent lecturer in, the United States, where, as in Europe, Individual Psychology Societies increased in number, activities, and influence.

Freud was correct in thinking that Adlerian doctrines would 'make a great impression'. Adler's understandable, rational, and optimistic approach to interpersonal and social problems contrasted favourably with Freud's psychobiological, more mechanistic, pessimistic concepts, and with the more mystical and esoteric ingredients of Jung's theory. Later developments of Adler's theory of personality included his concept of the 'style of life', which comprised not only the person's 'fictive' goal but his plans and schemes to achieve it, including selfevaluation. He came to regard the origin of a neurotic disposition or style of life as the result of the overburdening of the child with physical disorders and illness; pampering (his wishes being treated as laws); neglect (not knowing what love and cooperation can be); marital disharmony, and certain dispositions of sibling arrangements. Mental disorders of every sort were conceived as having a common cause, constructed by individuals who determine themselves by the meaning they give to situations.

Adler's therapeutic method avoided, as he stated, 'tedious excursions into the mysterious regions of the psyche'. It was sensibly concerned with the prevention of adult maladjustment by the early correction of the mistakes of the child, a task which he attempted to accomplish through the training of teachers. It was their duty to see that children were not discouraged at school but were put in a position, by being given tasks which they could accomplish, to gain faith in themselves. His own therapy, based on his understanding of the symptoms, problems, and the specific lifestyle of the patient, insisted on explanations to the patient of the predictable effects of his lifestyle, and an encouragement and strengthening of his social interest, which was Adler's criterion of mental health. This was done in a relationship in which blame was excluded, and resistance (the depreciation tendency) reduced by repeatedly drawing the patient's attention to the similarity of all his behaviour, and disarming him by refusing to adopt a superior role or engage in a fight. Devices included what are now called paradoxical injunctions and the use of humorous models and historical

instances.*Transference was recognized but avoided by teaching the patient to take full responsibility for his conduct. Aggression was recognized behind the patient's attempts to devalue the therapist, and blame others before himself. Narcissism resulted from the exclusion of obviously given social relationships or from not having found them. Symptoms were seen as attempts to safeguard self-esteem and the current lifestyle.

In 1935 Adler was appointed professor in medical psychology at the Long Island College of Medicine, and died in Aberdeen two years later, on the last day of a course of lectures given at the univer

Page 7

sity. The influence of the School of Individual Psychology receded after his death. Many of his ideas, however, while rarely attributed to him, became common currency in the so-called neoFreudian group of Sullivan, Homey, and Fromm, and are clearly recognizable in contemporary cognitive, problemsolving, and existential therapies. (See FREUDIANISM: LATER DEVELOPMENTS.)

Adler's writings are intuitively penetrating and frequently inspirational, but are at times confusing and lacking in objective rigour and refinement. It is a matter of regret that he took insufficient time to argue his ideas more closely and present them as a fully coherent alternative to those of Freud and Jung, although the Ansbachers' work (1956) has helped to correct this. It leaves him open to the criticism that while helping to lay the foundations of contemporary ego and social psychology his theories oversimplified the inherent complexity of their subject.

ADOLESCENCE. See HUMAN GROWTH; SEXUAL DEVELOPMENT.

ADRENALINE (EPINEPHRINE). One of the two main hormones released by the medulla of the adrenal gland, the other being the related noradrenaline. It produces effects similar to the stimulation of the sympathetic nervous system, increasing heart activity and muscular action, generally preparing the body for 'fright, flight or fight', hence the oftquoted need for sportsmen 'to get their adrenaline going'.

See NEUROTRANSMITTERS AND NEUROMODULATORS.

ADRIAN, EDGAR DOUGLAS, 1st Baron Adrian (1889-1977). Adrian was born in London and educated at Westminster School, where he became a King's Scholar at the end of his first term. Like his mentor at Cambridge, Keith Lucas (1879-1916), he at first studied classics but went over to science in his last year. He went up to Cambridge as a scholar of Trinity College, where he read medicine, and became a Fellow in 1913. On the outbreak of war in 1914, he completed his medical studies at St Bartholomew's Hospital, London. After qualifying, he obtained a resident appointment at the National Hospital for Nervous Diseases, Queen Square, London, following which he became Medical Officer at the Connaught Military Hospital at Aldershot. After the war he returned to the Cambridge Physiological Laboratory to continue the work he had started in association with Keith Lucas, who had died as the result of a flying accident in 1916. Keith Lucas's interest had centred on 'all-or-nothing' activity in skeletal muscle and in motor nerves, and there is no doubt that Adrian conceived it to be a pious duty to carry on and complete his work.

In November 1925 he succeeded in recording with Lucas's capillary electrometer the impulse traffic in a single afferent nerve fibre. He wrote of the experiment in this way:

At all events the great simplicity of the discharge from the sensory end organ came as an exciting and welcome surprise. Bitter experience does not encourage physiologists to suppose that their material will give predictable reactions except under the most rigorously controlled conditions, but the stretch receptors in the frog's muscle did not merely give a discharge which could be reproduced many times without variation, there was the added pleasure of finding that the discharge from each unit was a simple series of impulses varying only in frequency in accordance with the strength of the stimulus. It cannot be often that a general principle like this is as plainly revealed in the course of a single experiment.

This experiment finally proved that Lucas and Adrian's conception of the 'all-or-nothing' character of the propagated nervous impulse, based on indirect evidence, was true. The transmission in the nerve fibre occurs according to what today would be called impulse frequency modulation.

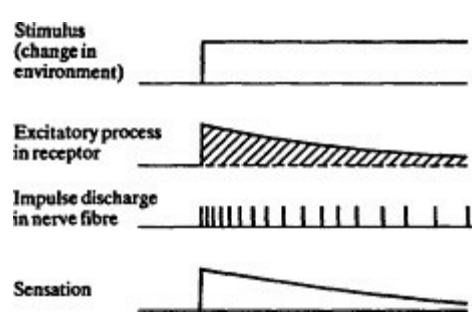

Adrian was always hunting big game: 'the unsatisfactory gap between two such events as the sticking of a pin into my finger and the appearance of pain in my consciousness', as he wrote in *Basis of Sensation* (1928). In this book he gives a summary of the experiments on the muscle spindle, on the

cutaneous senses (touch, pressure, and pain), and on the optic nerve, which he performed within the course of only two years.

It is amazing to read today how at that early date he had arrived at the following fundamental view on the relation between the sensation and the impulse frequency in sensory nerve fibres:

The simplicity of the relation is at once very natural and very surprising. It means that our mind receives all the information which can be got out of the messages from those receptors which are in touch with it, but it means also that the mental correlate is a very close copy of the physical events in the sensory nerves. The only kind of distortion which takes place in the transference from body to mind (or in the parallelism of the bodily and mental events) is that the sensations rise and fall smoothly, whereas the nervous message consists of a series of discrete impulses with pauses in between. Somewhere on the way between the two there must be a smoothing process which converts the disconnected impulses into a change of much slower period.

Adrian's study of the adaptation in various

Page 8

Fig. 1.

Relation between stimulus, sensory message, and sensation.

sensory receptors led him further to the suggestion, seen in Fig. 1, that the excitatory state in the receptor consists of a slow potential, the peak height of which varies with the strength of the stimulus. This receptor potential modulates the impulse frequency transmitted in the nerve fibre via relay stations (synapses) to the cerebral cortex, inducing there the 'evoked potential' which integrates the series of impulses into a 'quasisteady effect', as Adrian suggested in 1928. 'The diagram (Fig. 1) does not bridge the gap between stimulus and sensation,' he concludes in *Basis of Sensation*, 'but at least it shows that the gap is a little narrower than it was before'.

This was typical of his modesty. Recent parallel recordings in humans of the neural and perceptual responses to sensory stimuli have proved that there is a close linear relation between the two events, thus definitely confirming Adrian's pioneer conception of 1928.

From these early recordings followed a quick development. Adrian's simple amplifier and Keith Lucas's capillary electrometer and camera were gradually exchanged for new inventions—Matthews's irontongue oscillograph, cathode ray oscillographs, etc.—which enabled Adrian and the

hundreds of his followers all over the world to study the inflow and outflow of nerve impulses and to record the bioelectrical events within the whole nervous system. In nearly all these fields Adrian was the leader who opened the field or who made the proper analysis and interpretation of bioelectrical phenomena: for instance, the cochlear microphonics first described by Wever and Bray, and the*electroencephalogram discovered by Hans*Berger in Germany.

Adrian used to work alone and had not more than a dozen coworkers through all his active period in the famous basement room of the Cambridge Physiology Laboratory, which covered nearly sixty years. He was Foulerton Research Professor of the Royal Society from 1929 to 1937, when he succeeded Joseph Barcroft as Professor of Physiology at Cambridge. In 1951 he was appointed Master of Trinity College, and from 1950 to 1955 he was President of the Royal Society. He shared the Nobel Prize in Physiology or Medicine with Sir Charles Scott*Sherrington in 1932, received the Order of Merit in 1942, and delivered the Waynflete Lectures at Magdalen College, Oxford, in 1946. These lectures were published by the Clarendon Press in the following year under the title of *The Physical Background of Perception*.

Although Adrian never thought of himself as a psychologist, he was a founder member of the British Psychological Society and greatly encouraged the growth of experimental psychology in the University of Cambridge; in particular, he held the young Cambridge psychologist, Kenneth*Craik, in high regard and commented on his achievement in the Waynflete Lectures. Adrian was by no means unsympathetic to psychoanalysis in spite of his firm belief that psychology should develop on the model of the biological sciences.

In 1955 he was created Baron Adrian, and in 1967 was elected Chancellor of Cambridge University. He died in his eighty-eighth year, in August 1977. At his funeral, the Master of Selwyn College, Professor Owen Chadwick, said: 'I am not sure what wisdom is, but whatever it is, Adrian had it.'

AESTHETICS. Derived from the Greek verb *aesthanesthai* (to perceive), the term 'aesthetic' was until fairly recently used in connection with the philosophy of sensation and*perception. The present use of the label 'aesthetics' to refer to the study of criticism and taste in the arts is due to the German philosopher A. G.

Baumgarten, whose *Aesthetica* (1750) dealt with art and the nature of beauty.

The earliest and still probably the most influential discussions of aesthetics, embracing the beautiful and the good, are in*Plato's Socratic dialogues. In the *Hippias Major* a distinction is drawn between what *appears* beautiful and what *is* beautiful. It is almost accepted that the beautiful is whatever is useful or powerful; but Socrates objects that power may be used for evil, which is not beautiful, so power and beauty cannot be the same. One may reply by making a qualification (e.g.

power when used for good is beautiful); but this implies that the good and the beautiful are cause and

effect and therefore different things. Yet this is absurd, given the ancient and long accepted identification of the beautiful and the good. It is then suggested that the beautiful is a particular species of the agreeable or pleasurable—

comprising all things that give pleasure through the senses of sight and hearing. Socrates questions, though, why these pleasures should be so special compared with other pleasures, and, finding no answer, he rejects this account.

In the *Republic* Plato reveals his more metaphysical thinking, as he describes the beautiful as seen as approximating to the ideal forms of the timeless perfect reality of the universe hidden from mortal view. For Plato, the world as perceived is a rough and imperfect model of the hidden ideal world of
Page 9

the gods, as fully described in the early part of the *Timaeus*. In the *Republic*, Plato describes how works of art, and especially paintings, are at a still further remove from the ideal reality than are the objects of sense—which are but semblances of his perfect universe from which somehow spring truth and beauty. Thus:

... you may look at a bed or any other object from straight in front or slantwise or at any angle. Is there then any difference in the bed itself, or does it merely look different?

It only looks different.

Well, that is the point. Does painting aim at reproducing any actual object as it is, or the appearance of it as it looks? In other words, is it a representation of the truth or of a semblance?

Of a semblance [i.e. of the sensed object world].

The art of representation, then, is a long way from reality; and apparently the reason why there is nothing it cannot reproduce is that it grasps only a small part of any object, and that only an image. (*Republic*, Book X, 598)

Plato goes on to deny that artists or poets convey reliable truth, as they have neither knowledge nor correct belief, and he argues (*Republic*, Book X, 602C605C) that the errors of the artist, at this third remove from reality, are somewhat similar to perceptual errors caused by optical illusions that distance the perceiver from reality.

Only the intellect of philosophers can, for Plato, correct the errors of art and poetry, and the errors of perception. Here geometry is especially important, for the diagrams of geometry most nearly represent the mathematically elegant and unchanging underlying forms, which are true, good, and beautiful. This is still echoed by physicists and mathematicians who seek and find mathematical elegance in nature—for example, the Cambridge mathematician G. H. Hardy in *A Mathematician's Apology* (1941): 'Beauty is the first test; there is no permanent place in the world for ugly mathematics.'

Plato's account of aesthetics has had the most profound effects on art and architecture, and perhaps on music. The close association between the beautiful and the morally good, together with his rejection of action and change in the ideal world, promoted distrust and even distaste for the living body and its normal activities, which is a basis of puritanism.

A worldly kind of Platonism was developed by the English painter Sir Joshua Reynolds (1723-92), who held that beauty is given by the central idea, or by representative examples of classes of things, including faces and the human figure, while the deformed is what is uncommon. Thus beauty is above singular forms, local customs, particularities, and details of every kind. It was objected to this idea that in fact there are many different particular forms and examples of beauty in each species, including man. Reynolds replied that individuals can represent subclasses, which can have distinct forms of beauty, and that 'perfect beauty in any species must combine all the characters which are beautiful in that species'. He thus tried to bring Plato's ideal forms down to earth.

A theory entirely different from Plato's—based firmly on our bodily characteristics and sensations rather than on hidden ideal forms of the structure of the universe or the averages of classes—is the *empathy theory*. An early exponent was the artist William Hogarth (1694-1764), who in his *Analysis of Beauty* (1753) suggests that twisted columns are elegant (he prefers waving lines because they are more varied) but they displease when they are required to bear a great weight. The notion is that we identify ourselves with the columns: when thin they look inadequate, as we, if thin, would be too weak to support a great weight; and when too thick, they look clumsy, as we feel clumsy when too large for delicate work. This notion is no doubt related directly to the muscle sense of required effort. A golfer driving a ball high and long identifies himself with its flight by an empathy perhaps not so different from the power of art to take us out of this world.

The philosophers of mind of the eighteenth and nineteenth centuries, holding associationist theories, tended to believe that the beautiful is not intrinsic in the nature of things, or related to empathy, or to the muscle sense; but that it is given by associations with objects or concepts, such as whiteness associated with purity, or the grandeur of mountains with their creation by the superhuman power of gods or the magnificent forces of nature. On this account, what is associated determines what is seen as beautiful. So, there is a related fear that if belief, for example, in gods is abandoned the world will lose its beauty, and be drab and meaningless. No doubt scientific understanding imparts new beauties to the world; but this is surely no reason for it to destroy our appreciation of art, though it changes associations and the meaning of things so that we develop new appreciations.

Certain proportions have been regarded as intrinsically beautiful—that is, apart from associations with objects or concepts. This is especially so of the Golden Mean or Golden Section, the name given to a division of a line or figure in which the ratio of the smaller section to the larger section is the same as the ratio of the larger section to the whole. The notion can be traced back to Plato's obsession with the regular solids: cube, tetrahedron, octahedron, icosahedron, and their supposed association with the four elements. It is the root of much misty mysticism. There is no clear experimental evidence that the Golden Section is an aesthetically unique or specially preferred proportion; and it is suggestive that it is rarely found in the proportions of artists' pictures, or frames. Aesthetic proportions are often supposed to be based on the human form, as in the *Divina proportione* of Luca

Pacioli (c.1445 c.1514), who was a Franciscan, a celebrated mathematician, and a friend of*Leonardo and Alberti. Pacioli tries to relate Euclidean geometry to Christianity, and describes the sacred ratio as 'occult and secret'— the threeinone proportion of the Holy Trinity.

Page 10

There are several biologically based theories of aesthetics, with various emphases on innate properties of mind (perhaps derived from ancient experience) and associations with things and situations that give individual pleasure in life or are important for survival. A subtle notion is that repetitions and symmetries, which are characteristics of all decoration, are appealing because we have had to search out repetitions and symmetries in nature in order to predict, control, and survive by intelligence. The Austrian physicist Ernst*Mach points out the biological importance of discovering order, in a lecture 'On symmetry' (reprinted in his *Popular Scientific Lectures*, 1894). This general view is developed in detail by Sir Ernst Gombrich (1979).

In *Art and Illusion* (1960), Gombrich relates processes of perception and representative art. He is, however, concerned here not so much with theories of beauty as with issues of the cultural basis of the visual arts. He takes 'illusion' to mean the techniques and aims of the artist in representing reality rather than the sense of misleading error that the word usually suggests. (See ILLUSIONS.)

Is beauty objective, or is it in the eye of the beholder? The notion that the universe is beautiful apart from man, and so objectively beautiful as well as good, was an essential of Platonism. But how can beauty be objective? Agreement of aesthetic practice and judgement between different societies and over long intervals of time may be taken as evidence of some kind of objectivity; but it must be remembered that all human environments, and the human form itself, have much in common in all societies throughout history, so commonality of experience might be responsible for similarities of art forms. Also, there was a surprising amount of trade (by the Beaker people, for instance) with dissemination of artefacts over Europe and Asia even in neolithic times. This, indeed, works against C. G. Jung's argument (*Psychology and Alchemy*, 1944; *Man and his Symbols*, 1964) that the spontaneous emergence of 'archetypal' forms is evidence for the existence of innate symbols universally accepted as beautiful and especially significant, although not representational.

When Jung was writing, the extent of prehistoric and ancient trade routes was not appreciated. In addition, there is, perhaps, only a limited number of simple symmetrical shapes to choose from. What seems at least as remarkable as the frequent occurrence of certain formal designs is the local individuality and gradual changes of aesthetically accepted forms in particular communities, making it possible to date pottery and other artefacts with astonishing accuracy. Why should the craftsmen of a community or region accept current aesthetic standards or conventions? Why is art and design not a free-for-all—the individual expressing himself as he wishes? It has been suggested (Gregory, 1981) that there is a technological need for agreement over nonfunctional features of artefacts, if they are to be made cooperatively without endless arguments and disagreements that cannot be resolved or decided on functional grounds. Thus, the slope of a roof is, within limits, determined by the available building materials, and by the climate (for example, roofs for heavy snow are steep so that it slides off); but the proportion, if not the size, of windows is largely arbitrary. There are many features of boats, tools, pots, and other useful artefacts that may be varied over wide limits with no loss of function, but these have fixed conventional forms in given societies. Could it be that social leaders and artists set forms where discussion leads merely to argumentative waste of time and effort? Could this be so important that the aesthetic sense has developed over perhaps several million years as man has learned to make and use tools, and undertake effective cooperative projects? Could aesthetics be a byproduct of tool using? This seems a far cry from the beauty of pictures and music; but possibly the roots of style and fashion lie in ancient technology rather than in pictorial and decorative art. From this start, it may have grown to evoke almost the whole range of human experience, and at the same time serve to comment and to judge, and to lift us beyond Nature while revealing our own natures: such is the power of art.

AESTHETICS: SOME PSYCHOLOGICAL APPROACHES. There are five main ways in which psychological approaches are made to visual aesthetics. First, there is the use of special experimental methods of dealing with judgements about art and aesthetic feelings and attitudes. Next there is the application of existing psychological facts and theories—for instance, as formulated in the psychology of perception—to illuminate problems of art and aesthetics. Thirdly, there is the study of crosscultural and racial differences and similarities in aesthetic judgements and preferences. Fourthly, there is the study of the influences on the development of artistic styles and cultural changes in art exerted by the interaction of social groups. And fifthly, there is the approach to aesthetics and the understanding of art through the study of the lives of artists, and any influences which are due to personality qualities and psychiatric factors. These different approaches have been reviewed by Pickford (1972, 1976). The many aspects of psychology and the arts are discussed in O'Hare (1981). There has been an almost equally varied and extensive development in the psychology of musical aesthetics—as seen, for example, in the writings of Francès (1973) and Imberty (1976).

Page 11

G. T.*Fechner (*Vorschule der Aesthetik*, 1876) is generally regarded as the founder of experimental aesthetics, and he established the first method of approach mentioned above. He put forward a number of principles on which aesthetics could be approached as an experimental science 'from below', in contrast to the philosophical approaches 'from above'. He was a major contributor to the development of psychophysical methods in experimental psychology, and he argued that such methods, especially the method of paired comparisons, could be used to measure preferences for colours, colour combinations, figures, shapes, proportions, and actual works of visual art or musical composition. The essential foundations of aesthetics could thereby be established on a factual basis. He cast a wide net, with five main and seven subordinate principles (Pickford, 1972, p. 18), and was not as restrictive as is often supposed.

For about fifty years after Fechner's work only a small number of researches based on it were published, but by the 1930s it had begun to become popular among experimental psychologists, and the study of aesthetic judgements and preferences was introduced into laboratory courses on experimental psychology. Since then experimental aesthetics, although not always tied strictly to Fechner's concepts, has expanded rapidly. Now it is a major branch of experimental psychology, applying itself not only to the visual arts but also to auditory and musical problems, and using factor analysis, the analysis of variance, the semantic differential and other statistical techniques, and information theory (Moles, 1966).

With regard to the second method of approach mentioned at the start, it is clear that a very large part of visual art depends on (i) the representation of threedimensional scenes and objects, viewed in perspective, upon twodimensional surfaces; and (ii) the construction of solid shapes, in sculpture or architecture, in such a way that they create the best aesthetic impression when seen from one or even from many points of view. The representation of threedimensional scenes and objects on fiat surfaces has presented complex and interesting problems for artists, and, in turn, for psychologists in understanding and explaining how they worked. After the accurate handling of the geometry of perspective became important in Renaissance art, these problems came to be of outstanding interest (see Osborne, 1970).

Apparent depth perception in fiat pictures is essentially monocular, and viewing is assumed to be from a particular point. Viewing fiat pictures with two eyes, and from all sorts of positions and distances, tends to be a disadvantage. All distances or positions except one are unrelated to the perspective construction of the picture, and two eyes commit us to two viewing points, which, because the picture is fiat, cannot contribute to stereoscopic vision. Monocular depth perception depends on shadows, the overlapping of distant by near objects, decrease in precision of outline as distance increases, changes of colour, usually towards less saturation and more bluegrey or purplish hues in the distance, the recession of parallel lines towards vanishing points, and on the automatic variation in focusing of the eye in spite of the picture being fiat. When two eyes are used there is also a tendency to variation of convergence when looking at near or distant objects in a fiat picture.

The branch of psychology which has given most illumination to aesthetics is*Gestalt psychology. Its phenomenological principles are almost a practical guide for the artist and the viewer. The first of its four basic principles is that of 'figure and ground', according to which every form or object perceived is experienced as a figure standing out against a ground or background. The second principle is that of 'differentiation' or 'segregation', by which presentations tend to organize themselves into perceptual structures. The third is that of 'closure', by which incomplete or partly occluded figures or objects tend to be perceived or experienced as wholes. (Thus a face partly occluded by shadow is seen as a full face, as every artist knows.) And the fourth principle is that of the 'good Gestalt', according to which a strongly emphasized or more complete or adequate pattern or configuration will take precedence over weaker or less adequate patterns. These principles operate phenomenologically even though the physiological theory of 'isomorphism', that the excitations in the brain's visual area are the same as those in outward experience, cannot be supported. Indeed few people would suspect that it could be supported, or that it would clarify perceptual theory even if it were supported, by experimentally established fact. After all, even if a solid stimulus object when perceived were known to be represented in the brain by a solid pattern of neurological excitations, we should be no nearer to understanding how such a solid neurological pattern would give rise to the perception of the stimulus object as a threedimensional solid. The gap between neurology and experience cannot be bridged so easily.

Turning to the third psychological principle or approach, which deals with crosscultural and allied matters, there have been numerous experimental researches on colour preferences, preferences for figures, shapes, and complete works of art such as pictures, sculptures including African masks, and musical works. The central aim of these researches has been to test the hypothesis that there are

cultural or racial differences in aesthetic preferences. In the field of colour preferences, Eysenck (1941) showed that in sixteen studies of white people's colour choices and ten of choices by nonwhites, there was a surprising degree of conformity. The average order for six saturated colours among the whites was blue first, then red, green, violet, yellow, and finally orange. The order for nonwhites differed only in that yellow and orange changed places. Child and Siroto (1965), for instance, showed that, when

Page 12

American art experts' judgements of BaKwele ceremonial masks were compared with choices by BaKwele judges, the least degree of agreement was found with tribesmen, most agreement with those who actually carved the masks, and an intermediate degree of agreement with the ceremonial leaders who used the masks.

Similar results were found in other experiments, and it seems that, when competent judges of art are used, there is more crosscultural agreement than is often supposed. Differences of material, style, subjectmatter, or intention of the works of art do not necessarily imply basic differences of aesthetic evaluation (Pickford, 1972, 1976). A significant contribution to crosscultural studies has been made by Segall (1976). (See also PERCEPTION: The fourth approach of psychology to aesthetics is based on study of the interactions of groups and of individuals with groups in the history of art. F. C.*Bartlett's interesting and stimulating book, *Psychology and Primitive Culture* (1923), was based largely on the study of folktales and their changes and vicissitudes under varying cultural conditions. Sayce followed this with a study of primitive arts and crafts (1933), and Pickford attempted to apply a similar approach to movements in the history of painting (1943). Very interesting studies have been made by Brothwell (1976).

The fifth approach has been biographical and in the study of the relation of personality factors and differences to aesthetic judgements and preferences. Burt (1939) showed a relation between*extraversion/introversion on the one hand, and instability/stability of personality on the other, in aesthetic preferences for pictures. Unstable extraverts tended to prefer romantic art, while stable extraverts preferred realistic art; unstable introverts tended to prefer impressionistic whereas stable introverts preferred classical art. Eysenck (1940) showed a connection between introversion and liking for classical art, and between extraversion and liking for modern and colourful art. Many other researches have been carried out, and some of them are summarized by Pickford (1972).

The relations between various mental or psychiatric disturbances and aesthetic preferences have been studied experimentally, as by Katz (1931), Warner (1949), and Robertson (1952). Blue was the most preferred colour among mental hospital patients, as among normal people, but in one study male patients put green second while females put red in that position. Manicdepressives liked red, orange, and yellow more than did schizophrenics, who preferred green. Another study showed that anxiety neurotics preferred green to yellow, and also liked lighter colours. Male patients preferred cool hues more than did females. Robertsoh's study of paintings made by patients showed that red was more used by male than by female schizophrenics. It was also found that schizophrenics tended to be less aroused by colours than were psychopaths, depressives, and psychoneurotics, and that the difference

probably lay in a diminished reactivity to colour in the more seriously disturbed patients.

In recent years (1968, 1976), D. E. Berlyne with his concepts of 'aesthetic behaviour' and 'exploratory behaviour' has exercised great influence over psychological approaches to aesthetics, and his work has stimulated many important and interesting researches. His untimely death in 1976, while he was President of the International Association for Empirical Aesthetics, was a severe blow to all persons working in this field.

AFFECT. A term used in psychology for a feeling or emotion, particularly one leading to action.

AFFERENT. A word pertaining to the sensory neural inputs to the nervous system—the nerves Page 13

and their signals (action potentials) running from the senses to the brain. (Efferent nerves and signals control the muscles.) See NERVOUS SYSTEM.

AFTEREFFECT. See CONTINGENT PERCEPTUAL AFTEREFFECT.

AFTERIMAGE. An image seen immediately after the intense stimulation of the eye by light has ceased. For about a second, the afterimage is 'positive', and then it turns to 'negative', often with fleeting colours. The positive phase is due to afterdischarge of the receptors of the retina (see COLOUR VISION: EYE

MECHANISMS); the negative phase is caused by loss of sensitivity of the receptors as a result of bleaching of the photopigments by the intense light. Afterimages can be annoying, but they are usually ignored or suppressed. They are technically useful for visual experiments as they are precisely fixed on the retina. They are seen to move with the eyes during normal eye movement. See also CONTINGENT PERCEPTUAL AFTEREFFECTS; VISUAL ADAPTATION.

AGEING. Performance at many types of task studied in the laboratory rises to a peak somewhere between the late teens and late thirties, and then gradually declines into old age. It used to be assumed that the declines were due either to age effects in sense organs, muscles, and joints, or to older people being uninterested in, or out of practice at, the kinds of tasks set by laboratory experiments. Research since the 1940s has shown that, while peripheral changes may be important in later old age, central brain functions account for the main trends of performance in middle and early old age. The trends are by no means all adverse: certain kinds of 'mental agility', such as indicated by scores on typical*intelligence tests, decline from the early twenties—it has been estimated that by the age of

sixty they have returned to their level at the age of ten—but the decline is offset, at least partly and sometimes more than fully, by increased knowledge gained in the course of experience. The age of peak performance is thus usually in the thirties, forties, or fifties rather than in the twenties, and varies with the balance between demands for 'mental agility' and for knowledge: for example, it comes relatively early among mathematicians, and relatively late among historians and philosophers.

It must be emphasized that these statements are *of average* trends and that some individuals achieve their peak performance much earlier or later than the majority.

Indeed, the extent and rate of changes differ widely between individuals, so that performances tend to become more variable with age—some people in their seventies or eighties perform some tasks in a manner similar to that of people half a century younger, whereas others show profound differences. It is thus all too easy for ideas about old age to be coloured, for better or worse, by a few striking examples who are not typical of their contemporaries.

Psychological studies of ageing made during the last thirty years or so may be broadly divided into three areas.

Speed of performance. Perhaps the most characteristic age change is that performance becomes slower. The extent to which it does so is not, however, uniform for all tasks. For simple, aimed movements the change is comparatively slight—a loss of less than 10 per cent between the twenties and seventies. Slowing in sensory motor tasks is mainly in the making of decisions about what action to take—in other words, in cognitive and intellectual rather than in motor functions. When the relationships between signals for action and the corresponding responses are straightforward, as, for example, when the signals are a row of lights and response is by pressing a button under whichever comes on, the time to react increases typically by about 25 per cent from the twenties to the seventies. When the relationships are more complex, as, for instance, when lights on the right have to be responded to by pressing buttons on the left, and vice versa, increases of 50 per cent or more have been found between these ages. Slowing with age is also greater in continuous tasks, where each response immediately brings on the signal for the next, than in discontinuous tasks, where responses and ensuing signals are separated by an interval of a second or more. The reason appears to be that older people tend more than younger to have their attention diverted to monitoring the response they have just made, so that they cannot attend immediately to any fresh signal.

Much if not all slowing with age can be explained by the fact that signals from the sense organs to the brain and from one part of the brain to another become weaker, while at the same time random neural activity in the brain tends to increase. The latter blurs the former and leads to errors. The blurring can, however, be at least partly overcome by taking a longer time. This allows data to be accumulated, making the signals stronger and averaging out some of the random activity. As a result, older people, although slower, may be as accurate or more so than younger. With some highly complex tasks, however, such compensation is incomplete, so that the older tend not only to be slower but also to make more errors.

The laboratory findings accord well with studies of real-life situations. In industry, operatives tend to

move before retiring age not only from physically strenuous work such as coalmining, but also from lighter jobs where there is pressure for speed, such as on assembly lines. Industrial accidents sustained by older people tend to involve either being hit by moving objects or tripping and falling—in other words, slowness either in getting out of the way or in recovering balance—whereas younger people's accidents tend to be the result of either rashness or lack of experience. The same is true of road accidents and traffic offences: older people fail to react in time to rapidly changing

Page 14

situations, while younger people take undue risks. The problem of complexity is shown in difficulties often found by older industrial operatives with complex machinery and elaborate working drawings. It is also epitomized in the finding that some can no longer read a map while travelling south without turning it upsidedown.

Memory and learning. A six or sevendigit number heard once can be recalled immediately about equally well by people of all ages from the twenties to the sixties.

With more items than this, older people recall less than younger. The reason appears to be that they have difficulty in transferring material from a limited and ephemeral*shortterm memory to a more enduring longterm memory: some of the material is lost, and the traces of what is transferred are weaker. The strength of the traces can be increased by repetition, and with enough additional practice recall by older people can equal that by younger. Once material has been learnt, older people do not forget more rapidly than younger. Welllearnt facts, familiar events, and thoroughly practised motor skills such as riding a bicycle or driving a car are, therefore, retained well in old age even if there is difficulty in learning new facts and acquiring new skills.

Failure to register material in longterm memory probably accounts for many difficulties in*problemsolving and other tasks in which data have to be 'held in mind'

while other data are gathered: for example, when multiplying, say, 57 by 38, the product $57 \times 3 \times 10$ has to be held while 57×8 is obtained. Calculating the second product will destroy the shortterm memory of the first, so that it will be lost unless it has been transferred to longterm memory.

Probably the most successful method of training older people in industry has been the 'discovery method' whereby the trainee is given just enough information to enable him to discover accurately for himself how to perform his task. The active decisions required have the effect of facilitating registration in longterm memory, and the fact that the trainee can learn at his own pace means that he has time to sort out difficulties. It is fair to suggest that insufficient time devoted to mastering new facts and ideas is a reason why thinking often becomes hidebound in later middle age among those hard pressed by daytoday activities and responsibilities, and that time set aside to acquaint themselves with new developments would be well repaid.

Personality. This often appears to change with age, yet scores on personality tests show small, if any, trends. The apparent changes seem instead to represent reactions to altered circumstances in old age

which are not measured by the usual tests. For example, on the one hand retirement brings increased leisure and opportunities, while, on the other, changing capacities may restrict interests and activities and in extreme cases lead to dependency. The ways in which individuals adjust to these circumstances vary greatly. Some welcome the new opportunities and accept the restrictions. Others find little use for leisure, resent restrictions, and become selfcentred. This last reaction is well illustrated in many who complain of being lonely. Older people are understandably lonely for a time following bereavement: however, complaint typically comes from those who are surrounded by relatives, neighbours, and others, but whose selfcentredness makes normal social intercourse unrewarding. In all cases the manner of adjustment seems to have little relation to economic or material circumstances or, within limits, to health: it depends upon personality traits which have been present throughout life but which may not have had the opportunity to show earlier because of the exigencies of work or bringing up a family.

The changes in personality can perhaps be summed up by saying that old age is a revealing time, when the best and worst in us stand out in bold relief. As a recipe for contentment, we may cite a remark by Maurice Chevalier: 'Growing old is inevitable for all of us. The clever thing is to accept it and always plan your next move well in advance.'

AGEING: SENSORY AND PERCEPTUAL CHANGES. Since a person can deal efficiently with his social and physical environment only if his sensory and perceptual processes are not unduly impaired or distorted, changes which might be attributable to the inevitable process of ageing assume considerable importance. In briefly reviewing this topic, two generalizations need to be kept in mind. First, it is not always clear that a given impairment is a natural result of advancing age rather than the result of disease, trauma, or disuse. Secondly, individual differences in general become more pronounced with age, so that some elderly may exceed the norms in a particular function.

Certain reductions in the efficiency of seeing appear to be inevitable with advancing age, although there are, of course, individual differences. Most obvious is the change in ability to focus on nearby objects, and the use of reading spectacles or bifocals is commonplace. To understand the importance of this change, consider the plight of an artisan doing fine work before the advent of spectacles! Fig. 1 shows the approximate distance from the eyes of the limit of clear focus for 'normal' eyes—

or eyes corrected to normal by spectacles—as a function of age. Other apparently 'normal' changes

are ordinarily not so obvious to the individual. These include a reduction in resting

Page 15

Fig. 1.

The closest distance at which the average person of a given age can see clearly. There are no significant sex differences.

pupil size, an increase in yellow pigment in the eye media, some reduction in overall acuity, a slight narrowing of the visual field, some loss of colour discrimination, and increased susceptibility to glare. It can readily be appreciated that in our modern society these changes might have serious consequences for the automobile driver or pedestrian. However, tests of visual *efficiency* show that many of the old surpass many of the young, so that knowing a person's age does not permit us automatically to assume that he is visually inefficient. It is also true that we cannot be certain how much effect training might have on the maintenance of visual skills; nor has our physiological knowledge so far led to any great advance in the treatment of the ageing eye.

Although the changes in seeing are, barring some actual disease process, rather generally regarded as 'normal' effects of age, the case for hearing is not at all decided.

Fig. 2 illustrates the results of hearing surveys which find a progressive decline in the ability to hear the higher frequencies ('pitches') of sound. Fortunately, until the impairment involves frequencies below about 1,800 hertz (about three octaves above middle c), ability to comprehend speech, that basic ingredient of interpersonal interaction, is not significantly reduced. Of course we know that exposure to loud sounds will adversely affect the sensitivity of hearing, whether the exposure be in the boiler factory or the rock concert hall. The modern environment is rather noisy, and most if not all hearing loss is traumatically caused. In fact one investigator has found that persons living in a quiet, remote environment showed little or no loss. In any event, there are most certainly pathological causes of hearing loss or deafness, some of which (those involving conduction of sound to the inner ear) can be helped by 'hearing aids'. Also, lipreading and other skills can partially compensate for any kind of loss, provided that the perceptual inefficiency is not of cerebral origin.

When we consider 'bodily sensibility'—the skin senses, position sense, and internal sensations—the picture becomes very blurred by the effects of vascular and nervous disorders. Reported changes in some persons in sensitivity to touch and tem

Fig. 2.

The reduction in sensitivity for male and female persons as a function of age. Curves are shown for four sound frequencies.

Page 16

perature are rendered ambiguous by these possible disorders. Even so, there does seem, with age, to be a reduction in sensitivity to vibration and to pain, and some loss of sensitivity to the detection of fine movements of various joints, although the practical implications of these results have not been fully explored. Indeed, here lies a rich field for research.

Since dietary problems can be important in the elderly, changes in tasting and smelling that might affect the choice or enjoyment of food are of potential importance. It appears that loss of sensitivity does occur, although, especially in the case of smelling, pathological processes as simple as the common cold may also affect sensitivity.

In recognition of this decline, especially of smell sensitivity, flavour enhancers have been tried, with some degree of success. Also of considerable interest is the danger that loss of smell sensitivity may cause in the detection of warning agents such as the odorous agents added to domestic gas. Although some persons at any age are not sensitive to at least some of these agents, it has been shown that the elderly are particularly at risk.

It should be noted that demonstrably pathological states, such as senile dementia, which affect sensory and perceptual processes, have not been considered. Although such conditions are relatively rare, they may affect 10 per cent of persons aged over 65, with the frequency increasing to 22 per cent

among those aged 80 and over.

Nevertheless, to reiterate a previously made point, it is entirely possible that many sensory losses now considered to be 'normal' decline may be found to result from exogenous influences, or to loss of perceptual skill through disuse.

AGGRESSIVE BEHAVIOUR. Behaviour directed towards causing physical injury to another individual must clearly be labelled as aggressive; this is the hard core of aggression. Behaviour directed towards causing psychological harm is usually also included in the definition, and fantasies involving harm to others are closely related. The question of intent is crucial: accidental injury is not usually considered aggressive.

Since attack on another individual may involve risk of injury for the attacker, it is often associated with elements of selfprotective and withdrawal responses. This is especially apparent in the case of animal threat postures, which often consist of a mosaic of elements of attack and withdrawal (see FEAR AND COURAGE). For this reason attack, threat, submission, and fleeing are often lumped together as 'agonistic' behaviour.

Aggressive behaviour often settles status, precedent, or access to some object or space. Some, especially psychiatrists, choose to define aggressive behaviour so widely that all behaviour that leads or could lead to such results is included. Thus common speech uses such terms as 'aggressive salesmen'; this loose usage makes

'aggressive' synonymous with 'assertive'.

Heterogeneity of aggression. However defined, the category of aggressive behaviour conceals considerable internal heterogeneity, and numerous attempts have been made to subdivide it. Two examples may be cited.

In studies of children, four categories have been useful (Feshbach, 1964; Manning *et al.*, 1978): (i) Specific or instrumental aggression, concerned with obtaining or retaining particular objects, positions, or access to desirable activities. (ii) Teasing or hostile aggression, directed primarily towards annoying or injuring another individual, without regard to any object or situation. (iii) Games aggression, occurring when playful fighting escalates to the deliberate infliction of injury. (iv) Defensive aggression, provoked by the actions of others.

Turning to adults, Ticklenberg and Ochberg (1981) have classified criminal violence as follows. (i) Instrumental violence: motivated by a conscious desire to eliminate the victim. (ii) Emotional: impulsive, performed in extreme anger or fear. (iii) Felonious: committed in the course of another crime. (iv) Bizarre: insane and severely psychopathic crimes. (v) Dyssocial: violent acts that gain approbation from the reference group and are regarded by them as correct responses to the situation.

Such distinctions have been useful in a number of ways: for instance, the several types of childhood aggression have different developmental courses, and differ in their prognostic value for adult or adolescent behaviour problems. However, difficulties arise, partly because the different categories are not always clearly distinguishable.

This results in part from their motivational complexity.

Motivational complexity. Confronted with the astonishing range and diversity of aggressive (and courtship) behaviour in many nonhuman species, ethologists came to realize that the relations between the categories could be understood in terms of hypothesized underlying variables— aggression in terms of a motivation specific to the context (e.g. over food, or territory; see Meyer, 1968) and conflicting tendencies to attack and flee from the rival. These hypothesized motivations could be assessed by a number of methods, including analysis of the precise nature of the agonistic behaviour shown and the behaviour that immedi

Page 17

ately followed it. The diversity of the behaviour could be understood in terms of variations in the absolute and relative levels of the several motivations (Baerends, 1975). In a similar way it seems likely that the several types of human aggression can be understood in terms of different combinations of hypothesized underlying variables. Obvious candidates are 'specific acquisitiveness', or the motivation to acquire specific objects or situations; 'assertiveness', or the motivation to elevate one's position or push oneself forwards; and 'fear' (see below); as well as the propensity to behave aggressively (i.e. to harm others) itself (Hinde, 1985; Attali and Hinde, 1986).

Proximate factors predisposing to aggression. Whereas some writers have regarded aggression as dependent solely on emotional factors, others have regarded it as spontaneous and inevitably finding

expression. The issue could be of importance, since it affects the solutions that are sought for excessive social violence.

However, neither view is adequate. It is well established that, in many species, the tendency to show aggressive behaviour varies with hormonal condition, and considerable knowledge about the endocrine and neural mechanisms involved is now available (Svare, 1983): thus it is now realized that aggressive behaviour is not solely elicited. Neither is it solely internally generated: the catharsis view, proposing that aggression depends on spontaneously generated energy which must be dissipated in action, rests on an outdated model of motivation and has received no empirical support (Berkowitz, 1962). However, behaviour that serves to lower arousal level, specific acquisitiveness, or assertiveness may well also lower aggressive propensities.

Rejecting either one or the other of these views, research workers attempted to identify prime causes of aggression. Since by definition aggressive behaviour is directed towards other individuals an obvious candidate was the proximity of another member of the species. In animals the eliciting stimuli often proved to be quite simple—the red breast of a territoryholding robin is enough to elicit attack from an intruder (Lack, 1939). Of course situational determinants are also crucial: a male great tit will attack intruders if he is holding a territory, but flocks with other individuals if he is not.

Others emphasized frustration as a potent cause of aggression in man (Dollard *et al.*, 1939). Frustration has been demonstrated in animal experiments: a pigeon, trained to peck a key for food reinforcement, will attack another pigeon confined nearby during experimental extinction (Azrin *et al.*, 1966). One problem with this hypothesis is that practically any incident of aggression can be ascribed to frustration of acquisitiveness or assertiveness so the thesis is incontrovertible (Bandura, 1973), and another lies in identifying the precise nature of the factors that operate in a frustrating situation (Berkowitz, 1978).

Aggression can also be caused by pain or fear: for instance, rats confined together over a grid floor are likely to fight if the current is turned on. However, there is some doubt as to the similarity between natural aggression and that induced in these (often unnecessarily cruel) experiments (Ulrich, 1966).

So, rejecting any prime factor view, current research attempts to identify the spectrum of factors, internal and external to the individual, past and contemporaneous, that affect the incidence of aggression. These include constitutional factors and the current state of the individual (e.g. sex, genetic factors, hormones both prenatally and contemporaneously, temperament, and neural factors), current influences (e.g. frustration, peer example, the availability of weapons), and experiential factors. The latter include aspects of the family of origin (psychosocial disadvantage, unstable parental marriage, punitive and rejecting parents); details of family interaction patterns; and vicarious experience of aggression by others, especially if rewarded, including experience of violence on television (see, for example, reviews by Shaffer *et al.*, 1980).

It is clear that aggressive behaviour (like any other) has multiple causes, and that studies purporting to identify single, allimportant causes are bound to be simplistic. A recent study found that the

conditions related to the use by parents of harsh punishment were, in order of importance, perception of the child as difficult to handle, proneness to anger on the part of the parent, rigid parental power assertion, and intrafamilial problems and conflicts. Perceived harsh parental punishment was associated with either conduct disorder or anxiety and helplessness (Engfer and Schneewind, 1982). Although this study was crosssectional in design, it illustrates the manner in which aggressive behaviour can be seen only as one constituent of a complex causal nexus (see also Bandura, 1979).

Intergroup conflict. Most of the above concerns conflict between individuals. Different issues arise in conflict between groups. The most important are the degree of the actor's felt membership of his own group; the extent to which members of the other group are perceived (a) as individuals or as indistinguishable units and (b) as fellow human beings or as strangers, foreigners or even subhuman; and the extent to which reinforcement for the actor's behaviour comes from the approval of his own group or its effect on members of the other (see Tajfel, 1979, for example).

Ultimate causes. In addition to assessing what factors exacerbate or ameliorate an individual's propensity to aggression, we may ask why it is these factors that operate, rather than any others. Biologists seek answers in evolutionary terms, the hypothesis being that individuals have been shaped by natural selection to display or refrain from aggression in accordance with how it affects their

Page 18

own survival and reproduction and/or that of their close relatives. The data come mostly from animals, but there is growing evidence that the principles may be applicable to humans.

In the first place, in the course of evolution threat postures have become elaborated or 'ritualized' to make them effective as signals. At the same time, selection has modified the responsiveness of other individuals to the signals. The selection pressures on actor and reactor are of course distinct, as their interests are not the same.

Threat can be seen as a process of negotiation with the rival about what to do next (Hinde, 1985). (See also NEGOTIATING.) Now let us suppose that all individuals in a population used conventional threat signals but retreated from a context if there was any real danger. A new mutant who fought vigorously in every encounter would be clearly at an advantage, because he or she would be likely to win every encounter. However, if the mutant reproduced itself, vicious fighters would often meet vicious fighters. In such encounters someone would be liable to get hurt; if the gains of winning were less than the costs of losing (in terms of inclusive reproductive success), it might be better not to be a vicious fighter. Maynard Smith (1976) has shown that, given certain assumptions, a stable situation would arise when there were particular proportions of conventional and vicious fighters, or when each individual adopted each strategy for a particular proportion of the time. This is an example of an 'evolutionary stable state'.

In practice the advantages accruing to an individual from being a vicious fighter depend both on the benefits of winning encounters (and thus on the scarcity of the resources over which the encounters take place) and on the costs of engaging in them—benefits and costs being reckoned ultimately in

evolutionary terms. The benefits will vary between individuals and between classes of individuals. One issue here concerns the differences between the sexes. Human sex differences, interpreted in the light of comparative data on other species, suggest that in our environment of evolutionary adaptedness males have competed for females (see Short, 1979). Selection would then have enhanced aggressiveness in males more than in females. (This in itself says nothing about the way in which it would have come about: for instance, selection could operate to make males inherently more aggressive than females, or to make parents encourage aggressiveness in boys more than in girls, or both, or in some other manner.)

Considerations of costs and benefits (in either evolutionary or more immediate terms) should also warn us against expecting any simple relations between exposure to aggression in development, either at home or in the peer group, and aggressiveness in adulthood, for the costs and benefits of aggressiveness vary with the probability of meeting other aggressive individuals and with the scarcity of resources. In a population containing few vicious fighters and plentiful resources, the advantages to individuals of cooperating in group living may detract from the advantages of being an egotistical vicious fighter. In a population containing a moderate number of vicious fighters and in which resources are scarce, it may be necessary to be a vicious fighter or succumb. But if nearly everyone is a vicious fighter, so that the costs of encounters are certain to be great, it may be better to contract out and seek another means of access to the resources. These speculations about crude caricatures of

'cooperators' and 'vicious fighters' must not of course be taken too seriously, but they are useful in sounding a warning against expectations of simple monotonic relations between childhood experiences and later characteristics.

AGNOSIA. Originally Sigmund*Freud used the term agnosia to mean loss of perception. It is now applied to disorders whereby the patient cannot interpret sensory information correctly even though the sense organs and the nerves leading to the brain are operating normally. Thus in auditory agnosia, the patient can hear but he cannot interpret sounds (including speech).

AGORAPHOBIA. See PHOBIAS.

AGRAPHIA. The loss of the ability to write, which may or may not be connected with alexia, the loss of ability to comprehend the written or printed word. It is thought to be caused by a lesion in the cerebral cortex or by more generalized cerebral dysfunction.

AKINESIA. The severe reduction or absence of spontaneous movement, characteristic of the later stages of*Parkinsonism.

ALCOHOLISM. See ADDICTION.

ALEXIA (WORDBLINDNESS). Inability to read the printed or written word, usually caused by damage of cerebral hemisphere. See DYSLEXIA.

ALFARABI (Muhammad ibnMuhammad ibnTarkhan ibnUzlagh AbuNasr alFarabi, or Alpharabius) (870950). Born in Farab, Sughd, now in Uzbekistan, he was the first great Turkic exponent of*Islamic philosophy. He studied at Baghdad and taught as a*Sufi at Aleppo, now in Syria. He states that he read*Aristotle's *De Anima* two hundred times; he was certainly so well versed in it that he gained the Arabic title of *AlMu'allim alThani*—the Second Teacher (after Aristotle). The author of over a hundred volumes, he lived simply, taking employment as a nightwatchman so that he could work by the light of the lantern provided.

He harmonized Greek philosophy with Islamic thinking, thus continuing the work of*AlKindi and preceding*Avicenna; his considerations covered logic and rhetoric, geometry, psychology, and politics. Baron Carra de Vaux and others state that the logic of Farabi had a permanent effect upon the thought of the Latin schoolmen.

Farabi believed that God exists as the only ultimate reality and unity, intermediary agencies successively producing the world as we know it through conventional avenues of perception. Human society he regards as emerging through two impulses: a social contract not unlike that later proposed by*Rousseau, and an urge prefiguring the*Nietzschean will to power. Society, for Farabi, realizes its perfection (the Ideal City) through a ruler who has become a divine agent, or alternatively by the administration of a group of wise men, each specializing in one subject. The capacity to be detached from objects and concerns enables a human being to go beyond familiar dimensions, transcending the ignorance produced by regarding secondary phenomena, such as time and space, as primary.

ALGHAZZALI (Imam AbuHamid ibnMuhammad AlGhazzali, or Algazel) (10581111), born at Tus,

Persia. Originally a theologian and scholastic philosopher, professor at the Nizamiyyah College in Baghdad, Ghazzali is known as *Hujjat alIslam* (Proof of Islam) and is one of its greatest thinkers. He decided that ultimate truth could not be attained by intellectual means, and became a Sufi. He influenced all subsequent Sufic thought as well as many Western philosophers and theologians.

His *Ihya Ulum alDin* (Revival of the Sciences of Religion) is a classic which is widely believed to have had a great (some believe determining) effect upon Europe, through Latin and Hebrew translations, especially in his method of criticizing hypotheses and assumptions. Jehuda Halevi (in his *Khazari*) follows the Ghazzalian method as found in the remarkable *Incoherence of the Philosophers*, and the first Hebrew translations of the influential *Maqasid alFalasifah* (Aims of the Philosophers) were made by Isaac Albalagh, c. 1292, and by Judah ben Solomon Nathan, c. 1340. The Dominican Raymund Martin (d. 1285) used Ghazzali's arguments in his *Explanatio symboli apostolorum* and *pugio fidei*, continually quoting the devout Islamic thinker in support of Christian ideas. St Thomas Aquinas (1225-74) also cites Ghazzali. Blaise Pascal, writing on belief in God, echoes Ghazzali's *Ihya*, *Kimia*, and other writings, while Pascal's theory of knowledge (in *Pensées sur la religion*) closely follows Ghazzali's book *AlMunqidh*. Ghazzali's work is as widely studied today as it ever was.

ALGORITHM. A predetermined procedure or ordered sequence of instructions for carrying out an operation in a finite number of steps. Computer Page 20

programming involves designing such procedures since computing is precisely the automation and execution of algorithms. Moving the decimal point for multiplication or division by multiples of 10 is a commonly used algorithm. The Euclidean algorithm is a method for finding the greatest common divisor of two numbers by continued subtraction.

The origin of the term is from the name of an Arab mathematician, alKuwarizmi (c.830), who wrote an extensive account of the Hindu system of numerals and numeration from which our current system evolved. Writing numbers and performing calculations using Hindu numbers became known through his account as

'algorismi', and competitions were held between the abacists, who favoured the abacus for calculations, and the algorists, who preferred pencil and paper calculations.

To use an algorithm, perhaps as a rule of thumb, need not require an understanding of why it works,

and algorithmic thinking can be a term used derogatively. Yet making some mental operations a matter of mechanical routine can free the conscious attention for other more demanding matters.

ALKINDI (AbuYusuf Ya'qub ibnIshaq) (803/73). Born at AlKufah, now in Iraq, of a southern Arabian family, he worked mainly in Baghdad, and was the first Arab philosopher. He attempted to combine the views of*Plato and*Aristotle, and his collation of the *Theologia* ascribed to Aristotle had considerable influence on philosophy and theology in both East and West until the time of St Thomas*Aquinas.

AlKindi was a polymath, like almost all of the major Islamic philosophers: an optician, music theorist, pharmacist, and mathematician; he wrote 265 treatises, most of them now lost. He saw the universe as an architectonic whole, not as something to be observed piecemeal to discover causality. He asserted 'one of the most marked features of Islamic thought—the belief that there was only one active intellect for all humanity, and that every human soul was moved and informed by this separated active intellect' (Leff, 1958). More of his work survives in Latin (such as in the translations by Gerard of Cremona) than in Arabic. One of his major scientific contributions was *De Aspectibus*, on the *Optics* of*Euclid, which influenced Roger Bacon. His works show that mensural music was studied in his culture centuries before it appeared in the Latin West.

ALLOTROPY. Variation of physical properties without change of substance. Thus diamond and graphite are the two allotropes of the element carbon. Both are composed of pure carbon but have different physical forms. In most early philosophy, there was supposed to be underlying substance which maintained the continuity of objects even when they changed. This same idea was often applied to mind—that the mind of an individual is a continuing substance even though, throughout life, the individual changes in his ideas,*emotions, and behaviour. David*Hume took the opposite view, arguing that the self is no more than a 'bundle of sensations'. See also PERSONAL IDENTITY.

ALZHEIMER'S DISEASE. See DEMENTIA.

AMBIGUITIES IN PERCEPTION. See ILLUSIONS.

AMNESIA. The popular conception of amnesia is probably typified by the occasional newspaper report of the appearance of someone who has mysteriously lost his*memory. The person has no idea what his name is, where he comes from, or indeed about any of his past. Such cases usually recover their memory within a day or two, and typically turn out to be people attempting to escape from some

socially stressful situation by simply opting out through the mechanism of dissociation. The precise nature of their memory defect is variable and seems to depend very much on their own views about how the human memory system works. In this respect they resemble hysterical patients suffering from glove anaesthesia, numbness in the hand which extends up to the wrist but not beyond and bears no relationship to the underlying pattern of innervation of the hand, indicating that it is of psychogenic origin rather than based on a physiological defect. The extent to which psychogenic amnesia represents genuine inability to recall, as opposed to conscious refusal to remember, is hard to ascertain. For further details see Pratt (in Whitty and Zangwill, 1977).

The most extensively studied form of amnesia is that resulting from damage to the limbic system of the brain, typically involving the temporal lobes, hippocampus, and mamillary bodies. Such damage may occur in people suffering from Korsakoff's syndrome, which results from a prolonged period of drinking too much alcohol and eating too little food, leading to a vitamin deficiency of thiamine (vitamin B₁). Such patients often go through a delirious confused state, before stabilizing. They may then

show a range of symptoms extending from considerable general intellectual impairment with relatively little memory decrement to occasional cases in which a relatively pure memory defect occurs. A broadly comparable memory defect occasionally occurs following encephalitis, and may also be produced by other kinds of brain damage such as stroke, tumour, or coal gas poisoning. There is some controversy over whether such a wide range of patients have a common memory defect, or whether subtle differences occur but the broad pattern of symptoms is similar.

Such patients have no difficulty in knowing where they grew up or telling you about their job or family background. In the case of relatively pure

Page 21
amnesics at least, their ability to use language is unimpaired, as is their general knowledge of the world. Their short-term memory also appears to be intact, at least in many cases. Their ability to repeat back a telephone number is just as good as would be the case in a normal person, and if you present them with a list of words, they show the normal tendency for the last few words presented to be well recalled. Their retention of the earlier words in a list is, however, likely to be very poor indeed.

The amnesic defect in the case of these patients appears to be one of episodic memory. They would be quite unable to tell you what they had for breakfast, and would very probably have no idea where they were or how long they had been there. If you had spent the morning testing them, by the afternoon they would probably fail to recognize you, and if asked for items of current information such as the name of the Prime Minister, would be likely to come up with a totally inappropriate response, naming a figure from twenty or thirty years ago. They have great difficulty in learning lists of words, whether you test them by recall or recognition, and have similar problems in remembering nonverbal material such as pictures of faces or objects.

There are, however, aspects of long-term memory which seem to be relatively unimpaired. Amnesic patients can learn motor skills, and one case, a pianist who was taught a tune on one day, had no

difficulty in reproducing it on another. But characteristically such patients have no idea how or when they acquired the relevant information. A classic example is that cited by the Swiss psychologist*Claparède, who on one occasion secreted a pin in his hand before shaking hands with an amnesic patient. On a subsequent day when he extended his hand the patient withdrew hers. When asked why, she could give no justification other than the general comment that sometimes things were hidden in people's hands. As one would expect from this demonstration, amnesics appear to be quite capable of classical avoidance*conditioning. They are also quite capable of learning verbal materials under certain conditions. For example, Warrington and Weiskrantz used a learning procedure whereby subjects were presented with a series of words, and recall was tested by presenting the first three letters of each word and requiring the subject to produce the whole word. When tested in this way, amnesics were virtually normal.

What characterizes the longterm learning tasks that amnesics can do? This is still a controversial issue, but broadly speaking the tasks seem to be ones in which the patient simply has to use the information available in his memory store, without needing to worry about how it was acquired. The case where he is cued by being presented with the initial letters may be interpreted as simply a problemsolving task where he must find a word that fits these particular constraints. Having recently been presented with the relevant word will in fact make it more available, but he does not need to know this in order to take advantage of such an effect.

While classic amnesics like those just described are theoretically extremely interesting, patients having such a dense amnesia unaccompanied by more general intellectual deterioration are relatively rare. It is much more common for memory disturbance to stem from the aftereffects of a blow on the head, as is often the case in road traffic accidents. Consider, for example, a motorcyclist who is involved in an accident involving a severe head injury. He is likely to lose consciousness for a period which may range from a few seconds to several months; if and when he regains consciousness he is likely to show a range of memory problems. It is usual to distinguish three separate types or aspects of such traumatic amnesia, namely retrograde amnesia, posttraumatic amnesia, and anterograde amnesia.

On recovery there will be evidence of loss of memory extending over the period between the injury and full return of consciousness. Following a head injury there will be a period of confusion characterized by the patient's inability to orient himself in time and place. The duration of posttraumatic amnesia, which will comprise the duration of total and partial loss of consciousness, provides a useful measure of the severity of the patient's injury and so permits some estimate of the extent of probable recovery to be made. On emerging from posttraumatic amnesia the patient is still likely to show considerable retrograde amnesia. This is indicated by an inability to remember events before the accident. In the case of a severe blow the amnesia may extend over a period of several years. Typically this blank period becomes less and less, with earlier memories being recovered first, although the process is far from systematic, with 'islands' of memory cropping up in periods that are otherwise still blank. Typically the retrograde amnesia shrinks up to a point within a few minutes of the accident. These final few moments are seldom ever recovered, possibly because the memory trace was never adequately consolidated. This point was illustrated rather neatly in a study of American football players who had been

'dinged' (concussed) during a game. As they were led off the field they were asked the code name of the play in which they had been engaged when concussed (e.g.

'Thirtytwo pop'). Typically they were able to supply this information immediately on leaving the field, but when retested 20 to 30 minutes later they were quite unable to provide it. A subsequent study showed that this was not simply due to normal forgetting, nor to the mnemonic limitations of American football players, but suggests that failure of memory traces to consolidate during the concussed state may be an important factor.

The third memory disturbance associated with head injury concerns difficulty in learning and retaining new information. During the process of Page 22

recovery from a dosed head injury, memory problems are commonly reported, together with difficulties in concentrating and a tendency to become fatigued much more rapidly than was previously the case. While the memory problems of patients with head injuries have been rather less extensively investigated than those of the classic amnesic syndrome, we do know that they show some of the same characteristics. Typically shortterm memory is not greatly affected, and if one presents an amnesic headinjured patient with a list of words, he is likely to do reasonably well on the last few presented, but relatively poorly on the earlier items in the list.

Although not much work has been done in directly comparing such patients with other types of amnesics, it seems likely that the pattern will be somewhat different, since closed head injury appears to cause neuronal and vascular damage in large areas of the brain as opposed to specific subcortical damage in the classic amnesic syndrome. Furthermore, whereas the classic amnesic patient does not completely recover, headinjured patients typically do improve quite substantially from the time when they emerge from their initial period of posttraumatic amnesia. In many cases they return to performing at what appears to be their level before injury.

Amnesia is an important component in senile and presenile*dementia. In both these cases intellectual deterioration probably results from a substantial loss of cortical neurones, and in addition to showing memory problems such patients usually show a more general intellectual deterioration. This in turn increases the memory problem, since they seem unable or unwilling to use effective learning strategies.

We have so far discussed patients who have long. term learning problems but normal shortterm memory. However, the reverse has also been reported. Shallice and Warrington (1970) describe a patient who had great difficulty in repeating back sequences of numbers, the longest sequence he could repeat back reliably being two digits. He was, however, quite unimpaired in his longterm memory as measured both by his ability to learn word sequences and by his memory for faces and for the events of everyday life. As is suggested in its entry, shortterm memory is almost certainly not a single unitary function, and there is some evidence to suggest that there are other patients who have different defects of the shortterm memory system.

Theoretical interpretation of the various ways in which memory can break down obviously depends crucially on one's interpretation of normal memory. As such, amnesia presents a theoretically important though difficult question. We have in recent years made progress in exploring and defining more precisely the amnesic syndrome, but are as yet some way from constructing a completely adequate interpretation at a psychological, neurological, or biochemical level.

AMPUTATION, EXPERIENCE OF. See NOTHINGNESS; SPATIAL COORDINATION OF THE SENSES.

ANAESTHESIA may be described as a reversible loss of consciousness produced by a drug, from which arousal does not take place even with painful stimuli such as setting a fracture or surgical operation. In this latter respect it differs from sleep or the change in consciousness following sensory deprivation; and it is this that made it so revolutionary a discovery, opening the gateway to modern surgery and safer childbirth. The name is not quite exact, since loss of consciousness is not the same as loss of feeling; and a good anaesthetic in clinical practice should exert other actions, such as some analgesia (to diminish reflex responses to what would be very painful stimuli) and muscular relaxation (to facilitate the surgeon's work). When an anaesthetic such as ether or chloroform is given, there is a characteristic progression of effects, first described by Guedel in 1937: first analgesia, some loss of memory, and perhaps euphoria; then consciousness is lost, but the patient may struggle, breathes irregularly, is sweating and flushed; in the third stage, the patient becomes quieter with regular breathing, but the eyeballs move rhythmically and a good many reflexes are still present. As anaesthesia deepens, and the patient passes through the successive planes of the third stage, various reflexes progressively fall away, the breathing becomes shallower, and eventually death may ensue (the fourth stage). In modern practice anaesthesia is induced with a suitable barbiturate (such as thiopentone) injected intravenously: the patient then passes through the early stages within seconds; once 'under', anaesthesia is usually maintained by some other substance.

How do anaesthetics work? It is paradoxical that more is known at the molecular level than at any other. A remarkable feature is the astonishing range of substances that can produce anaesthesia: in addition to the classical anaesthetics and the barbiturates, nitrogen in the air (if given at high pressure) and many other gases, alcohols, dry cleaning fluids (such as trichloroethene), industrial solvents, and certain steroids can all produce typical anaesthesia. There is no common chemical structure such as would suggest a specific action on some particular part of the brain. Instead, as two pharmacologists, Overton and Meyer, pointed out over eighty years ago, anaesthetics all share the

property of dissolving in fat; and it is remarkable that one can predict the potency of an anaesthetic quite accurately by measuring the pressure of a gas

Page 23

or the concentration of a vapour which will produce a given concentration (about 0.05 moles per litre) of the substance concerned in olive oil. Modern work has revealed the significance of this: the cell membrane, which defines the cell's limits, and across which an electric potential is maintained, consists of an ordered array of fatty molecules (mostly phospholipids and cholesterol); the anaesthetic dissolves in it, and slightly expands and disorders the membrane. Since the membrane also carries large protein molecules (enzymes, ion channels, receptors, transport mechanisms) which mediate its 'traffic' with its environment and with other cells, disturbance of their normal function becomes possible. A fascinating aspect is that very high pressures (which compress and reorder the membrane) cause recovery from anaesthesia. Conversely, a suitable amount of an anaesthetic can be used to neutralize the adverse effects of high pressure. The 'high pressure nervous syndrome', which includes tremor, bursts of 'microsleep', and convulsions, threatened to limit the depth to which divers could go; but the addition of nitrogen (using it as a small dose of anaesthetic) to the diver's heliumoxygen mixture has extended that limit.

But if one asks, 'On what synapses, or on what cell groups of the brain, is this molecular action particularly exerted?', no satisfactory answer exists. The simple fact of surgical anaesthesia shows that higher brain functions are particularly sensitive, while respiration and simple reflexes, as well as other bodily processes like the heartbeat, are relatively resistant. Detailed analysis yields a bewildering variety of effects, with actions both pre and postsynaptically, varying with the synapse and with the anaesthetic. A simple view is that the anaesthetic picks out any delicately poised nervous activity, and that the pattern of anaesthetic activity is simply that of reduced activity in the most vulnerable nervous pathways—particularly complex nervous functions rather than (for example) simple reflex movement. Theories include the idea of a specific effect on the 'ascending reticular activating system', in the absence of whose activity the cerebral cortex is believed to relapse into a sleeping state, or on cortical cells generally. Some recent drugs (such as ketamine), which produce the so-called 'dissociative anaesthesia', may help to throw light on the problem;

these differ, both in having a specific chemical structure, and in producing a rather different pattern of anaesthesia.

There is an abundant literature on the effects of anaesthetics on mental function, short of anaesthesia, and Humphry Davy's description (in 1800) of the effect of nitrous oxide (*laughing gas) on himself and his friends (including Southey, Coleridge, Roger, and Wedgwood) reveals the salient features recorded many times subsequently: considerable variation with the individual; excitement; euphoria or sometimes dysphoria; compulsive movements or laughter; 'thrilling' sensations in the limbs; feelings of deep significance; rush of ideas; synaesthesiae; drowsiness; warmth, rapid breathing, palpitations, giddiness; and often a strong desire to repeat the performance. This last characteristic brings the risk of addiction in its train, particularly for those (such as anaesthetists and nurses) with easy access to the drugs; and it shows itself again in 'gluesniffing' in children, or with workers using

some solvents in industry.

An important feature with all these volatile substances is the speed with which effects are produced by inhalation, by which the vapour passes very quickly into the circulation. More familiar to most people will be the effect of anaesthetics such as alcohol or barbiturates taken orally, with an onset delayed by circulatory absorption;

and the fact that by this route some of the more dramatic effects are lacking (although euphoria and the risk of addiction remain) suggests that these effects are largely due to especially rapid access to, and uptake by, particular parts of the brain, producing a selective action which fades as distribution of the drug becomes general.

With sustained exposure to any anaesthetic, the adaptation known as 'tolerance' develops, by which an increasing dose is required to produce the effect. 'Crosstolerance' occurs between different anaesthetics—hence the difficulty often encountered of anaesthetizing an alcoholic! When exposure stops and the drug is withdrawn, characteristic symptoms appear: for example, insomnia after a short course of any sleeping pill, or delirium tremens (d.t.'s) after prolonged high exposure to alcohol, or convulsions after chronic barbiturate use. While some of the adaptive changes may be biochemical, some of them certainly represent a change in nerve cell function, and there are interesting indications that the composition of the cell membrane changes so as to reduce the effect of the anaesthetic.

One would like to think that experience with anaesthetics would deepen our understanding of consciousness, mood, sensation, pain, memory. Yet it is still impossible to move convincingly from the subjective phenomena to physiological understanding. Perhaps it is unreasonable to expect to do so until our knowledge of normal neurophysiology is more satisfactory, or perhaps pharmacology and physiology need to proceed, collaboratively, in parallel. Some areas may be picked out as potentially fruitful.

1. The effect on *sense of time*. There is a puzzle here: nitrous oxide and alcohol appear to reduce 'felt' time compared with 'clock' time, whereas ketamine (like cannabis) prolongs it. With the latter drugs, one can readily suggest, as William*James suggested, that 'disinhibition' in the brain, allowing a greater than normal sensory input, could give rise to an experience of more numerous mental impressions than usual per unit of 'clock' time, and hence a greater 'felt' time. But why should other anaesthetics differ?

2. The effect on *pain sense*. There is some evidence that enkephalins or endorphins may play Page 24 a part in analgesia produced by anaesthetics. (See NEUROPETIDES.) But there remain remarkable differences between anaesthetics, some with pronounced analgesic action, some potentiating the response to a painful stimulus. Bearing in mind its practical relevance, as well as the recent advances in our knowledge of the neuroanatomy and neurochemistry of the nociceptive pathways, and the successful application of decision theory to the study of pain, a systematic study of the action of a range of anaesthetics on pain discrimination and pain report seems well worth while.

3. The effect on *sensation generally*. An intriguing but neglected observation is that anaesthetics facilitate the generation of impulses in the vagal nerve fibres registering the inflation of the lung, which accounts for the ability of many anaesthetics to produce what is known as 'rapid shallow breathing'. It is an intriguing action, and exerted peripherally on the proprioceptive endings in muscles might account for the 'thrilling' sensation described by Davy. But more generally there might also be an important effect both on the pattern of sensory input to the brain, and on subsequent processing.
4. Effect on *memory*. With the recent advances in our knowledge of registration, consolidation, and retrieval, systematic study of the effect of a range of anaesthetics on memory is overdue, although the problem is complicated by 'state dependence'. An old method of anaesthesia for childbirth, 'twilight sleep', exploited the effect of the drug hyoscine on memory, so that even if pain was felt, it was not remembered. The method has been abandoned because of the effect on the baby, but the approach is still interesting.
5. The concept of *disinhibition* is constantly, and plausibly, invoked to account for phenomena such as the rush of ideas, synaesthesia, and electroencephalographic synchronization. The underlying idea is that the great complexity of mental activity does not merely need some neurones to be active, but also needs others to be actively 'switched off' (inhibited): if the latter process were interfered with (disinhibition), then differential activity and 'gating' of information transfer could become progressively impaired. Simple model systems exist, illustrating how depression of an inhibitory pathway can lead to release phenomena; but no serious attempt has been made to extend the idea to more complex systems. Yet if certain inhibitory mechanisms are particularly vulnerable, it should be possible, by careful choice of systems sharing common elements, to identify them more closely.
6. A tedious but necessary development is that of knowledge about the kinetics of *anaesthetic distribution* in the brain. Some knowledge exists of the rise and fall of the concentration of an anaesthetic during and after an exposure, for samples of brain containing thousands or millions of neurones. But this is merely a gross average, telling us nothing of local concentration in synaptic detail. Equilibrium with an anaesthetic is virtually never reached in clinical practice, and rarely in experimental work, so that (as mentioned earlier) there is ample scope for differential effects arising, not from the properties of the drug itself, but from varying access and uptake. For instance, evidence is accumulating that if any part of the brain becomes particularly active it consumes more energy, with a corresponding increase in bloodflow; that would at once open the way to differential access by an anaesthetic.
7. Finally one must recall that, despite all the advances in neuroanatomy, it is only a tiny minority of nervous pathways that can be precisely and completely described in anatomical and neurochemical detail, with the specific neurones and their connections specified. But some beautiful techniques now exist for mapping out these pathways, for recording the activity of single or groups of neurones, and for neurochemical analysis (see NEUROANATOMICAL TECHNIQUES): the new methods of anaesthesia that a deeper understanding will provide are not far away.

ANAGLYPH. A picture that can be used to create a stereoscopic image. It uses two colours (in practice red and green, or sometimes red and blue) with corresponding colour filters, so that a picture with different colours can be presented to each eye. This method is used for presenting stereoscopic pictures in printed books, instead of using separate pictures that require a stereoscope to present one picture to each eye. See STEREOSCOPIC VISION.

ANALOGUE. See DIGITAL.

ANALYTIC PROPOSITION. The idea behind the notion of an analytic proposition is that at least some of our concepts can be represented as complexes of simpler concepts and that a proposition may state nothing more than what an analysis would reveal, namely a relation between a simple concept and a complex concept of which it forms a part. Thus *Kant, taking judgements expressed by propositions to have the form '*A* is *B*' defined an analytic judgement as one where 'the predicate *B* belongs to the subject *A* as something which is (covertly) contained in the concept *A*'. In more linguistic terms, if the criteria for calling something 'a body'

include the criterion, being extended, then the latter is 'contained in' the former and the proposition 'a body is extended' is analytic. An analytic statement thus cannot be denied without contradiction and is logically necessary (*possibility). That this necessity can be seen simply from a grasp of the concepts or words involved leads to speaking of analytic propositions as true in virtue of the meanings of words.

Page 25

Gottlob Frege freed the notion of analytic proposition from the assumption that the logical structure of all concepts is based upon conjunction of criteria, by taking as analytic any proposition whose proof rested only on general logical laws and definitions. This also made clear that whether a proposition is regarded as analytic is relative to what are recognized as legitimate means of definition and what general logical laws are accepted as valid.

A proposition that is not analytic is synthetic. The arguments of W. V. Quine showed that the analytic/synthetic distinction is not as sharp as had previously been assumed, but not that the distinction is wholly without foundation.

ANGELL, JAMES ROWLAND (1869-1949). An American psychologist, James Angell worked at Harvard with William*James, then at Chicago, where he became a founder of the Chicago 'functionalist' school which stressed the importance of physiological processes (see FUNCTIONALISM). This was a direct development of much of James's thinking, and led to*behaviourism. The founder of behaviourism, J. B.*Watson, was a student of Angell's.

Artger showed that*reaction times have two components—sensory and muscular—and that unpractised subjects have greater individual differences in reaction time than when they are practised. This raises a curious question. Specially trained or skilled subjects give more reliable results—but they are not typical subjects. So, should subjects be given special training, to get more consistent results which look better on paper; or should relatively naive subjects be used, as they are typical of most people and so represent normality? This is quite a general problem in experimental psychology, even for simple skills or tasks which seem close to basic physiological limits, such as designing and interpreting experiments on reaction time.

Boring, E. G. (1950). *A History of Experimental Psychology*, 2nd edn., ch. 24. New York.

ANIMAL. Although in its widest sense the term 'animal', as contrasted with vegetable and mineral, includes mankind, in common usage the term is restricted to

'lower' or nonhuman animals—the 'brutes' or 'beasts'. For*Descartes (whose *Discourse on Method*, 1637, examines the difference between men and beasts), the crucial point is that animals lack language: their 'utterances' are always elicited by a specific stimulus, and thus can never amount to genuine speech. It follows, on Descartes' view, that animals lack thought, and that their behaviour can be explained on purely mechanical principles—a view which led later Cartesians to the notorious doctrine of the ' *bêtemachine*' and that animals are merely mechanical automata. In recent times the linguistic theories of Noam Chomsky have reinforced the view that animals lack genuine (i.e. creative, stimulusfree) language; current empirical research, however, suggests that chimpanzees, at least, may have a degree of linguistic competence. Current work in moral philosophy has stressed the fact that animals, though they may lack thought, are at least sentient, and hence are entitled to moral consideration. (See PRIMATE LANGUAGE.)

ANIMAL BEHAVIOUR. See ETHOLOGY.

ANIMALHUMAN COMPARISONS. How far can animal data help us understand human behaviour and experience? We may consider the question in two stages. First, do animals resemble humans sufficiently closely for data derived from their study to be relevant? And second, in what ways could animal data be used?

With respect to the question of similarity, the human brain is very like those of the great apes, somewhat similar to those of monkeys, and is built on generally similar lines to those of other mammals. There is also a general structural similarity with the brains of other vertebrates, but very little with the nervous system of invertebrates.

On anatomical grounds, therefore, we might expect similarities in behaviour between humans, nonhuman Primates, and perhaps other mammals, an expectation supported also by palaeontological evidence. (See PRIMATES EVOLUTION OF THE BRAIN IN.)

The complexity of the behaviour of higher mammals confirms this view. Much of their behaviour can be interpreted only in terms of the trying out of alternative strategies to reach a goal. Problems requiring an animal to respond to the middle of three objects, to the odd one out, or to an abstract number of objects (up to about five), or to form concepts of categories of objects, have been demonstrated many times in laboratory studies of mammals, and also in some birds. Field studies show that chimpanzees not only use but also make tools, and that many Primates have an extraordinarily complex social organization based on elaborate signalling systems.

Observation also indicates that chimpanzees have a concept of self and can dissemble and deceive others. Chimpanzees can cooperate in that one can learn to ask another for one out of six possible tools required to obtain food, which is then shared. It has even been claimed that they impute mental states to others. The evidence here is that a chimpanzee, shown pictures of a human actor struggling with a problem, can select from a series of photographs the one portraying the solution.

Page 26

Although we can have no direct knowledge of animal affective states, there is strong evidence that dogs have pleasant and unpleasant dreams, and it seems likely that the greater the similarity in brain structure, the greater the similarity in affective experience.

The main difference, of course, lies in the complexity of human language. All animals communicate by a repertoire of signals, and chimpanzees can learn to use complex systems of signs or symbols for communicatory purposes. (See PRIMATE LANGUAGE.) However, these fall so far short of human language that the difference is best seen as one of quality rather than quantity. One immediate consequence of this is that anything corresponding to human institutions is virtually nonexistent in animals, and cultural differences, though present, are minor. Local traditions can be acquired only through individuals' experience and their observation of the experiences of others, and perhaps to a limited extent by parental training. Lack of linguistic complexity no doubt also restricts animals' abilities to solve problems by the manipulation of symbols, to reflect on the past and future, and so on. In so far as our emotions are culturally influenced, it may limit the range of affective states

animals can experience. Finally a human being, and perhaps a higher Primate, can interpret his own behaviour as goaldirected ('I am reading a book') or as impelled ('I fell asleep'), but it may be only a human being who monitors his own monitoring, seeing his behaviour as more or less efficiently goaldirected ('I was trying to read, but fell asleep').

Given, then, that the behaviour of higher mammals, and especially that of higher Primates, resembles that of humans in some respects while differing in others, in what ways can animal data help our understanding of the human case? In practice, there are three main ways of using such data.

First, one can search for an animal model, suitable for investigating the problem in hand. 'Suitable' in this context usually means 'resembling humans' in relevant ways;

models are usually evaluated in terms of their similarity to the original. As we have seen, Primates resemble humans in brain structure more closely than do other mammals, and are thus more likely to produce relevant data about behaviour and brain function.

However, the value of models in science lies in part in their differences from the original. Three issues must be considered here. (i) Models are useful because, by virtue of availability or simplicity, they pose questions, suggest relations, or can be manipulated in ways not possible with the original. When a model becomes an exact replica, it loses its *raison d'être*. (ii) If a model is very like the original, it is easy for an investigator to assume that all the properties of the model exist also in the original, and to confuse the two in arguments in which the model is employed. (iii) The third issue is of crucial importance where animals are confined or experimented upon. The more closely related the experimental animal to humans, the more the infliction of suffering requires justification in terms of potential benefit to animals or humans.

For these reasons, the most useful animal models are not always those most similar to humans. Much of our knowledge of brain function is based on experiments with rodents and carnivores, for instance. For some purposes, relative simplicity is an advantage. Furthermore, for many problems resemblance to humans in a particular feature is more important than overall close evolutionary relatedness. For example, the sexual behaviour of chimpanzees is adapted to quite different social conditions from that of humans, and would provide a poor model. And some anthropologists have argued that the savannahliving baboon may provide a better model for the social structure of early man than the more closely related but forestdwelling chimpanzee.

While animal models have been of great value in studies of brain function, their use can involve great dangers. The very act of comparing humans with animals may lead us to neglect the complexity of the human case. For instance, studies of animals have facilitated isolation of many factors conducive to aggression, such as proximity, male sex hormone, and 'frustration'. But animal studies alone will never permit us fully to understand human aggression in all its deviousness and complexity. A second danger arises from the fact that interactional influences between causal factors are ubiquitous. For instance, the effect of stimulation in infancy on the behaviour of adult rats in an open field depends on the sort of cages they are kept in both before and after weaning. Thus the finding that a given treatment does or does not produce a given effect in an animal may not be valid even for that species in all

circumstances, let alone for man. A third danger, related to the last, arises from the multiplicity of animal species; so much depends on selecting the right models. For instance, the effects of temporarily separating mother and infant monkey vary between species, and thus extrapolations to humans might easily depend on which species was used. The problem is exacerbated by the diversity of human cultures; factors important in one may not be so in another.

A second way of using animal data can sometimes avoid these dangers. If we compare a range of animal species, and abstract principles, the validity of those principles to the human case can then be evaluated. For instance, in mammals the protein content of maternal milk is inversely related to the frequency of suckling;

human breast milk composition suggests that newborn babies should be fed more often than the fourhour schedule often recommended in hospitals. Again, experiments with a number of species suggest that the longterm effects of separating mother and infant monkey depend primarily on the degree to which the motherinfant relationship was disturbed; this principle seems directly applicable to Page 27

humans, although the treatments most disruptive of the motherinfant relationship differ between species and between human cultures. (See ATTACHMENT.) And, on a broader horizon, crossphyletic comparisons suggest trends in brain evolution, extrapolations of which to humans can guide research endeavours.

A third but often neglected type of argument involves focusing not on the similarities but on the differences between animals and humans. For example, human social structure is usually described in terms of languagebound institutions— marriage, the monarchy, and so on. Yet monkeys and many other mammals have societies of extraordinary complexity. If complex social structure can exist without language, perhaps we should look also for nonlanguagebased determinants in humans. Again, if motherinfant separation induces depression in infant monkeys, that depression must be explicable in terms of concepts applicable to the monkey level of cognitive functioning, and comparable depression in humans may *need* no additional ones. And, as a third type of example, the relative simplicity of the animal case can provide scope for the sharpening up of concepts which can then be applied with greater advantage to the human case.

In conclusion, animal models can provide data relevant to human behaviour and experience, but their use involves dangers of which the experimenter must be aware.

Abstracting principles from comparative data, and assessing their relevance to humans, is often a safer course. And the differences between animals and humans can also be usefully exploited.

ANIMAL MAGNETISM. See MESMERISM.

ANIMISM. 1. The belief, common among primitive peoples, that all things in the world (including stones, plants, the wind, etc.) are imbued with some kind of spiritual or psychological presence; this may imply that things are 'ensouled' or 'animated' by a universal 'world soul', or by individual spirits of various kinds. 2. The philosophical doctrine, sometimes known as 'panpsychism', that there is some spark or germ of consciousness present in all things. A version of this view was developed by the German philosopher G. W. Leibniz. (See LEIBNIZ'S PHILOSOPHY OF MIND.) For a recent attempt to take panpsychism seriously, see T.

Nagel (1980), *Mortal Questions*, ch. 13, Cambridge.

ANOESIS. Literally, the absence of thought. It seems clear that there can be 'anoetic' mental states—that is, states in which there is some form of consciousness (for example, sensation), but no thought.

ANOKHIN, PIOTRE KUZMICH (1897-1974). Soviet psychologist whose work did much to place the work of Ivan*Pavlov and other reflexologists of his time on a broader biological foundation. Anokhin worked first under V. M. Bechterev, the self-styled reflexologist, and later under Parlor before he became Head of the Department of Physiology in the University of Gorki, where much of his best work was done. He later became a senior professor in the University of Moscow.

Early in his career, Anokhin became convinced that animal behaviour cannot be satisfactorily explained in terms of a mere colligation of discrete unconditioned and conditioned*reflexes. It should be viewed, he contended, as a functional system, in which the separate links are related to a particular biological goal. Such a system plays a decisive role in the organization of behaviour involving the whole organism.

In support of his view, Anokhin devised a series of experiments in which the relations of the central and peripheral portions of a pair of nerves innervating an extremity, e.g. flexors and extensors, were interchanged so that the central parts of the extensors now innervated the flexors and vice versa. This led to a reorganization of the functional system such that its basic biological role was preserved, the new adaptations being executed by novel neural relationships.

These ideas of flexibility in nervous adaptation were followed up in conditional experiments. Anokhin devised a novel technique which combined salivary and motor responses while allowing the experimental dog freedom of movement. He pointed out that there is a preliminary stage of orientation to the situation before*conditioning begins and that the whole reaction, whether unconditioned or conditioned, does not end with a final reflex. The result of the action has to be evaluated and only if intention and final result are in accord does the action cease. If result and intention do not accord, further trials take place and behaviour continues. Thus the simple concept of a reflex arc is replaced by that of a system regulated by the results of its own actions, showing that functional systems are

essentially selfregulating systems, as Norbert Wiener appreciated many years later (see CYBERNETICS).

To this formulation, Anokhin later added the idea of 'forward afference' or 'feedforward', i.e. a form of anticipation which serves to prepare the system for action (see FEEDBACK AND FEEDFORWARD). Anokhin later devoted much study to the physiological and biochemical processes which he believed to be involved in the functional systems of the brain that regulate its behaviour. For Anokhin's work on conditioning and its neurology, see his *Biology and Neurophysiology of the Condi*

ANOREXIA NERVOSA AND BULIMIA NERVOSA. Many people are now familiar with the disorder of anorexia nervosa, which is diagnosed by the criteria of selfinduced weight loss (which may be so severe as to result in amenorrhoea in female patients) coupled with a morbid fear of becoming fat and a relentless pursuit of thinness. Other distinguishing features of the condition include a denial of the subjective feelings of*hunger, a distortion of body image, and a desire to increase energy expenditure by elevated physical activity. It is potentially a fatal disorder, with mortality rates ranging from 5 to 15 per cent, mainly from suicide.

Anorexia nervosa most commonly occurs in middleclass females, although it has also been reported in males. The disorder appears generally during adolescence, though it has been known to begin prior to this period, or even during adulthood. In Britain, the incidence in young women has been estimated to range between 1 and 4 per cent. Many believe that it is a disorder of very recent origin; however, patients with such a disorder have been described by physicians practising from the seventeenth century onwards.

The related disorder, bulimia nervosa, is far less well known, perhaps partly because of its antisocial and somewhat shocking symptoms, which may have retarded its identification. Bulimia was not differentiated from anorexia and was not described as a distinct disorder until very recently. Like anorectics, bulimics have a distorted body image, are obsessed with their body weight, and have a tremendous fear of becoming fat. However, bulimics have an overwhelming desire to eat large quantities of food at a single sitting (termed 'compulsive' or 'binge' eating); they then immediately selfinduce vomiting, abuse laxatives, or use both these forms of purging before the food has had time to be digested and absorbed. The majority of bulimics induce vomiting by pushing their fingers into

the throat, thus producing the gagging reflex.

Use of this method frequently results in calluses over the dorsum of the hand caused by its rubbing against the upper teeth (see Russell, 1979, Fig. 1). But some bulimics have developed their purging techniques to such a degree that they simply need to stoop over the toilet to vomit.

Thoughts about food and body weight are obsessional, and the behaviour related to food becomes compulsive. For example, some bulimics have as many as twenty or thirty episodes of bingeing and vomiting in a 24-hour period. The energy value of food consumed during frequent binges has been measured, and it was found that a bulimic subject may be eating food with an energy value of at least 26 megajoules (about 6,214 kilocalories) per day. Obviously, much of this energy would never be absorbed, because the partly digested food would be expelled by vomiting immediately following the binge. By contrast, women with no history of eating disorders and with comparable indices of body weight were eating food with an energy value of under 15 megajoules (approximately 2,585 kilocalories) per day.

Many bulimics have never been treated for their disorder, since many retain normal or slightly below normal weight through the use of these bizarre purging methods.

Hence, unlike the painfully thin anorectic, whose illness is obvious to both her doctor and others around her, the bulimic may be ill for years without anyone discovering her secret disorder, not even her husband, parents, or friends.

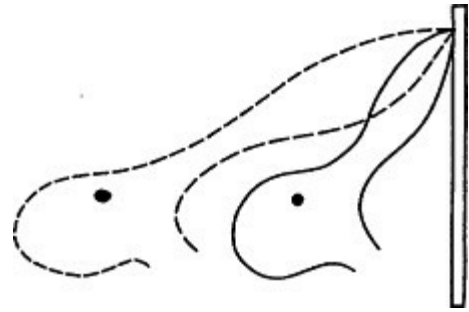

The causes of these two disorders are not known; there is no convincing evidence for either inherited or biologically determining factors. Anorexia nervosa has been viewed in the psychodynamic sense as a struggle towards a self-respecting identity, as a 'defensive, biologically regressed' attitude taken in response to pressures (especially sexual ones) experienced in puberty, and as an attempt to realize society's current view of the ideal feminine figure as sylphlike. Similarly, evidence has been provided that the development of bulimia is related to the struggle to attain a perfect stereotyped female image of beauty, helplessness, and dependence.

Treatment. Both anorexia nervosa and bulimia nervosa are very resistant to treatment, with a less favourable prognosis for bulimia nervosa than for anorexia nervosa.

Thus physical complications, such as potassium depletion, urinary infections, and renal failure, are more frequent and dangerous, and the risk of suicide is greater for those suffering from bulimia.

Pharmacological treatment is possible, and the drugs that have been used exert their behavioural actions through the central monoamine and opiate*neurotransmitter systems. Certain drugs that have been shown to be effective in the treatment of other psychiatric or neurological disorders—for example, chlorpromazine used predominantly in treating schizophrenia and which appears to have had some success in combating compulsive behaviour—have been used to treat patients with anorexia or bulimia nervosa. In addition, tricyclic antidepressants have been tried in several studies. The results of these drug trials to date have been unconvincing, however, because of the small number

of subjects studied and the failure in general to use control procedures. Indeed, in the few studies where the latter procedure has been implemented, pharmacological treatment has *not* been shown to be effective.

Page 29

It has been reported in one study that inpatient treatment for anorexia nervosa was required in 80 per cent of cases. When the patient was separated from her family, weight was usually restored but only with some difficulty, using a combination of psychotherapy, capable nursing, and, in about half of the cases, treatment with chlorpromazine. Most patients were reported to take between one and five years to stabilize their weight at a reasonable level, to lose their fear of increasing weight, and to be considered fully recovered.

Some success has been reported in treating bulimic patients using a 'cognitive behavioural' approach. This focuses on increasing the patient's control of eating, eliminating food avoidance, and changing maladaptive attitudes. A recent approach, with some similarities to this, combines dietary and cognitive techniques. The patient is placed on a caloriecontrolled diet that allows her to control her weight at an acceptable level while enabling her to eat a balanced diet, including food rich in carbohydrate, which is normally irrationally avoided. This dietary regimen is coupled with behavioural modification techniques, together with cognitive and selfcontrol strategies.*Behaviour therapy is employed to help render normal the patient's eating patterns, while the cognitive techniques enable her to concentrate on other creative, positive aspects of her life, rather than on ruminations about her body weight and feeding behaviour.

ANORTHOSCOPIC VISUAL PERCEPTION. If a simple outline drawing or geometric figure is placed behind an opaque screen which contains a slit, and if that figure is moved quickly past the slit (thus exposing the figure 'slice by slice'), an observer will often experience a faint, brief glimpse of the pattern (Fig. 1). Thus, even under such poor ('nonproper') conditions, veridical*perception can be achieved (with the sole exception that the figure will appear to be foreshortened on an axis parallel to the direction of motion).

These facts were known to various nineteenth-century psychologists, but were, by and large, lost until their independent rediscovery in 1965, by Fig. 1.

The white rabbit reappearing out of his (very narrow) rabbit-hole. In a line drawing (dashed line above) is passed rapidly behind a slit in an otherwise opaque screen, viewers will often see that line faintly, briefly, and moving slightly, in the vicinity of the slit (solid line above).

The screen extends far enough to the right, as well as left, that the figure is visible only through the slit.

At which time visual methodology and theory had advanced to a point where it was possible both to assess, quite precisely, the conditions requisite to the effect and to appreciate, much more fully, its theoretical importance. As a result, extensive research made it obvious that not only was (almost) veridical perception under such conditions a most impressive feat of the visual system, but also that the manner in which that feat is accomplished represents an outstanding example of the cognitive, problem-solving nature of the visual system.

To appreciate the difficulty posed for the visual system, it is only necessary to reflect upon the precise nature of the input received by that system under these conditions. First of all, the various parts of the passing figure are received at (slightly) different times. This, however, is not a major (nor unique) difficulty, since several lines of evidence suggest that our experience of briefly presented stimuli persists beyond the presentation itself in the form of. '*iconic images'. The major source of difficulty is the fact that the effect can be achieved even when all of the successive 'slices' strike the same strip

of retinal receptors (as, for example, when the entire display apparatus is retinally stabilized by appropriate optical devices). In this event, not only must all of the slices persist, but they must persist somewhere other than within the retinal receptors and they must be tagged for relative time of arrival so that they can finally be reassembled in proper sequence.

Considering such difficulties, it is not surprising that a percept of the stimulus pattern is sometimes not achieved. Moreover, such failures, when they occur, are instructive both with respect to the phenomenological nature of success, when it occurs, and with respect to the operations of the visual system which underlie success.

As to the former, some observers report a difficulty in deciding whether they merely come to 'know' the given pattern or whether they actually can be said to 'see' it.

As Irvin Rock (1981) pointed out, however,

Page 30

subjects who have been exposed to very poor inducing conditions (who, for example, have been shown simply an oblique straight line with the result that, while they can understand that the hidden pattern is an oblique line, nevertheless experience a short line moving up or down the slit) have little difficulty in deciding that success, when achieved, is visual.

In addition, the conditions which lead to such failures (when contrasted with more effective circumstances) strongly suggest, as do many other phenomena, the presence of cognitive, problemsolving, preconscious processes within the visual system. To take just one example drawn from an extensive and incisive series of investigations carried out by *Rock* and his colleagues, if the oblique line mentioned above is replaced by an undulating line, it is more likely that success will occur and especially if the slit is widened; precisely the result that would be expected from a system faced with the problem of deciding 'what's there?' and governed (in part) by the principle that coincidence is to be eschewed as much as is possible. That is to say, if the display does not consist of an extended line being revealed through the slit, then the alternative is, again, that a small line is moving up and down the slit—and, in this case, is at the same time bending and curving in just such a way that, *coincidentally*, each part blends into the next in a smooth continuous fashion. Apparently, rejecting such coincidences as improbable (but not impossible—the display *is* sometimes seen that way), the system reaches the more 'reasonable' (and veridical) conclusion instead, and imposes that conclusion upon conscious visual experience.

ANOSMIA. The loss of the ability to*smell. It may be congenital but can be caused by a variety of reasons, including the common cold and lesions in the olfactory tract incurred as a result of head

injury.

ANTICIPATION (or **PREDICTION**). The development of the nervous system through the evolution of species is characterized by increasing powers of anticipation—the ability to survive against nature and predators. Anticipatory behaviour is not initiated by stimuli; so a stimulus-response account of the behaviour of higher animals is essentially inadequate. Intelligent anticipation requires stored knowledge, and the ability to draw analogies from past situations, which may be in many ways different from the current situation. This ability is uniquely developed in humans. Its neural localization is essentially in the frontal lobes of the cerebral cortex; but it may be the case that damage to the frontal lobes produces personality changes such that the future is judged less important.

Anticipation allows organisms and societies to avoid danger before disaster strikes; it allows strategies to be devised and individual and communal plans to be made for overcoming nature and enemies, and for achieving goals. Such abilities are quite foreign to inanimate matter, and are beyond the capacity of many living things: anticipation requires a mind. Some would argue, however, that computers may reasonably be said to have the ability to anticipate and warn of situations and events, and hence to be 'mindful'.

ANTIDEPRESSANT. See **DEPRESSION**.

ANXIETY. The characteristics of anxiety as an emotion are that it is distressing, and that its sources are indefinite. In the latter respect it is unlike fear, which has reference to a specific aspect of the outside world. Fear with a more or less specific reference but out of proportion to the real danger is a phobia. Agoraphobia, for instance, is a morbid fear of public places. An anxious person is in suspense, waiting for information to clarify his situation. He is watchful and alert, often excessively alert and overreacting to noise or other stimuli. He may feel helpless in the face of a danger which, although felt to be imminent, cannot be identified or communicated.

Hope and despair tend to alternate, whereas depression describes a prevailing mood of pessimism and discouragement.

With the emotion of anxiety may be associated such bodily symptoms as feelings in the chest of tightness or uneasiness which tend to move upwards into the throat, sinking feelings in the epigastrium, or light feelings in the head which may be described as dizziness. The patient tends to be pale or, less often, flushed. His pulse is rapid, and his heart overacting. He shows effort intolerance, mild exertion producing an undue increase in pulse and respiration rate; he tires rapidly. His posture is tense, his tendon reflexes brisk. Sexual interest tends to be in abeyance. The function of every organ in the body is affected in some degree. Numerous studies have examined physiological changes associated with the experience of anxiety. Among the better known is the change in skin conductivity, the galvanic skin reflex (GSR) the basis of action of the so-called 'lie detector' (see **ELECTRODERMAL. ACTIVITY**). Increased anxiety causes sweating and a sharp drop in the resistance between the two electrodes attached to the subject's finger. In an anxious person, however, spontaneous fluctuations of the GSR will be recorded. Such an individual, when tested by a lie detector, would show even greater fluctuations in the tracing, sufficient, probably, to make an

interpretation of the results invalid.

*Freud's psychoanalytic theory offers explanations of anxiety, which occurs in greater or lesser degree in almost every form of mental disorder. In his earliest formulation, Freud argued that anxiety is a vicarious manifestation or transformation of

Page 31

sexual tension (libido) not discharged through normal sexual activity. It might sometimes be a repetition of the experience of being born. In his later work he wrote of it as reflecting motives which, although excluded from consciousness by repression, threaten the dissolution of the ego. The contemporary explanation, although similar, is expressed in different terms.

Anxiety has also been used in a broader sense as a term for the drive aroused by a danger signal, i.e. a conditioned stimulus associated in previous experience with *pain, physical or psychological. To a danger signal a response is made which has proved effective in avoiding the pain. The pain is not experienced again, but the response is reinforced every time it reduces the anxiety aroused by the danger signal. Responding by avoidance has other consequences. It precludes further exploration of the danger situation, and, not being explored, the sources of the danger remain illdefined, and other ways of coping with them are not learnt. Avoidance responses tend, therefore, to become firmly established.

The emotion of anxiety is felt whenever responses made to a danger signal appear to be ineffective. Because it is frustrated, the behaviour associated with anxiety tends to become vacillating and disorganized; also, destructive impulses occur. The anxiety is then mixed with anger. To these effects are due some of the special qualities of anxiety as an emotion.

The agoraphobic patient does not feel anxious while he succeeds in avoiding whatever dangers public places contain for him; otherwise he would feel helpless in the face of whatever demands being in a public place might make. These demands might represent threats to his conception of himself or to the assumptions he makes about the world. Akin to agoraphobia is 'separation anxiety', which arises when a person faces demands while being denied, as a result of separation, the reassurance and support of a parent or other significant person. Existentialist theory equates anxiety with the dread of being alone or of being nothing; without the reassurance given through a relationship with another person, the sense of self is threatened.

D. R. D.

APHAKIA. See EYE DEFECTS AND THEIR CORRECTION.

APHASIA. The ability to talk may not, as was once thought, be the crucial factor that distinguishes humans from the animals, but loss of the power of speech is one of the most distressing things that can happen to a human being. Aphasia (the disruption of speech) commonly follows a stroke—especially if the stroke also impairs movement of the right arm or leg. The loss of articulated language is not always or necessarily accompanied by loss of other linguistic functions, like reading and writing.

Least of all is it necessarily accompanied by loss of comprehension: a sufferer often knows that the words he is uttering are wrong, but he cannot correct or alter them ('Pass me the bread—no, not the bread the *bread*—no!'). However, where one of the linguistic skills is seriously disturbed, one or more of the others tends to be somewhat reduced as well. Neither does the disruption of speech mean that all aspects of it are obliterated, nor, even if it is seriously reduced in the early stages after the disrupting incident, that it can never be regained. But the recovery of abilities by an aphasic person does not follow the same principles of learning as the acquisition of learning a language by a normal, healthy child or adult. Asking the patient to repeat a word or phrase over and over again is not necessarily going to help him to say it later on; it is more likely merely to make him angry and depressed. Impairment of language does not necessarily imply loss of other faculties, such as intelligence or memory.

The three aspects of aphasia which have been studied most intensively are the manner in which speech breaks down, the causes of the breakdown, and treatment of and recovery from it.

The manner of breakdown. The different forms of breakdown can be classified in different ways, but most people nowadays consider just two major groups: nonfluent (or*Broca's) and fluent (or*Wernicke's), the names in parentheses being those of the neurologists who first described them. (See LANGUAGE, NEUROPSYCHOLOGY OF, for a fuller discussion.)

In nonfluent aphasia, the sufferer has difficulty finding words, particularly uncommon ones. He has difficulty naming objects, and his syntax is often faulty. He tends to talk hesitantly and gropingly, although he is often acutely aware of how stupid he sounds. The fluent aphasic, on the other hand, emits a stream of words the intonation of which is perfectly normal. Heard from a distance, they sound obscure or clever, but closer listening reveals meaningless jargon. Unlike the nonfluent aphasic, the fluent one seems undisturbed by, and even unaware of, his poor communication. In each of these conditions, concomitant disorders of reading, writing, and comprehension may be present in some degree, but are usually more severe in fluent than in nonfluent disorders.

The causes of breakdown. Aphasia is caused by damage to tissue within the brain. But whether injuries to different areas of the brain cause different types of disorder, and whether the same patterns of disorder occur in all individuals, is less certain. Each hemisphere of the brain not only controls movement and sensation of the opposite side of the body (the left hemisphere controls the right side, and the right hemisphere controls the left), but seems to specialize in particular mental functions. (See NEUROPSYCHOLOGY.) It is the left hemisphere that seems to be most closely concerned with language, although in lefthanded people and those with a family history of left

Page 32

handedness the association is not so strong. Moreover it is not inevitable. People whose left hemispheres are damaged in early infancy or childhood can 'learn to speak' perfectly adequately with their right. By and large, however, it is damage to the left hemisphere that most commonly causes aphasia; that to the anterior part causing nonfluent disorders, and that to the posterior part causing those of the fluent type. It is sometimes held, though, that in fluent aphasia there is also usually some

damage to the right or nondominant hemisphere as well as to the left.

An important factor relating to breakdown is the degree to which a person made use of language before his injury. Although after breakdown the words and phrases previously used most commonly can usually be found more easily than others, this does not necessarily mean that the first language of a bilingual or polyglot is the one best preserved: it is frequency of usage rather than recency that is important. Even so, there is a tendency for sufferers of nonfluent aphasia to emit swearwords and taboo words when searching for those they cannot find. Here it is the words which have *not* been uttered in the past that appear before those which have. The reason for this is probably that inhibition or repression of an act gives it particularly strong emotional force; and the emotional aspects of mental behaviour are not controlled by the same areas of the brain as language. Indeed, they tend to be released when intellectual control is removed.

Recovery. The vast majority of aphasic people, especially in the younger agegroups, recover a good deal of speech as time goes on; and a few of the more literary ones have written accounts of their experiences. Unfortunately these seldom contain information about how the faculties were regained, probably because such processes—like many other forms of learning and remembering—occur at a level which is not available to normal consciousness. Psychologists who have been able to watch and study these people have, however, identified several factors which seem to be involved, especially in nonfluent aphasia.

1. Arousal of previous or common contexts. In most languages there are words that have different meanings in different contexts. In English, the word *hand* can be applied to a part of the human body, parts of a clockface, a unit for the measurement of horses, a style of penmanship, a pledge of fidelity, a member of a ship's crew.

The first usage here is undoubtedly the commonest, and aphasics can often name the bodypart when asked to do so, even when they cannot find the word 'hand' in its other contexts. However, once a word has been found in its most common context, it can often be found in others too ('Of course, those are called "hands", aren't they?').

2. Narrowing of syntactical constraints. In most languages, words are uttered and understood in sequences rather than individually, and are controlled by those preceding them. For instance, in the sentence starting 'The man was bitten by ———', there is a limit to the choice of words that can follow. Narrowing the field of possibilities by such means seems to be very helpful to the aphasic patient, who can often find words if they form parts of familiar sentences (or song phrases) when not able to do so otherwise.

3. The hesitancy seen in nonfluent aphasia is usually due to the patient's knowledge that the first words which occur to him are wrong and must be corrected. Yet if these words *are* uttered, they are usually far from random. Indeed, they tend to be closely related to the word being sought. They arise from the same semantic field or consist of functional descriptions of the object to be named ('They're the things that point to the time—the fingers—no, the pointers—no!').

Summing up, it seems that in nonfluent aphasia the difficulty is one of having lost not the ability to speak, but only the ability to find the right words at the right moment.

Any stimulus which gives a 'lead in' to the general semantic field helps. After this, it is a matter of sifting through the various items until the target is found. (How one recognizes the target is a different problem, and although this ability seems to be intact in the nonfluent aphasic, it seems to be at fault in the fluent one, who does not try to inhibit or correct his 'near misses'.)

Experiments with normal, healthy humans indicate that the processes whereby they find and utter words are very similar to those seen in aphasia, but that the processes take place more quickly and efficiently. But rare words take longer to find than common ones; and if the sorting/sifting/correcting process is impeded by external factors (such as distraction) or internal ones (such as intoxication), 'near misses' of much the same sort as those given by the aphasic may be emitted.

APHRODISIAC. One of the ineluctable facts of life is that male potency reaches a peak in late adolescence and thereafter undergoes a slow decline, to be extinguished in most men in late old age. Unfortunately there is not a commensurate fall in sexual desire in the female, and it may even increase in middle life after the menopause. Understandably, therefore, there has been an age-long search for substances to restore male potency, but so far there is very little evidence that any of the more popular remedies are based on any factual demonstration of their efficacy. Aphrodisiacal properties have been attributed to many foods, including oysters, mushrooms, and various fishes.

Page 33

In addition, on the basis of the ancient Doctrine of Signatures, it was believed that substances with similar appearances would have the same therapeutic effects.

Consequently a symbolic likeness between genitalia and certain plants and animal parts led to the assumption that powdered rhinoceros horn (popular in China), mandrake, ginseng, and asparagus would produce the desired action.

Magic and suggestion are important contributions to the alleged aphrodisiacal properties of many

substances, but certain drugs have been used, the most dangerous of which is cantharides, a powerful vesicant (causing blistering of the skin). When taken internally it causes acute inflammation of the urinary tract, resulting in painful priapism and the passage of bloody urine. Yohimbine, a central excitant which enhances the release of noradrenalin, has an unproven reputation as an aphrodisiac.

Cannabis is said to increase the pleasure experienced by both sexes during coitus but has no effect on male potency. Treatment with androgens, the male sex hormones, does not generally produce the sought-after effects and is not without hazard as it may cause cancer of the prostate in the middle-aged man. Alcohol, the oldest and most often tried of aphrodisiacs, acts more as a disinhibitor of sexual drives than as a promoter of sexual capacity.

F. A. W.

APPARENT. Appearance is traditionally contrasted with reality, and the 'apparent' qualities of things with their 'real' qualities. Thus (to use a time-honoured example) a stick in water 'appears' bent but is 'really' straight. The distinction between appearance and reality arises in at least four contexts. (i) The 'appearance' may be an optical illusion—due for example to the refraction of light rays when passing through water—or a perceptual illusion (see ILLUSIONS). (ii) More generally, a property may be ascribed to something, or its meaning defined, with reference to standard conditions: thus an object's 'true' colour is normally defined in terms of how it looks to a normal observer in ordinary light, even though it may appear differently under different conditions. (iii) Often, when we speak of 'apparent' qualities, there may be a 'perspectival' element involved—an implicit reference to the position or frame of reference of the observer. Thus the earth is *apparently* stationary (from the perspective of an observer on the surface) but is *really* rotating (i.e. from the wider perspective of an observer in space). (iv) Finally, even when all considerations about perspective, and standard conditions of application, have been taken into account, it may be thought that there is still an important gap between how we see the world and how it really is. Thus some of the qualities we ascribe to objects may be thought to involve an irreducibly subjective element which debars them from counting as 'real' qualities of objects. According to John Locke, our ideas of redness and sweetness, for example, do not resemble anything really in the objects themselves. For this issue see LOCKE, JOHN and QUALITIES.

APPERCEPTION. When experimental psychology became a fact towards the end of the nineteenth century, the only concepts available to it were those developed in either a philosophical or a biological context. 'Apperception' belongs to the former category, having played an important role in the German philosophical tradition since the beginning of the eighteenth century. Wilhelm*Wundt, who initiated the first systematic research programme in experimental psychology and trained many of its early practitioners, was steeped in this tradition and actively contributed to it. As a result, the concept of apperception occupied a prominent place in the early literature of experimental psychology.

The term was originally used by G. F.*Leibniz, particularly in his critique of Lockian sensationalism,

as a way of emphasizing the distinction between a passive sensation and a mental content selfconsciously 'apperceived'. It became the major technical term used by German philosophers to express what they considered to be the two fundamental features of the human mind: the fact that mental experience is not composed of separate bits but forms a unity, and the fact that this unity involves a constructive activity of the mind itself rather than a passive reflection of external events.

This usage is found in the highly influential philosophy of Immanuel**Kant*, where a clear distinction is introduced between the empirically observed unity of experience and a *transcendental apperception*, a cognitive act, which makes this unity possible. This distinction devalued the introspective analysis of inner experience as being concerned only with effects and appearances, but it also acted as a challenge for nineteenthcentury psychologists to find a more satisfactory explanation for the empirical unity of experience.

The challenge was taken up by Kant's successor, J. F.**Herbart*, whose model of mental functioning involved the notion of ideas combining to form powerful 'masses'

that dominated the mental life of the individual. Apperception occurred through the assimilation of new ideas by an existing complex of ideas. Herbart's concepts achieved wide popularity among nineteenthcentury educationists, so that the concept of apperception began to descend from the lofty heights of philosophical speculation.

This process was continued in the work of Wundt, who proposed to subject the process of apperception to experimental investigation in the psychological laboratory.

The original vehicle for accomplishing this was provided by*reaction time experiments which had been developed by physiologists. Wundt conceived the idea of using variations in reaction times that occur with different patterns of stimulus presentation as an empirical

index of central apperceptive processes. Responses to sequences of stimuli or to distracting stimuli, for example, had to involve the kind of synthesizing cognitive activity that was traditionally referred to as apperception. These early experiments constituted the first systematic attempt to subject central psychological processes to precise laboratory investigation.

The notion that the process of apperception occupied measurable periods of time implied that it was not transcendental but involved physiological processes of definite physical duration. Wundt speculated that these processes were localized in an 'apperception centre' in the forebrain that coordinated the activity of lower sensory and motor centres.

This was the physical side of Wundt's psychophysical theory of apperception. The more prominent psychological side treated the phenomenon of*attention as the primary subjectively observable expression of the apperceptive process. While this provided further opportunities for experimental study, Wundt also used the theory of apperception to explain the structure of language, developing an early version of psycholinguistics (see NEUROLINGUISTICS, LURIA ON).

Thus, apperception became the major unifying concept in the first important theoretical system of

modern psychology, attempting to synthesize evidence from psychophysiology, from laboratory studies of human cognition, and from comparative studies of symbolic structures. It is noteworthy that, while the effects of apperception were generally investigated in the context of cognition, Wundt believed that its psychological *sources* lay in affective processes.

This theoretical *tour de force* proved to be premature. Wundt's successors, including his most prominent students, abandoned the concept of apperception, restricting themselves to observables, like attention. This generation of psychologists was anxious to cut psychology's ties with philosophy which Wundt had wanted to maintain.

Apperception was rejected as excessively metaphysical. Possible practical applications of their findings became more interesting to many empirical psychologists than were broad theoretical syntheses, and from this point of view apperception was a redundant concept. For many years work on central integrative processes was neglected in favour of a more simplistic sensorimotor psychology. Some of the phenomena that apperception had been intended to explain were more effectively reinterpreted in the framework of Gestalt psychology. Thus the term went out of use rather quickly and permanently. Contemporary cognitive science has revived an interest in many of the problems that the theory of apperception had been concerned with, but the term itself has not been resurrected.

APRAXIA is the inability to make purposeful skilled movements. Like the aphasias, the apraxias are classical syndromes in human neuropsychology. Animals do not develop apraxia as a consequence of brain lesions, no matter where the lesion is located. In man, apraxia occurs, as a rule, after a lesion in the hemisphere dominant for language, usually the left hemisphere. In those rare instances where language is processed in the right hemisphere, apraxia might be expected after rightsided brain damage.

This observation might suggest that apraxia should be considered among those neuropsychological symptoms which are languagedependent. An inherent relationship between the two syndromes, however, has not been demonstrated. Both aphasia and apraxia vary independently. After leftsided brain damage there can be recovery of language functions in the presence of persisting apraxia, and vice versa.

There are two varieties of apraxia, traditionally termed ideomotor apraxia and ideational apraxia. These terms reflect late nineteenthcentury views on the organization of psychological processes in the brain; in particular, they imply a twostage model of motor processing, similar to the traditional

two-stage model of sensory processing (*perception and *apperception) developed during the same period. Although these models have been abandoned in favour of a multistep, multimodal integration model of processing, it is still convenient to adopt the terms ideomotor and ideational in modern research provided they are used as neutral denominators and do not confer a priori theoretical implications.

Ideomotor apraxia is a common syndrome in which the execution of simple or complex, meaningful (or symbolic), or meaningless (or nonsymbolic) movements with the orofacial musculature and/or with the limbs is impaired in a characteristic way. The paramount feature is not clumsiness of movement or absence of execution, but rather a distortion of movements, which Hugo Liepmann termed *parapraxia*. Parapraxias are brought about by inadequate selection of the elements that contribute to a motor sequence, and/or by impairment in the sequential combination of these elements. Both aspects, impaired selection and sequencing of elements, are of equal importance. In order to arrive at the diagnosis of ideomotor apraxia, one has to make sure that the motor disorder is not explained by paresis, sensory impairment, disturbances in the coordination of movements, or by problems in understanding a specified task because of either language disturbance or impaired intellectual performance.

Page 35

A striking feature of ideomotor apraxia is that the execution of movements is impaired only when they are required out of their natural context. Traditionally, the examination is done by making the patient perform certain movements, like whistling, sticking out his tongue, blowing out his cheeks, performing the sign of the cross or a military salute, or placing the back of his hand on his front. These and similar movements are required either on verbal command or by imitation after demonstration by the examiner. It is important to note that a patient with ideomotor apraxia is perfectly able to brush his teeth in the morning, in a natural setting, whereas he performs the same movement in a rather parapraxic way when required to do so in the doctor's examination room. A convincing explanation for this well-recognized feature has not yet been put forward. One could be tempted to entertain a disconnection model, specifying that movements are impaired when they are elicited by input from the language system or from the visual system, but not when the input is generated in the limbic system. The reliance of spontaneous, context-dependent actions on limbic input to the motor system, however, still has to be demonstrated in both physiological and anatomical terms.

The structure of apraxia has been investigated on the basis of qualitative analysis of the parapraxic errors. This analysis was based on studies by David Elton, who was the first to apply sophisticated methods for the description of expressive movements in a study of gestural behaviour. He used the term 'linguistic' to denote the referential aspect of symbolic movements. While his analysis was focused only on movements as a whole, single components of movements were systematically studied by Birdwhistel, who applied the methods of structural linguistics to the study of normal movements. He recognized posture and movement as patterned behaviour, and he developed a notation system which permitted a description of a hierarchy of motor elements similar to the description of speech elements in a linguistic hierarchy.

Stimulated by this research, Poeck and Kerschensteiner have developed a method permitting the quantitative and qualitative assessment of single components constituting the apraxic movements. A code has been elaborated which enables one to transcribe the characteristics of the single components of the motor sequence.

Error analysis showed that the most *characteristic* behaviour in apraxia is perseveration (the inappropriate repetition of parts of speech or movement). In apraxia it occurs not only as the repetition of a whole movement or motor sequence but also, much more importantly, as the intrusion of motor elements that were part of a movement correctly or incorrectly performed many tasks before. To give an example, the patients not only repeated the military salute when they were asked to touch their chin but they perseverated on the rhythmic elements of the movement 'to show that somebody is crazy' when they performed the static movement of the military salute—i.e. they tapped their temple while their hand was in correct military salute position. The perseveratory tendency is so strong that when asked to imitate a movement, the patients were likely to repeat a movement or an element of a movement carried out earlier in spite of the visual evidence of the correct execution by the examiner.

In a systematic study with 200 apraxia tasks given to 88 patients with leftsided brain damage, 10 patients with rightsided brain damage, and 10 control subjects, no differences between the right and left limbs were found. Meaningful (i.e. practised, easily verbalized) and meaningless (i.e. unpractised and difficult to verbalize) tasks were equally impaired. The aphasic language disturbance did not explain errors on verbal command. No qualitative relation between aphasia and apraxia was detected, nor any subtypes of apraxia characterized by certain patterns of error.

Therapy is not necessary because ideomotor apraxia occurs only under the conditions of examination and does not impair the patient's spontaneous actions.

Idearenal apraxia is a rare condition. It is observed in patients with lesions in the languagedominant hemisphere. There is only one case on record where the syndrome was the consequence of a rightsided brain lesion. This patient was lefthanded and had rightsided or at least bilateral representation of language functions.

Patients with ideational apraxia are seriously impaired when they are about to carry out sequences of actions requiring the use of various objects in the correct way and order necessary to achieve an intended goal. These patients are conspicuous in everyday behaviour because they have problems in, for example, preparing or even eating a meal, or doing some professional routine they have performed for years. The behavioural disturbance of these patients is most frequently misinterpreted as indicating mental confusion—and all the more so since, in addition to ideational apraxia, they are regularly aphasic.

Patients do not fail these tasks because they have problems in the recognition of objects. In spite of their aphasia they frequently give pertinent verbal comments on the task, indicating that the language problem cannot be the determinant factor. Ideational apraxia is not a very severe degree of ideomotor apraxia; although both syndromes may occur in the same patient, they vary independently of each other. On the basis of a small number of observations it is suggested that the ideational apraxia

syndrome is due to a disturbance in the associative elaboration of various inputs with motor programmes. This would be in line with modern concepts of the hierarchical organization of the motor system. Ideational apraxia is a great handicap for the patient, and therefore it is necessary to develop appropriate lines of treatment. Such

Page 36

treatment should first attempt to teach the patient to avoid perseverative behaviour.

A PRIORI is a term applied to statements to reflect the status of our knowledge of their truth (or falsehood). It means literally 'from what comes before', where the answer to 'before what?' is understood to be 'experience'. Loosely, one may speak of knowing some truth 'a priori' where it is possible to infer the truth without having to experience the state of affairs in virtue of which it is true, but in strict philosophical usage, an a priori truth must be knowable independently of *all* experience. *Kant held that the criteria of a priori knowledge were (i) necessity, for 'experience teaches us that a thing is so and so, but not that it cannot be otherwise', and (ii) universality, for all experience can confer on a judgement is 'assumed and comparative universality through*induction'. Gottlob Frege stressed that the issue was one of justification, and defined an a priori truth as one whose proof rests exclusively on general laws which neither need nor admit of proof, while a truth which cannot be proved without appeal to assertions about particular objects is a posteriori.

Statements such as 'A vixen is a fox', whose truth is*analytic are accorded a priori status without dispute. Kant held that in addition truths of arithmetic and geometry, and such statements about the natural world as 'Every event has a cause,' were not analytic but nevertheless had the hallmarks of

being a priori. The central question that his philosophy addressed was how such synthetic a priori truths were possible, whereas the strategy of his twentieth-century empiricist critics has been to argue that there are no a priori truths which are not analytic.

AQUINAS, ST THOMAS (1224/574), the greatest of the medieval scholastics. Aquinas was primarily a theologian, but in his theological work he was led to develop a comprehensive treatment of the philosophical issues at stake; hence we can extract from his writings a philosophical psychology which he considered capable of standing on its own feet, without requiring support from Christian revelation.

St Thomas, the seventh son of Landulf, count of Aquino, was born at the family's castle of Roccasecca, near Aquino (about halfway between Rome and Naples). He was educated at the Benedictine abbey of Monte Cassino and at the University of Naples. In 1244 he decided to join the newly established Dominican order, and afterwards studied at the University of Paris and at the Dominicans' institute in Cologne, where one of his teachers was St Albert the Great. Aquinas lectured at various times at the universities of Paris and Naples and at the papal court. He died while on his way to the Fourth Ecumenical Council of Lyons, and was canonized in 1323.

Aquinas rejected much contemporary Christian theorizing about man, based on the thought of St Augustine and, via Augustine, on Plato and neoPlatonism, and instead took over and developed many of Aristotle's conclusions. Like Aristotle, he viewed human activity as taking place on three levels, vegetative (comprising the powers of nutrition, growth, and reproduction), sensitive (comprising sensory activity and locomotion), and intellectual (comprising reason and will). Among bodily creatures, only man possesses reason and will, but these powers are found also in angels and, in a very much higher manner which we cannot adequately comprehend, in God; and it is because man shares, to some degree, in these divine attributes of reason and will that the Scriptures speak of man as made in the image and likeness of God (Genesis 1: 26-7).

Aquinas followed Aristotle in defining the soul of a living being as its substantial form, i.e. as that inherent principle by which it is the kind of entity or substance which it is; and he contrasted the soul as form with the matter which it organizes or 'informs': both soul and matter are necessary constituent principles of the living being. So, he believed, all living creatures have souls, but only human beings have spiritual souls. Aquinas rejected the medieval Augustinians' belief that in man there are three distinct souls, vegetative, sensitive, and intellectual, each accounting for human activity at its corresponding level. This view, he said, would destroy man's natural unity by breaking him up into

three distinct entities; rather, there is just the one soul, which is responsible for all of a man's activities, regardless of the level to which they belong.

Following Aristotle, Aquinas distinguished the five external senses of sight, hearing, touch, taste, and smell, and four 'internal senses'. These latter are: the 'common sense' by means of which senseimpressions or 'phantasms' produced by different external senses are referred to a single entity existing outside the perceiver;

secondly, the imagination (*imaginatio* or *phantasia*), which

Page 37

stores senseimpressions and can combine them into complex images of hithertounperceived things and events; thirdly, the 'cogitative power' (*vis cogitativa*), which corresponds to instinct in animals and by which we can apprehend things and events in the world as either beneficial or harmful to us; and finally the sense memory (*vis rememorativa*), in which information gained by the cogitative power is stored.

In sensory cognition we appropriate the sensible forms of objects, that is, their observable characteristics, without the matter of the objects themselves; so (for example) in seeing a silver coin I receive its colour into my sense organ, but not the actual matter of the coin. Likewise, he thinks, the two kinds of human activity at the rational level, thinking and willing, involve receiving into the soul the *intelligible* form of whatever one's thinking or willing is about. For an entity or substance in the external world is made to be the sort of thing that it is by possession of a certain nature or form—the form of oak tree, for example—and we understand and think about things by mentally receiving their forms: in this way, as Aristotle said, 'the mind is in a way all things'. But matter as such, considered in isolation from any determining form, is unintelligible, and so we can 'latch on' to a thing in thought only by mentally disengaging or 'abstracting' its intelligible form from the material conditions of sensation. This process of abstraction, Aquinas said, is carried out by a power called the agent intellect (*intellectus agens*); and another power, the receptive intellect (*intellectus possibilis*), then receives and stores the forms abstracted by the agent intellect. Thus the form of (say) cat which is present in cats themselves, thereby making them the kind of animal they are, is also present in the minds of human beings, thereby making them capable of thinking about cats. In this way Aquinas accounted for the fact of*intentionality, that is, the fact that our thoughts are *about* things. The form of something, as stored in the receptive intellect, is a concept. Unlike sensations, which are particular modifications of the sense powers, concepts are universals because they enable us to think about a potentially indefinite number of things of a given kind; and the receptive intellect employs these concepts in carrying out such intellectual operations as judging, reasoning, and deliberating. A form present in someone's mind as a concept is, Aquinas said, obviously present in a very different way from that of a form present in an external thing, and he called this mental mode of presence 'intentional being' (*esse intentionale*).

Against the Latin Averroism of Siger of Brabant and others, St Thomas denied that the agent intellect is a single entity which is distinct from all human beings but in which the latter somehow participate.

Rather, he said, it is a constituent power of each human mind. There are, then, as many agent intellects as there are men.

Because he believed that human beings can acquire concepts only by abstracting forms from senseappearances, Aquinas can be called an empiricist. He insisted that without some sensory input on which the mind's abstractive power could get to work, no concepts would ever be constructed, nor would any rational activity ever take place: there are no 'innate ideas'. Moreover, any actual use of concepts in thinking or willing must— at least in this life, in which the soul is embodied— be constantly referred to sensecontents, either of perception or memory or imagination. This necessary human orientation to sensory data is what Aquinas called

'conversion to senseexperience' (*conversio ad phantasmata*).

Since conceptformation involves the abstraction of intelligible forms from all material conditions, Aquinas concluded that the formation and utilization of concepts are activities which cannot in principle be performed by any physical organ or organism. For, he said, if there were a physical organ of thought it would be unable to do something which it obviously can do, namely, receive the forms of all physical objects, but would be restricted to receiving the forms of only one particular kind of object, as the eye is restricted to receiving colours. Nor would any physical organ be capable of that selfconscious awareness which is so prominent a feature of human thought. Our concepts are, then, present in us in a nonmaterial way; hence that which performs mental acts must be a wholly nonmaterial, that is, spiritual, principle. So the human soul, as well as being the substantial form of the body—that by which the human body *is* a body—must also be a spiritual substance in its own right.

Because man's soul is a spiritual substance, it can survive death. For it is not made up of physical parts and is therefore, unlike the body, free from corruption and dissolution. Admittedly, since man depends on his sense organs W provide him with appropriate objects of thought—things to think about—it seems that a disembodied soul will be unable to exercise its mental abilities without some special help from God; and in any case, since the human soul is the substantial form of the human body, disembodiment is clearly an unnatural condition for it. Thus, although we can have reason to accept the Christian doctrine of the resurrection of the body only on the basis of God's revelation, that doctrine is entirely appropriate to the human condition. For only if soul and body are eventually reunited will there be a fullyconstituted human being once more; until then, the souls of the departed will exist in a condition which is abnormal, contrary to nature (*praeter naturam*).

For Aquinas, man is not the highest of all created beings, because angels far exceed him in intellectual power. But he is the highest of all bodily creatures, and as a partly material, partly spiritual being, man forms the bridge, so to speak, between the physical and spiritual realms.

How does a human being come into existence? Is he generated out of physical elements, as is a plant, or is some higher, nonphysical agency required?

Aquinas replies that since the soul is a purely spiritual entity it must be created directly, out of nothing, by God. But there is no preexistence of souls: when God creates a soul he immediately infuses it into the appropriate matter which is present in a woman's womb.

Just as man's cognitive powers are present on both sensory and rational levels, so it is with what Aquinas calls man's appetitive or striving functions. The latter include such activities as wishing, willing, desiring, intending, and feeling emotions. Here we shall concentrate on Aquinas's account of the will, which he defines as the rational appetite, that is, the appetite or tendency which belongs to the rational part of the soul. As rational, it is directed not to any particular good, as are the sensory appetitive powers, but rather to goodness as such: it is the power by which man strives towards that which he rationally apprehends as in some way good or desirable.

Aquinas analyses the process of deciding to do something into a whole series of 'component' acts, some belonging to the intellect and some to the will. The decisive choice (*electio*) which results in some action's being performed is an act of the will, but the will cannot function without the intellect's aid; we can will something only if we have already recognized it to be good. However, Aquinas also believes that the will very often operates freely, i.e. without being determined to any particular outcome. For, he says, we choose to do one thing rather than another because our intellect apprehends the goodness of what is chosen; but nothing short of the supreme and final good of man (which, for Aquinas, ultimately consists in the vision of God in heaven) can irresistibly attract the human mind; everything other than this will be attractive in some respects but unattractive in others. Hence the will can choose freely among goods which fall short of the complete and ultimate good. This is St Thomas's principal argument for the freedom of the will, or 'free choice' (*liberum arbitrium*), as he calls it; but he also argues that unless man were capable of making free choices, 'advice, exhortations, precepts, prohibitions, rewards, and punishments would be in vain'.

While some of Aquinas's arguments rest upon outdated theses of Aristotelian science, his major conclusions concerning thinking, willing, and the nature and destiny of the human soul escape this limitation and still find defenders today. P. T. Geach's *Mental Acts*, for example, is a particularly interesting analysis of human mental activity which owes much to Aquinas.

Aquinas's account of the nature and workings of the mind is presented, above all, in the *Summa Theologiae* (English translation in 60 vols., ed. T. Gilby, London, 1963/75), especially vols. 1113, and in the *Summa contra Gentiles* (English translation by A. C. Pegis et al., New York, 1955/7), especially vol. 2. A useful selection of readings is Pegis, A. C. (ed.), *Introduction to St Thomas Aquinas* (New York, 1948).

ARISTOTLE (384-322 BC). Aristotle was born in the obscure Chalcidic village of Stagira, far from the intellectual centre of Greece. His father, Nicomachus, was court physician to King Amyntas III of Macedon; and it is pleasing to speculate that Nicomachus encouraged his son to take an interest in matters scientific and philosophical. However that may be, in 367 Aristotle migrated to Athens, where he joined the brilliant band of thinkers who studied with Plato in the Academy. He soon made a name for himself as a student of great intellect, acumen, and originality.

On the death of Plato in 347, Aristotle moved to Asia Minor, where he spent some years devoted principally to the study of biology and zoology. In 343 he moved to Pella, where he served as tutor to King Philip's son, the future Alexander the Great. (What influence Aristotle may have had on that obnoxious young man is uncertain.) After further migrations, Aristotle returned to Athens in 335, and for the next decade engaged in teaching and research in his own school in the Lyceum. He fled from Athens on the death of Alexander in 323, and died a year later in Chalcis. His will, which has survived for us to read, is a humane and touching document.

Aristotle was a polymath: his researches ranged from abstract logic and metaphysics to highly detailed studies in biology and anatomy; with the possible exception of the mathematical sciences, no branch of knowledge was left untouched by him. His contributions were both innovative and systematic: no one man has achieved more, no one man has had greater influence, and Aristotle remains, in Dante's phrase, 'the master of those who know'.

Aristotle's main contributions to the study of mind are to be found in his treatise *De anima* ('On the Soul' or 'Concerning Psyche') and in a series of short papers known collectively as the *Parva naturalia*. He regarded the study of psychology as a part of the general study of animate nature (see. PSYCHE): there is no division in his thought between the study of mind and the study of matter, and his psychological writings are continuous with his overtly biological works.

An early work, the *Eudemus* (only fragments of which survive), betrays a juvenile interest in a Platonic account of the psyche: there Aristotle argued that the psyche was independent of the body, preexisting it and surviving its death. But that separation of mind from body is foreign to Aristotle's mature works: in the *De anima* he defines the psyche as 'the first actuality of a natural

Page 39

organic body'; and he associates psyche with the animate functions of nutrition, perception, thought, and motion. Psychology is thus by definition linked to the biological sciences; and Aristotle explicitly states that the student of the psyche must investigate the behavioural and physiological aspects of his subject—he must know, for example, that anger is the boiling of the blood around the heart:

*Perception receives a lengthy discussion in the *De anima* and in the *De sensu*, a component treatise of the *Parva naturalia*. Aristotle regards perceiving as a special sort of change in the perceiver:

objects of perception, acting via some medium of perception, causally affect the perceiver's sensory apparatus; the apparatus changes inasmuch as it 'receives the form of the object without its matter', and that change is perception. For example, if you look at a white piece of paper, your eyes (or some part of them) actually become white: the eyes are made white by the paper, although no material part of the paper enters them. Similar stories are told of the other four senses. (Aristotle thinks he can prove that there can be no more than five senses.) Each sense has its own 'proper objects' (colours for sight, sounds for hearing, etc.), but some objects (for example, shape, size, motion) are 'common' to two or more senses. Other objects (men or trees, say) are only perceived

'accidentally' or indirectly: you see a man by virtue of seeing something white and moving, which happens to be a man.

The different sense modalities are somehow unified by a 'common faculty', sometimes called the 'common sense'; that faculty, which is located in the heart, is employed to explain various perceptual and quasiperceptual phenomena, the most important of which is the 'unity of consciousness'. Colours are perceived by way of the eyes, sounds by way of the ears; but nevertheless, both perceptions belong to one and the same unitary subject or perceiver, who can compare and associate the data given by the two senses. By my eyes I see the colour and shine of the trumpet; by my ears I hear its tones: but it is a unitary I who perceives the trumpet, and I perceive the trumpet as a unitary substance. That task of perceptual unification is performed by the 'common sense'.

Perception is fundamentally a physical change, and it leaves physical traces in the body. Aristotle refers to those traces as 'phantasms', and they constitute the objects of *phantasia* or the faculty of imagination. The imagination is invoked in a number of contexts: thus it has an important role to play in the analysis of memory, which Aristotle discusses in his *De memoria*, and in the account of sleep and dreaming which he gives in the *De somno* and *De somniis*. (All three works are parts of the *Parva naturalia*.) Most importantly, the imagination supplies the link between perception and thought.

Aristotle's account of thought or 'the intellect' (*nous*) is one of the most perplexing aspects of his mental philosophy. On the one hand, he tends to treat thought on the model of perception: thought, like perception, is a change, and in thinking of things the mind somehow 'becomes' what it is thinking of (as the eye becomes what it is seeing, for example, white). Less obscurely, Aristotle holds that thought is dependent on imagination, and hence on perception: phantasms are, or represent, or accompany, the objects of thought, and we cannot think without phantasms. Since phantasms are the traces of perceptions, it follows that we cannot think without having perceived, and that the scope of our thought is determined by the extent of our perceptual experience. On the other hand, that strongly empiricist approach to the problems of thought seems to be modified by some remarks in one of the most celebrated and painfully difficult chapters in the whole of the Aristotelian corpus: in *De anima*, iii. 5, Aristotle distinguishes between two types of intellect: one, the 'passive' intellect, is securely tied, by way of phantasms, to perception and the body;

the other, the 'active' intellect, is pure and unmixed, free from physical trappings, and capable of independent and eternal existence. The 'active' intellect has been discussed for more than two

thousand years, and scholars are no nearer understanding Aristotle's doctrine than was his own first pupil, Theophrastus. It is legitimate to suspect that Aristotle's brief notes on the two varieties of *nous* represent no more than a passing fancy or a temporary aberration; in any event, their presence in the *De anima* should not blind us to the fact that for the most part that treatise is uncompromisingly empiricist and materialist in its doctrines.

Movement is treated in the *De anima*, and also in certain of Aristotle's ethical and biological works. (The short treatise *On the Movement of Animals* is a particularly rich source for Aristotle's views on the subject.) Aristotle's treatment is remarkable for its attempt to combine a physiological explanation of animal locomotion (in terms of 'spirit' or *pneuma*, which runs through the body like current in an electric motor) with a psychological account in terms of desire and thought (imagination and perception). The physiology is inevitably crude, but Aristotle's aim is sophisticated: he thinks it possible to account for animal (and human) movements purely in terms of the physical events taking place in the body, while at the same time he wants to explain action, at a philosophical or analytical level, by way of the interaction of desires and beliefs. The attempt to combine those two approaches raises questions of their mutual consistency: Aristotle did not face up to those questions; but it is fair to observe that the issue is still a central and unresolved problem in the philosophy of mind.

An outline survey of Aristotle's psychological theories does scant justice to his contributions to the subject; indeed, it may have the unwanted effect of belittling those contributions, since it is bound to stress the more abstract or general elements in Aristotle's thought. It is above all in the

Page 40
detail—both scientific and philosophical—of his account that Aristotle's genius shines out: a single page of his own writings will reveal more clearly than any summary the perspicuity, the intellectual acumen, and the scientific richness which justify his preeminence in the history of the study of mind and its place in nature.

J. BA.

The standard translation of Aristotle, and the only complete English translation, was prepared by several scholars under the general editorship of J. A. Smith and Sir David Ross; usually known as the 'Oxford translation', it is now available in two volumes (revised by Jonathan Barnes) under the title *The Complete Works of Aristotle* (1984).

AROUSAL. Arousal differs from*attention in that it involves a general rather than a particular increase (or decrease) in perceptual or motor activity. There can, however, be quite specific 'arousal', such as sexual arousal. General arousal is mediated by a diffuse neural system, centred in the brainstem, which not only sets a level from*sleep to wakefulness (and sometimes overarousal) but also provides momenttomoment changes of arousal which are usually appropriate to the prevailing situation, or task in hand. A great deal is known of the neurology of arousal (Milner, 1971), especially in the amygdala.

Subtle momenttomoment changes of arousal are experienced, for example, while driving a car; arousal immediately increasing with any small unexpected event or situation. It has been suggested

that fatigue results from overarousal; the blurring of perception perhaps being due to raised 'neural noise', or increased randomness of neural signals (which may also occur in ageing) in overarousal. Experiments conducted on vigilance during the 1939-45 war found that radar operators and others looking out for infrequent signals or events rapidly became inefficient as their level of arousal dropped—errors or misses increasing in as short a time as half an hour.

This loss of arousal in repetitive or boring situations (though it also occurs in the stress and danger of battle) can be distinguished experimentally from fatigue.

Arousal has been related to stress; indeed stress may be overarousal. There is an optimal level of arousal, which has been thought of as following an inverted 'U', for performing a task. But the performance of skills at low arousal differs from that when arousal is 'over the top' of optimal arousal; this suggests that the arousal function is not truly U-shaped. Errors under conditions of underarousal tend to be omissions while overarousal tends to lead to errors of commission or overcorrection.

Learning is improved with increase of arousal—again up to an optimum level, when overarousal becomes associated with distractions of various kinds (Bills, 1927;

Sherwood, 1965). There is considerable evidence that long-term but not short-term recall is improved with increased arousal. This is presumably because the laying down of memory traces is more efficient, perhaps with more cross-associations for future reference, for learning while arousal is high. Many people learn to control and optimize their arousal level when working or studying, by varying the task, or perhaps with the aid of music, or (not to be recommended!) smoking. There is little point in working when arousal falls close to the level of sleep.

ART AND VISUAL ABSTRACTION. The following attempts to demonstrate the role played by abstractive processes of contour, areal contrast, body axes, and movement in pictorial representation. Some of these abstractions show parallels with physiological mechanisms of the visual brain, as is demonstrated in Fig. 1. The treatment is restricted to the graphic arts in which mostly white-black contrasts are used. Colour effects are not treated, although they, too, may contribute to these

abstractive processes.

In drawing, the artist uses a reduction to contours similar to that found in vision. A physiological basis of pattern perception in the visual system is the signalling of outlines signifying the contoured forms of the object seen. The draughtsman usually first sketches these linear outlines and later fills them in with hatching or wash to give the illusion of light, shade, and plastic form. In vision the eye receives the projections of bright and dark areas on the retina, and the neuronal systems code them for relative brightness or darkness respectively, and enhance their linear borders. During the transfer of visual information from the eye to the brain, the contoured borders are accentuated progressively in the retina, the lateral geniculate, and the visual cortex (Jung and Baumgartner, 1965). By means of this border contrast enhancement, the neurones of the visual cortex can signal complex patterns with linear contours. Fig. 1 shows the principles of this neurophysiological contour abstraction.

In sketching, the artist acts in accordance with the same visual laws, but proceeds in a direction opposite to the abstractive process of vision. He begins with the linear outlines and ends with a picture showing also the values of light and space (Jung, 1971). In addition, he can delineate the structures and movements of the human body graphically, using oriented lines without contours, as is illustrated in Fig. 6.

Abstractions of contour, structure, and movement. Three main kinds of linear abstraction can be distinguished in the graphic arts: (i) the enhance

Page 41

Fig. 1.

Contour enhancement in the visual system by progressive effects of simultaneous contrast. The halftone picture (a) is transformed into the linear figure (b) by neuronal mechanisms of border contrast (c). The order of contour

signalling neurones in the visual cortex is shown in d.

a, b. Photographic imitation of contour abstraction, obtained by copying from displaced positive and negative photographic plates. a may correspond approximately to the retinal image, b to the information of the visual cortex. c.

Neuronal responses to a light bar on black background show progressive contour enhancement from retina to cortex in the brightness system B (oncentre neurones signalling contrast brightness) and the darkness system D (offcentre neurones signalling contrast darkness). A comparison of the discharge rates of diffuse illumination (...) with contrast stimulation shows the contrast enhancement in the hatched and crosshatched areas for the brightness and darkness systems respectively. d. Scheme of neuronal columns in visual cortex areas for information about contours and angles of certain orientations. In the orientation columns the retinal image is abstracted into linear contours similar to b.

ment of form and contour by linear outlines; (ii) the emphasis of the structural axes of the body, independent of contoured forms; and (iii) the representation of movement by schematic line drawings. To put it simply: outlines determine the form (Fig. 2), axial lines show the structure, and certain relations of structural axes signify a body in motion (Fig. 6).

Only the contour form of linear abstraction (i) can be explained by neurophysiological processes, as is shown in Fig. 1. Although the physiological basis of abstractions (ii) and (iii) is unknown, they may be characterized in cybernetic terms as a reduction in redundant information about visual forms, in favour of information about axial orientation.

Figs. 26 show works of art, selected from different ages and cultures, in which the human body is predominantly depicted by linear contours, nonlinear brightness contrast, or structural axes for the representation of motion. The figures demonstrate the power of linear expression in the graphic arts and the truth of the ancient saying that drawing is the art of omission. This omission is effected by abstractions to the essential values of contour, light, and movement.

Contour dominance. Forms and individuals can be recognized from a few contoured lines without other brightness or colour information. The building in Fig. 1a is perceived almost as clearly in the linear abstraction of Fig. 1b. This linear simplification is used by caricaturists to characterize individuals or constructs. Contoured drawings or prints are examples of this contour dominance. They may provide both form perception and aesthetic value, as in Figs. 2a and 2b.

Thus it seems to be true that outlines give sufficient information to characterize a form and that areal and colour contrast provide only additional and redundant information. With more radical reduction of redundant information even contours may be renounced, information being limited to the axial lines of body and limbs, as is shown in

Page 42

Fig. 2

Contoured representations of the human body from the thirteenth and the twentieth centuries. The examples show opposite contrasts: black on white (a) and white on black (b). a. Medieval drawing of a sitting man in Villard d'Honnecourt's sketchbook (c. 1230). It is limited mainly to the body contour with a few added lines indicating muscles and ribs. Pen on parchment. Left side, 14×7 cm of a 14×22 on page. b. Modern contoured print by Matisse in white lines on black background (1944). It shows the essential outlines of a sitting female nude wearing a pearl necklace and surrounded by some background decoration. Linocut. 24.3×17.7 cm.

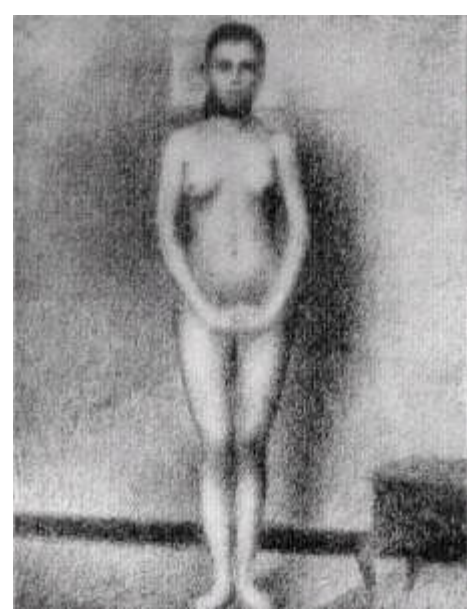

Fig. 6. The Stone Age pictures of the FrancoCantabrian group, for example in Lascaux, have mainly contoured outlines in the naturalistic style of ten to eight thousand years BC, whereas axial line reduction is mainly used in the late Stone Age rock painting of the sixth to fourth millennium BC in eastern Spain.

Uncontoured brightness contrast. Physiologists have demonstrated two kinds of visual contrast: one is border contrast, which enhances the contours by the so-called Mach bands (Ratliff, 1971); and the other is areal contrast, which exaggerates the brightness differences of large surfaces, as investigated by Ewald*Hering (1878). In Hering's contrast, a bright area is seen brighter in a dark surround; and vice versa: a dark area appears blacker when framed by bright areas relatively independent of contoured borders. Hering's contrast may be seen as nonlinear brightness differences. Some artists, such as Seurat and Signac, avoided all linear contours in their drawings and pictures, producing only a pointillistic surface effect (Ratliff, 1971). This is demonstrated in Fig. 3, a typical uncontoured drawing by Seurat. Contours may be seen, at the borders of nonlinear bright and dark areas, as a linear illusion caused by Mach bands.

The special uncontroled technique of Seurat is exceptional in the art of drawing. Most artists combine lines with areal contrast by supplementing the linear design with added brushwork and wash in different halftone gradations of brightness, In etchings, these halftones may be added by the mezzotint technique as shown in Fig. 4.

Here Turner designed the original contoured etching (Fig. 4a) and a professional engraver completed it with mezzotint (4b). Linear and areal contrast are also combined in the socalled* Craik illusion, resulting in borderinduced brightness and darkness, which Ratliff (1971) discusses for East Asiatic brush paintings. The Craik effect may enhance areal contrasts.

Wash and colour supplementing contour. Visual forms and patterns are most easily reproduced as outline drawings. This linear contour abstraction may remain dominant, as in Fig. 2, or may be

Page 43

Fig. 3.

Nonlinear drawing of a female nude made by G. Seurat in 1887 using pure brightdark contrast. Light values, atmosphere, plastic form, and contour effects are obtained without lines by more or less dense rubbing of black chalk (crayon conté) on granulated paper. The black granules contrast with the white paper. Seurat avoided linear contours with his pointillistic technique, both in blackwhite drawings and in coloured pictures. This

sketch for the painting *Poseuses* was preceded by a contoured

outlinedrawing. 29.7×22.5 cm.

supplemented by surface effects adding brightness and colour contrast (Fig. 4b). Both types are found in the pictorial art of all ages. The most ancient examples come from neolithic cave art, which produced many contoured and coloured drawings of animals. In this Stone Age naturalistic style, the first outline sketch either remains linear or is completed in colour. A linear style is also prominent in medieval pen drawings and in the earliest woodcuts. All woodcuts of the fifteenth century were contoured, before Dürer introduced more or less dense hatchings and crosshatchings to the woodblock to depict the values of light and shade. The frequent colouring of the early woodcuts and the adding of wash to contoured drawings shows that there was a need for additional colour and surface values. These are often completed by refined brushwork, so that the subjects drawn appear as plastic forms in an envelope of light. Some artists also prefer linearity for light and shade and achieve these effects by the use of hatching and crosshatching—for example, Dürer and Raphael. Others express nonlinear values of light, shade, and colour by additional brushwork (e.g. Tiepolo), or by special techniques with chalk (Seurat, Fig. 3). All variations, including the soft shining surface of the late Nazarene or Pre

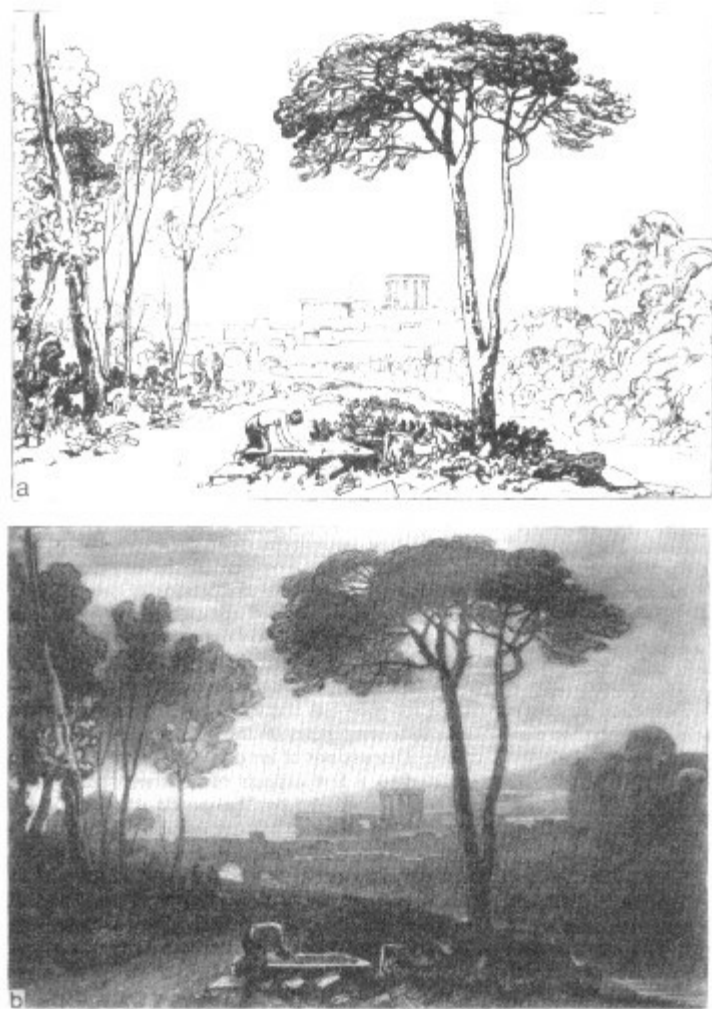

Raphaelite drawings of the nude, and the vigorous linear or surface contrasts of modern art (which often deform or destroy the contours), have their special aesthetic appeal. In prints made as reproductions, aquatint and mezzotint techniques are used to represent surface values of bright and dark areas similar to brushwork and wash in the drawings (see Fig. 4b).

Linearity, light effects, and style. The linear and nonlinear tendencies of the graphic arts vary in different style epochs, often alternating in a process of reaction and counterreaction (Jung, 1971). For example, in the nineteenth century academic linearization and classicizing contour enhancement provoked the emphasis on light and colour in the Romantic movement and in Turner's aquarelles. Later the rather dry figure drawing of historical painters gave way to the impressionists' turbulent drawing style with dissolution of patterns and dispersed light. This again was followed by the sharply contrasting boundaries seen in art nouveau, the blackwhite areal contrast of the expressionists' woodcuts, the contour distortions of the fauvists, and the tendency to deformation in many modern artists following Picasso (Jung, 1974).

Although the neoimpressionists, such as Seurat, used physiological concepts of colour contrast for their art theories, the influence of these scientific tendencies on the pictorial arts was negligible. Discussions of art on the basis of science are limited to a few aspects of contrast and colour, already mentioned by*Leonardo da Vinci in his treatise on painting written around 1500. Many a limit can be transgressed in free artistic creation, but even the artists followed physiological laws of visual perception when they applied principles of contour and brightness vision almost instinctively in their work, as*Helmholtz remarked as early as 1871. The abstractive processes of vision in art receive little attention in the monographs on art and visual perception. Ratliff (1971) has depicted good examples of contourinduced brightness effects in oriental art.

Dynamic linear structures. Many purely contoured drawings from all historical periods—for example, the medieval Fig. 2a or the classicizing drawings by Flaxman and others—appear static, dry, and often somewhat boring. To avoid this the artist tends to vivify or dissolve these pure contours by interrupting them or adding a variety of line or light values. Dynamic effects may be obtained by irregular contours and lively hatching without wash and areal brightness contrast. Fig. 5 shows two modern drawings of human figures in which dynamic linear structures are added. In*information theory, these dynamic additions would be called redundant, since they do not supply further information about the forms, but they are aesthetically rewarding.

A vivid drawing technique and a dissolution of

Page 44

Fig. 4.

Linear contours of an etching by J. M. W. Turner (a)

completed in 1812 as a mezzotint (b) in halftones of light and

shade. 18.7 × 26.5 cm. a. The pure linear etching depicts the

landscape mainly by contours, with a few hatchings at

the trees and on the human figure. It was sketched by Turner

himself and intended to be mezzotinted by a professional

engraver. b. Completed mezzotint. The engraver, W. Say, has

added the halftones, varying from a dark blackish brown

in the foreground to light yellowish brown in the

buildings of the background. The scraped, smooth parts of the

plate ground are seen as light areas in contrast to the

dark, roughened, unscraped areas.

contours may depict emotional values or physical movement. However, dynamic lines are not necessarily expressions of lively motion. In Fig. 5 the dynamically drawn women appear to move slowly from a standing or sitting posture, in Fig. 5a bending forward during the act of washing, and in Fig. 5b turning sideways. Slight modifications to this dynamic drawing technique are used to depict moving figures. Motion *per se*, however, can also be expressed without any linear redundancy by very simple drawings of the essential body axes in single lines, as is shown in Fig. 6. Here the redundancy is reduced, whereas in Fig. 5 it is increased.

In modern art the tendency towards contour distortion and expressionist deformation is counteracted by a tendency in the opposite direction, towards natural contour representation and calm. Matisse is a good example of this predilection for clean, simple, and balanced line drawings, avoiding extreme expression and wild movements or gestures. This return from excessive extravagance to the rules of classic art is marked more in the works of French than German or British artists of recent decades. From his Fauves period (1905), when he used contrasting surfaces or dissolved outlines, Matisse turned to clear and serene contours. The odalisquelike women of his pen drawings, etchings, and linocuts made in 1930-48 show sharp outlines without effects of light or movement. The background is usually formed by decorative additions at a distance from the body, as in Fig. 2b. His contoured bodies signify relaxed rest or perhaps quiet movement. Matisse himself remarked: 'Je veux un art d'équilibre, de pureté, qui n'inquiète ni trouble. Je veux que l'homme fatigué, surmené, éreinté, goûte devant mes peintures le calme et le repos.'

Page 45

Fig. 5.

Dynamic structures with dissolving contours in modern drawings of female bodies. a. Weisgerber's woman standing in front of a dressingtable is drawn with irregular hatching and restless contour lines. Hence body and objects appear more vivid than in pure contour drawings, but the impression of quiet stance bending forward prevails over movement. Pen black. c. 1913. 20.7×15.3 cm. b. Friesz's sitting woman turned to the left, and the signature, are drawn in vivid lines. Quick and turbulent hatchings and interrupted contours enhance the impression of a turning movement from a quiet sitting posture. Pencil. c. 1928. 39.6×29.0 cm.

Structural axes and representation of movements. The oriented axis of a body or limb can be drawn in a single line. The combined arrangement of these lines depicts *characteristic* postures of the human figure that can be recognized at a single glance. These axes are independent of body contours but are related to the position of the joints in various postures. When the limbs are drawn in positions of walking or running, the viewer immediately recognizes these movements in the immobile picture. Fig. 6 shows examples of this depiction of motion in various cultures, from Stone Age rock paintings down to modern art.

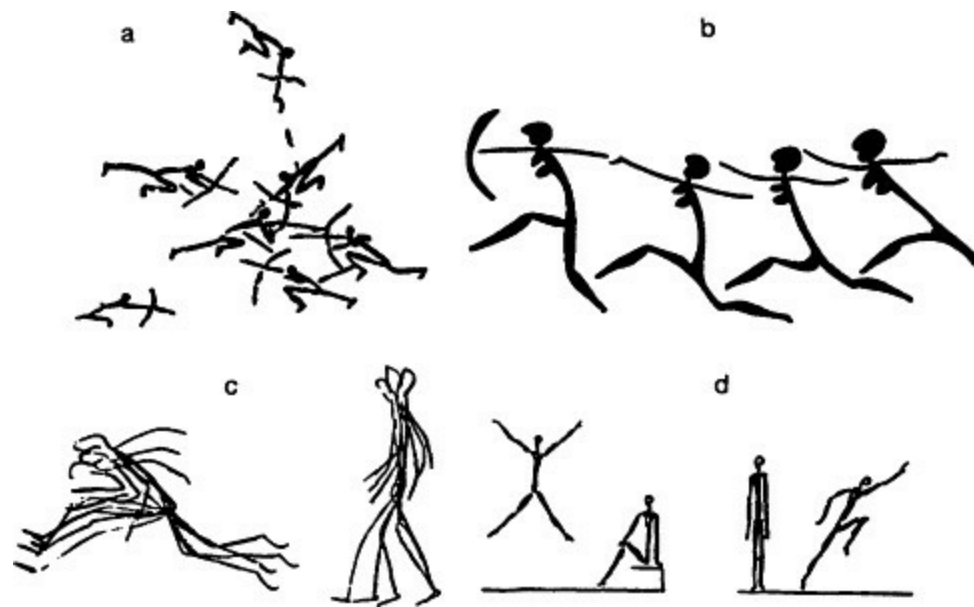

Axial structures have been used since prehistoric times to depict men and animals in motion. Linear human figures of this type are typical of the 'Levante' rock paintings in eastern Spain made about 5000 BC (Fig. 6a). Similar figures appear in Viking pictures in Scandinavia in the first centuries AD, in the later South African bushman drawings, and in Australian aboriginal rock pictures (Fig. 6b). Their use by these very different populations, who had no cultural relations with each other, demonstrates that the representation of axial structures and movement is a universal feature in the human visual arts. Such linear figures depicting running men are recognizable at a glance and are even understood by children as signifying movement.

Perception of axial clues and motion. The neuronal mechanisms of the visual abstraction of body

axes are unknown. One can only presume that they may be related to*Hubel and Wiesel's orientation columns and directionspecific responses in the visual cortex (Hubel and Wiesel, 1959) (see VISUAL SYSTEM: ORGANIZATION). The perception of axial clues, however, has been well investigated since Marcy began his chronophotographic analyses of body movements marked by axial lines of the limbs. G. Johansson (1973) has shown that we can recognize complex movements of human bodies in a film from a few dots positioned at the limbs. This extremely reduced information on spatiotemporal patterns is integrated into a*Gestalt perception of moving bodies.

Conclusion. We have come to the general conclusion that forms are determined by outlines, organic structures by axial lines, and bodies in motion by arrangements of structural axes. These principles of visual abstraction appear to be valid for both visual representation and cognition.

The few examples of visual abstractions in graphic an discussed with Figs. 26 show that the artist, albeit dependent on the physiological laws of vision, has some freedom of selection and variation. According to his concepts he can express what he wants to say by different techniques. In

Page 46

Fig. 6.

Human motion depicted by oriented axial line patterns in Stone Age rock paintings and in modern drawings. a. A battle of archers (eastern Spain), painted in simple axial lines of limbs and trunk signifying moving and shooting men.

Red lines on grey rock. c. 5000 BC. 10·5 × 12·0 cm. b. Running and dancing women drawn in simple line figures by Australian aborigines. Red paint on grey rock. c. AD 1700 (?). 50 × 150 cm. c. Modern drawing of a running and walking man with multiple axial lines of body and limbs. Pen black. c.6 × 10 cm. d. Sitting, standing, jumping, and running men, with slightly thickened orientated lines indicating the limb postures. Pen black. c. 6 × 10 cm.

spite of these various possibilities, art is not completely autonomous, since its effect on the viewer is

processed by the viewer's visual system. The draughtsman can add colour and wash to contour drawings to obtain surface values in an envelope of light, but the effect on the viewer is determined by the mechanisms of contrast vision. The draughtsman can depict motion in a static picture by arranging contours and axial lines, but this is only an illusion of movement. We perceive moving figures in these drawings, although there is, of course, no real movement in them. Visual recognition, trained by experience and memory, helps us to see motion in the simple line figures of Fig. 6. A further information reduction to an immobile pattern of spots positioned at the joints, such as used by Johansson in his experiments, is not seen as moving. Only real motion of these spots, as seen in a film, transforms them into apparently moving bodies.

In general, the significance and the beauty of art are only apparent to those who can see and are trained in viewing. The artist himself is not interested in the process of seeing, and lets the physiologist investigate visual mechanisms. Leonardo, who discovered certain laws of contrast vision, was unique in being both an artist and a scientist; The vain attempts of the neoimpressionists to build a theory of painting on the physiology of colour contrast show the limits of the relation between physiology and art. Modern techniques of Op Art, deliberately using optical illusions to induce stereopatterns and movement perceptions, are confined to a narrow field.

Although it may be useful for the artist to know some of the principles of vision and their possible applications to the visual arts, the relevance of physiological laws to the visual arts and to aesthetic values is limited. Art has a greater degree of freedom than science. Even if the scientist elucidates certain principles and limits of the visual perception of form, science cannot dictate to the artist what he should do. The frontiers of the visual arts must be set by the creative artist himself.

ART AS PERCEPTUAL EXPERIENCE. The objectivity of images. For most practical purposes, human beings do not get into much trouble when they base their conduct on the conviction that the world they see is the world as it is. It is a reasonable simplification, and only occasional refinements call for minor corrections.

'This colour looks yellower than it is in the daylight.' 'In this dress she looks taller than she is.' 'The mountains are farther away than they look.' Corrections of this kind consist in revising a particular view on the basis of one's total perceptual resources. One may correct, for example, an observed size by comparing it with the length of a yardstick, or test a colour against a sample swatch.

These corrections are necessary as long as we use visual images as intermediary information for the purpose of getting along in what we call the physical world. The physical world, known to us through the totality of our perceptual experiences and the inferences suggested by these experiences, is governed by laws we cannot ignore with impunity. If one builds a house whose walls look vertical but are not, the house may collapse. Hence the need for correcting our images.

In the visual arts such corrections are inappropriate because a painting or piece of sculpture is not a standin for physical objects, to be subjected to physical handling.

Rather a work of art is a statement *about* such objects and other facts of experience. Being perceptual statements, the images produced by art objects are final in all their properties. A giant in a painting by Goya is as large as he looks. The Rialto bridge in a view of Venice is, rightly or wrongly, as far away as we see it. The weightiness of a wooden figure by Ernst Barlach has little to do with the weight of the wood; and a certain orange in a painting by Matisse is orange, even though it might look red when put somewhere else. What *looks* vertical *is* vertical.

Are we then to say that the perceptual features of the mental images we call works of art are purely subjective? 'Subjective' is a dangerous term, to be used with caution. Those visual qualities are subjective in the sense that they require a pair of functioning eyes in the observer. Without eyes there is no picture. And yet, images have an objectivity of their own, which we acknowledge when we say that a tired tourist looking at Leonardo's cartoon of the Virgin with St Anne may see something pale, stiff, indifferent; but his image has to be discounted. The tourist has failed to see the picture. The cartoon contains objective qualities of expression and compositional relation that must be fully

perceived to be appreciated. Only because art images are objective facts can there be critical dialogue about their nature.

Only because images are objective facts can the eyes of a student be opened by a perceptive teacher.

Somebody may assert, 'In this etching by Picasso the head of the Minotaur is much too large in relation to his body', and be told, 'But in relation to all the other small figures in the picture, the large size of the head is exactly right!' The first judge has been convicted of misinterpretation caused by restricted vision. There is no way of avoiding the debate about the true perceptual structure of the picture by insisting on one's right to look subjectively.

The observer, however, has a mental structure of his own. When one of Picasso's paintings is used by psychologists in a personality test—as in fact has been done—

someone who is being tested may report that the figures in the painting look at each other with bitter hatred. Such a response cannot be brushed aside as irrelevant. It may not do justice to the picture, but it describes the result of the encounter between two mental structures, namely the perceptual image received and the personal views, needs, attitudes of the beholder. Such encounters attain more general importance when a historian notes how differently certain cultural periods react to works of a particular style, for example to Gothic architecture, Roman portraiture, or the paintings of El Greco. The interplay between the viewer and the work of art viewed sheds light on the objective structures of both parties. These structures can be extrapolated from the context by a comparison between many different works seen by the same viewer or, vice versa, between many different responses to the same work. If you collect and compare the responses to the Laocoön group in the Vatican over the last five hundred years, you will learn something about the work's objective nature and qualities.

The perception of images. The ability to see visual representations at all cannot be taken for granted. At closer scrutiny this ability turns out to be a combination of two abilities. (i) The viewer can recognize the subjectmatter, even though the image varies from the model in size, colour, spatial dimensions, etc. A primitive tribesman, confronted with a photograph for the first time, may see only a flat object with a mottled surface. But the same tribesman may recognize simply shaped outlines of human faces, fishes, or the sun. So may a monkey, looking at similarly simple pictures—a remarkable feat of perceptual abstraction. (ii) The viewer is able to conceive of images as representations of kinds of subjects existing elsewhere. Instead of, or in addition to, responding to a portrait by saying, 'A smiling woman is looking at

me'—an experience that can lead in extreme cases to actual delusions—the viewer realizes, 'This picture is meant to look like someone who actually lived in Italy in the past.' A monkey, as far as we know, could not treat a picture in this way as a referential statement.

A picture may be called a *selfimage* when it is taken as a visual expression of its own properties, and a *likeness* when it is taken as a statement about other objects, kinds of objects, or properties. The first conception, more elementary, can exist without the second; the second, more sophisticated, combines with the first.

Both abilities to deal with images may occur at various levels of abstraction. Man and animal would be unable to see a simple outline figure as a human face unless perception consisted in the grasping of general structural features rather than in the mechanical recording of all individual detail. In the arts, this fact is demonstrated to us, for example, when we step close to a portrait by Frans Hals and find that the face, moustache, and lace collar disintegrate into a qualitatively different pattern of brushstrokes. With changing distance, the level of abstraction has shifted.

Observe now that the structural features of shape and colour which make us see a Dutch cavalier on the canvas are perceptual generalities. The roundness of a face, the curliness of hair, the whiteness of a collar are examples of very general qualities, found everywhere. Hence, seeing a clearly shaped thing means also seeing a *kind* of structural behaviour. This sort of generality remains subordinated to the objects portrayed in the naturalistic paintings of a Van Eyck or Holbein. It comes increasingly to the fore in highly abstract styles, for example in the arts of our century. In such works the formal features predominate to such an extent that they subdue the vehicle of subjectmatter. In a reclining woman by Henry Moore the particular shapes of a female body are reduced to very general although characteristic curvatures of surfaces and volumes. Viewed even more abstractly, the sculptor's piece of wood or stone becomes an image of man's relation to the earth, on which his body reposes; and finally one may go beyond the distinction between the organic and the inorganic and see a grouping of masses in which characteristics of living bodies and rolling hills combine indistinguishably in an image of the forms of nature.

When the references to natural subjectmatter are entirely suppressed and representation is entrusted to purely 'abstract', nonmimetic shapes, colours, and movement, the artist probes the outer limits of the imagery which is accessible to man as a symbolizing animal.

R.A.

ARTIFICIAL INTELLIGENCE (AI) is the science of making machines do the sorts of things that are done by human minds. Such things include holding a conversation, answering questions sensibly on the basis of incomplete knowledge, assembling another machine from its components given the blueprint, learning how to do things better, playing chess, writing or translating stories, understanding

analogies, neurotically repressing knowledge that is too threatening to admit consciously, and recognizing the various things seen in a room— even an untidy and illit room. AI helps one to realize how enormous is the background knowledge and thinking (computational) power needed to do even these everyday things.

The 'machines' in question are typically digital computers, but AI is not the study of computers. Rather, it is the study of intelligence in thought and action. Computers are its tools, because its theories are expressed as computer programs which are tested by being run on a machine.

Other theories of intelligence are expressed verbally, either as psychological theories of thinking and behaviour, or as philosophical arguments about the nature of knowledge and*purpose and the relation of mind to body (the*mindbody problem). Because it approaches the same subjectmatter in different ways, AI is relevant to psychology and the philosophy of mind.

If we think of a program as a picture of a part of the mind, we must realize that a functioning program is more like a film of the mind than a portrait of it. Programming one's hunches about how the mind works is helpful in two ways. First, it enables one to express richly structured psychological theories in a rigorous fashion (for everything in the program has to be precisely specified, and all its operations have to be made explicit); and secondly, it forces one to suggest specific hypotheses about precisely *how* a psychological change can come about. For example, one might say that a person reacts to a policeman in a particular way because he sees him as an 'authority figure'.*Freudian psychologists suggest some ways in which this sort of interpersonal perception and attitude might function, and ways in which it might have developed in the person's mind—tracing it back to early infancy. But if one were to write a computer program that was able to recognize the analog between a policeman and a father, one would have to specify the conceptual comparisons that underlie this recognition.

Of course, one could cheat: one could simply write into the program the information that 'All policemen may be treated as one would treat a father'; but this would both lead the program into some very strange behaviour—such as buying Christmas presents for the policeman—and fail to capture the general concept of an

'authority figure', so that the program had no inkling of the affinity between fathers, policemen, government ministers, and God. Clearly, a program able to recognize this general affinity would need to have a great deal of knowledge about interpersonal relationships in Western society, as well as being able to make subtle comparisons between various aspects of different concepts. The attempt to write

Page 49

such a program, even if it were unsuccessful, could not fail to indicate the richness of the equivalent psychological phenomenon in human minds.

Similarly, attempts to write programs that can interpret the twodimensional image from a TV camera

in terms of the threedimensional objects in the real world (or which can recognize photographs or drawings as representations of solid objects) help make explicit the range and subtlety of knowledge and unconscious inference that underlie our introspectively 'simple' experiences of seeing. Much of this knowledge is tacit (and largely innate) knowledge about the ways in which, given the laws of optics, physical surfaces of various kinds can give rise to specific visual images on a retina (or camera). Highly complex computational processes are needed to infer the nature of the physical object (or of its surfaces), on the basis of the twodimensional image.

In addition, 'visual' computer programs help to show how the perceptual system copes with ambiguity in the input, and how it is able to recognize certain inputs as pictures of 'impossible' objects. These achievements rest on the active interpretation of the pictureparts by reference to an implicit*schema or representation, where the 'parts' are largely identified by way of this overall schema. Work in computer vision thus helps to clarify plausible but vaguely expressed notions in theoretical psychology, such as*Helmholtz's 'unconscious inference' and supports the*Gestalt psychologists' slogan, 'The whole is greater than the sum of its parts'.

Traditional philosophical puzzles connected with the mindbody problem can often be illuminated by AI, because modelling a psychological phenomenon on a computer is a way of showing that—and how—it is *possible* for that phenomenon to arise in a physical system. For instance, people often feel that only a spiritual being (as opposed to a bodily one) could have purposes and try to achieve them; and the problem then arises of how the spiritual being, or mind, can possibly tell the body what to do, so that the body's hand can try to achieve the mind's purpose of, say, picking a daisy. It is relevant to ask whether, and how, a program can enable a machine to show the characteristic features of purpose. Is its behaviour guided by its idea of a future state? Is that idea sometimes illusory or mistaken (so that the

'daisy' is made of plastic, or is really a buttercup)? Does it symbolize what it is doing in terms of goals and subgoals (so that the picking of the daisy may be subordinate to the goal of stocking the classroom naturetable)? Does it use this representation to help plan its actions (so that the daisies on the path outside the sweetshop are picked, rather than those by the gas station)? Does it vary its meansend activities so as to achieve its goal in different circumstances (so that buttercups will do for the naturetable if all the daisies have died)? Does it learn how to do so better (so that daisies for a daisychain are picked with long stalks)?

Does it judge which purposes are the more important, or easier to achieve, and behave accordingly (if necessary, abandoning the daisypicking when a swarm of bees appears with an equally strong interest in the daisies)? Questions like these, asked with specific examples of functioning programs in mind, cannot fail to clarify the concept of purpose. Likewise, philosophical problems about the nature and criteria of knowledge can be clarified by reference to programs that process and use knowledge, so that AI is relevant to*epistemology.

AI is concerned with thinking *in general*, not just with mathematics and logical deduction. Computers are not mere 'number crunchers', but are general symbol manipulators, systems which alter and combine symbols according to the instructions expressed in the program. Just as a spy could use

numerals and arithmetical rules as a code to represent the information that the Prime Minister is having an affair with his secretary—which is semantic rather than numerical information—so the apparently 'numerical' symbols manipulated 'arithmetically' by computers can be given semantic meaning by the programmer. Thus computers are not limited to handling only information about numbers. Nor are they limited to purely deductive, or rigorous reasoning: like people, computer programs can use 'fuzzy' methods of reasoning which work fairly often, fairly well, although they may sometimes lead them into error. Visual programs, for instance, are in principle liable to visual illusion or mistake, just as humans are. Programs can even represent *inconsistent* beliefs and reasoning, much as some verbal psychological theories try to give an (internally consistent) explanation of why people often make logical errors. Indeed, AI has shown that to insist on logical rigour in the use of knowledge is often *not the* intelligent thing to do.

The main areas of AI include natural language understanding (see SPEECH RECOGNITION BY MACHINE), machine vision (see PATTERN RECOGNITION), problemsolving and gameplaying (see COMPUTER CHESS), robotics, automatic programming, and the development of programming languages. Among the practical applications most recently developed or currently being developed are medical diagnosis and treatment (where a program with specialist knowledge of, say, bacterial infections answers the questions of and elicits further relevant information from a general practitioner who is uncertain which drug to prescribe in a given case); identification of unknown substances by spectroscopic analysis; teaching some subject such as geography, or electronics, to students with differing degrees of understanding of the material to be explored; the automatic assembly of factorymade items, where the parts may have to be inspected first for various types of flaw and where they need not be accurately positioned at a precise point in the assemblyline—as is needed for the automation in widespread use today; and the design of complex systems, whether electrical circuits or

Page 50

living spaces or some other, taking into account factors which may interact with each other in complicated ways (so that a mere 'checklist' program would not be adequate to solve the design problem).

The social implications of AI are various. As with all technologies, there are potential applications which may prove bad, good, or ambiguous in human terms. A competent medicaldiagnosis program could be very useful, whereas a competent military application would be horrific for those at the receiving end; and a complex datahandling system could be well or ill used in many ways by individuals or governments. Then there is the question of what general implication AI will be seen to have for the commonly held 'image of man'. If it is interpreted by the public as implying that people are 'nothing but clockwork, really', then the indirect effects on selfesteem and social relations could be destructive of many of our most deeply held values. But it could (and should) be interpreted in a radically different and less dehumanizing way, as showing how it is possible for material systems (which, according to the biologist, we are) to possess such characteristic features of human psychology as subjectivity, purpose, freedom, and choice. The central theoretical concept in AI is *representation*, and AI workers ask how a (programmed) system constructs, adapts, and uses its inner representations in interpreting—and changing—its world. On this view, a programmed computer may

be thought of as a subjective system (subject to illusion and error much as we are) functioning by way of its idiosyncratic view of the world. By analogy, then, it is no longer scientifically disreputable, as it has been thought to be for so long, to describe people in these radically subjective terms also. AI can therefore counteract the dehumanizing influence of the natural sciences that has been part of the mechanization of our worldpicture since the scientific revolution of the sixteenth and seventeenth centuries.

ASTIGMATISM. Defect of vision due to the radius of curvature of the optics of the eye— especially the cornea—being unequal at different orientations around the visual axis. Lines or bars at different orientations are not all simultaneously in focus, and there can be distortions for some orientations. It is well corrected by suitable spectacles, though not so easily by corneal lenses as they may be placed in the eye with any orientation.

See also EYE DEFECTS AND THEIR CORRECTION.

ASTROLOGY. Anyone who has taken even the most casual interest in astrology will have noticed that, contrary to all common sense, it *seems* to work. That is to say, the personal characteristics that are supposed to be governed by the 'sun signs' often appear curiously accurate. People born under Aries (between 21 March and 19 April) are supposed to have drive and enterprise; Tauruses are supposed to be practical and stubborn; Geminis clever but changeable; Cancers homelovers with a tendency to oversensitivity; Leos dominant extraverts with a touch of egoism; Virgos hard workers

who are obsessed by detail; Libras charmers who know how to get their own way; and so on. And most of us can, without much trouble, recall acquaintances who are typical Leos, Cancers, Geminis, etc.

Scientifically speaking, of course, this proves nothing; the sceptic can always point to untidy Virgos, modest Leos, timid Aries. Yet it is not difficult to feel that the 'hits'

are striking enough to be worth closer investigation. In a case like this, the obviously sensible method is statistical—how many people can be shown to fit their astrological 'type'? In the early years of this century, a Frenchman, Paul Choissard, tried the statistical approach, and his work inspired a Swiss mathematician, Karl Ernst Krafft, to even more ambitious efforts. Emphasizing his strictly scientific approach, Krafft preferred to call the subject 'astrobiology'; his immense *Traité d'astrobiologie* appeared (in French) in 1939; but the times were unpropitious, and it attracted little attention. It was Krafft who, in a letter of 2 November 1939 (to a member of Himmler's Secret Intelligence Service), predicted that Hitler's life would be in danger between the 7th and 10th of the month—he specifically mentioned

'assassination by explosive material'. When Hitler narrowly escaped death in the Munich beer cellar—he had just left when the bomb exploded—on 8 November 1939, Krafft's prediction was remembered and he was brought to Berlin. For a while he became a kind of semiofficial astrologer to Himmler, but soon fell out of favour, and died in a concentration camp.

Krafft had attempted to 'prove' astrology by examining the birth certificates of thousands of professional men—he concentrated on musicians—and trying to show that their temperament corresponded to their sun sign. In 1950, a Sorbonnetrained statistician and psychologist, Michel Gauquelin, became interested in Krafft's *Traité*, Page 51

and fed its results into a computer. His conclusion was that Krafft was deceiving himself when he believed his figures proved anything—he had allowed himself too much leeway of interpretation. Gauquelin's book, *Songes et mensonges de l'astrologie* (1969), was a scathing attack on astrology, as its title (*Dreams and Delusions of Astrology*) indicates. Yet the unsatisfactoriness of Krafft's experimental method led Gauquelin to devise a few simple tests of his own.

He concentrated his analysis on two straightforward questions. The first was whether astrologers are correct in stating that people born under 'odd' signs of the zodiac—Aries, Gemini, Leo, Libra, Sagittarius, Aquarius—tend to be extraverts, while those born under even signs—Taurus, Cancer, Virgo, Scorpio, Capricorn, Pisces—are likely to be introverts (see EXTRAVERSIONINTROVERSION). The second question was whether a person's choice of profession is in any way governed by the planet that is in the ascendant (coming up over the horizon) at the moment of birth.

Greatly to his surprise, the evidence in both cases was positive. The tests were repeated many times, in four European countries, and the results continued to favour these assertions of astrology. Professor H. J. Eysenck was asked to check the results. He agreed, apparently with the expectation that they

would prove to be invalid;

and was equally surprised to find that they were positive.

The method used by Gauquelin—and later by Eysenck (and two associates, Jeff Mayo and A. White)—was as follows. Certain professions were chosen—sports champions, actors, scientists—and their birth certificates consulted for the exact time of birth (which is recorded on the Continent, though not in England). The subjects were 'famous'—to be found in reference books—and the numbers ran into thousands.

Astrologers believe that the 'rising sign' (the sign coming up over the horizon at the moment of birth) and the rising planet are of basic importance in governing the subject's temperament. Gauquelin's computer analysis seemed to show that three other positions were equally important: directly overhead, sinking below the horizon, and directly underfoot—the four quarters of the heavens, as it were. The findings were perfectly clear. Sportsmen tended to be born when Mars was in one of these critical positions, actors when Jupiter was there, and scientists (and doctors) when Saturn was there. Eysenck (1979) states: 'The results were extremely clearcut and so significant statistically that there is no question whatsoever that the effects were not produced by chance.' But Eysenck, like Gauquelin, is careful to state that he does not consider these results 'prove' astrology; rather, he says, they should be regarded as the possible foundation of a new science of astrobiology.

Now there can be no possible doubt that astrology, as traditionally practised, is a pseudoscience. Early astrology—as practised by the Sumerians and Babylonians—

was a jumble of old wives' tales. 'When a yellow dog enters a palace there will be destruction in its gates', says a Babylonian text; 'When the planet Mercury approaches Aldebaran the king of Elam will die', says another; and the two assertions sound equally absurd. But they are no more embarrassingly silly than modern popular books on astrology with titles like *Love Signs* and *The Stars and You*. How, then, is it possible to take seriously any 'science' that asserts a connection between 'the stars' and human destiny?

It must first be noted that the stars, as such, play no part in astrology. Because they are 'fixed', they can be used as reference points for the positions of the planets—

that is to say, they could be regarded as the figures around the face of a clock, while the planets are the hands. It is the bodies in our own solar system that are believed to exert forces upon the earth, which, in turn, exerts forces on human beings. How? Astrology has never been concerned with this question, but Gauquelin suggests that the answer lies in the earth's magnetic field. In 1962, Y. Rocard, professor of physics at the Sorbonne, conducted an investigation into the claims of waterdiviners, and demonstrated that the dowser's muscles react to weak changes in terrestrial magnetism caused by underground water, and that a capacity for detecting extremely small magnetic gradients is surprisingly common among human beings. It has long been widely accepted that the moon can produce emotional tension—hence 'lunatics'—and the statistical evidence has been documented by Arnold Lieber (1978). Leonard J. Ravitz, of the Virginia Department of Health, investigated the

influence of moon cycles on mental patients in the late 1950s and found that the difference in electrical potential between the head and chest is greater in mental patients than in normal people, and increases at the full moon. In the late 1930s, Maki Takata of Tokyo discovered that when there is high sunspot activity, the 'floculation index'—the rate at which albumen curdles in the blood—rises abruptly. It also rises before dawn, as the blood responds to the rising sun. At about the same time, Harold Burr of Yale observed that the electric field produced by living creatures—trees, for example—varied with the seasons, as well as with the cycles of the moon and sunspot activities.

So the basic medical facts may seem to be fairly well established. It may also be worth mentioning the discovery of John H. Nelson, an electronics engineer, that most magnetic storms (causing radio interference) occur when two or more planets are in conjunction, or at angles of 180° or 90° from the sun. This seems to establish a foundation for a science of astrobiology; what still remains to be discovered is how forces of terrestrial magnetism could influence a human being to the extent of predisposing him to one profession or another—or even what regular monthly cycle could possibly determine whether a person is introverted or extraverted.

Page 52

I should emphasize that I am not now asserting that the claims of astrology must somehow be 'reduced' to a series of statements about the influence of magnetic fields on animal organisms. Even a sceptical historian of astrology like Ellic Howe (1967) concedes that a 'good astrologer' can produce results of astounding accuracy—

describing not only a person's temperament, but the pattern of his life. Similarly, anyone who has ever investigated dowsing will feel that the dowser's powers of detection—of other substances besides water—go far beyond the results obtained by Rocard. When the old wives' tales have been sifted out, there still seems to be more to explain than science is at present willing to admit. Modern computer analysis of structures like Stonehenge, the stones of Carnac, and the Great Pyramid suggests that their original purpose was connected with astronomy, which in turn suggests that our neolithic ancestors (the outer ditch of Stonehenge was constructed about 2900 BC) had a far more precise knowledge of astronomy than we give them credit for. Incised reindeer bones dating back twenty thousand years earlier still, suggest that CroMagnon man went to the trouble of tabulating the phases of the moon. It is difficult to imagine why, unless our ancestors possessed their own primitive science of 'astrobiology'—undoubtedly involved with magic and religious ritual—which later degenerated into traditional astrology.

Eysenck has said: 'At the moment the only feedback that most research workers in the field get is to be shouted down by both sides—by the astrologers for daring to have any doubts, and by the scientists for daring to look at the alleged phenomena of planetary influences on humankind at all.' But this statement in itself indicates that some of the investigations he wishes to see are already beginning to take place.

ASYLUMS: A HISTORICAL SURVEY. In England the care of the insane in special asylums dates from the eighteenth century and institutional care on a large scale came to be practised in the nineteenth century. The origins of the madhouse system are probably to be found in the practice of boarding out lunatics and idiots to private households. This custom persisted until well into the nineteenth century and was, predictably, much abused. Abuse occurred in two areas: firstly in the unjust confinement of sane persons, and secondly in the quality of care provided. Illegitimate confinements were already feared in the eighteenth century. In a *Review of the State of the English Nation* (1706), Defoe described the convenient ploy which alleged insanity provided in the case of unwanted wives or other relatives, particularly where inheritance was at stake. This fear has haunted public imagination ever since the beginnings of confinement and has provided a favourite theme in nineteenth-century literature. (For example, *Jane Eyre*, *The Woman in White*, *Melmoth the Wanderer*, and *Hard Cash* all deal with unjust or, at least, mysterious confinement.)

The second area of abuse, namely the physical conditions of the insane, was brought to public notice by the vigilant activities of nineteenth-century philanthropists.

Parliamentary reports on the condition of lunacy relied on the evidence of these men and described instances of lunatics kept for many years in chickenpens or coalsheds, and generally under conditions of extreme barbarity and neglect.

The law did not make separate reference to lunatics until 1714. This act (12 Anne, c. 23) distinguished between lunatics and 'rogues, vagabonds and sturdy beggars and vagrants'. It authorized two or more Justices of the Peace to detain a lunatic and confine him in a safe place. The cost of the detention was to be borne by the lunatic's parish of settlement. Although the Act did not require treatment to be provided, it at least exempted the lunatic from the customary whipping legally sanctioned for rogues, vagabonds, and vagrants. The Vagrant Act of 1744 (17 Geo. II, c. 5) added the cost of cure to the expenses to be defrayed by the parish.

During the time that separate legal provision was being made for lunatics, private madhouses and asylums grew up to cater for their needs. Evidence from newspaper advertisements and books written by madhouse proprietors suggests that the practice of confining the insane in private madhouses was

well established by the beginning of the eighteenth century and that it grew steadily thereafter. In 1774 an act (14 Geo. III, c. 49) was passed for the regulation of private madhouses within a sevenmile radius of London. It made obligatory the licensing and inspection of private madhouses by five commissioners to be elected from the Royal College of Physicians. However, the Act was largely ineffective. For example, it had no influence over provincial madhouses, over single lunatics, or over public subscription asylums. The commissioners could refuse to license a house to which they had been denied admission, but illtreatment and neglect were not grounds for refusal. Thus they had no powers to bring about improvements. Nevertheless, the Act marked the beginnings of state control of lunacy.

The illness of George III (1760-1820) played an important part in the development of public awareness and tolerance of insanity. George III suffered from several distinct episodes of what was thought to be insanity, and the state of his health became a

Page 53

matter of grave political consequence and a point of national discussion. (For a fuller discussion, see Macalpine and Hunter (1969), in which they claim that the king was, in fact, suffering from a rare metabolic disorder called porphyria, which is liable to cause phasic attacks of mental disorder.) What is important is that the king was thought to be insane and that the nation was much moved by his sufferings. During the latter part of his reign the lunacy reform movement got under way.

From the beginning of the nineteenth century parliamentary reports on the condition of lunacy followed one another in steady succession. The establishment of county lunatic asylums was prompted partly by moral outrage felt upon the discovery of the revolting and inhuman conditions of the insane and partly by the newly found faith in the possibility of cure. The committees submitting these reports consisted of wellmeaning people who displayed some of the best features of Victorian philanthropy, namely, scrupulous attention to detail and a compassion for the destitute. They took it upon themselves to visit all workhouses and asylums where lunatics were kept.

The committee of 1807 concluded that 'the practice of confining such lunatics and other insane persons as are chargeable to their respective parishes in gaols, houses of correction, poor houses and houses of industry is highly dangerous and inconvenient'. They therefore recommended that 'the measure which appears to your committee most adequate to enforce the proper care and management of these unfortunate persons and the most likely to conduce to their perfect cure, is the erection of asylums for their reception in the different parts of the kingdom'. The following year (1808) an act was passed recommending that each county erect an asylum for the care of the insane. The asylums were to be supported by public funds. The Act was a permissive one, since it had no powers to enforce its regulations. As a result few county asylums were built for the time being.

The following years saw the growth of 'a free market in lunatics' and private madhouses multiplied to cope with increasing demands. Although some asylums provided a high standard of care, many more kept lunatics in dreadful conditions. These were publicized by the reports of 1815 and 1828. In York Asylum, a series of tiny cells was discovered, each housing many filthy and incontinent patients. For

example, one cell measuring 12 feet by 7 feet 10 inches (3.7×2.4 m) housed thirteen incontinent women. At Bethlem the case of William Norris, who had been chained by the neck to a stone wall for nine years, was given much *publicity*. Throughout the 1815 report conditions are described as inhuman and the patients as animallike. In Bethlem Hospital this was particularly true. For example, the report says, 'the patients in this room were dreadful idiots, their nakedness and their mode of confinement gave this room the appearance of a dogkennel'. The 1828 committee looked into the conditions within metropolitan madhouses. Their findings include the earlier ingredients of darkness, overcrowding, filth, and stench. They provide a catalogue of abuses and horrors.

The idea of moral management provided theoretical support for asylumbased treatment (see INSANITY: EARLY THEORIES). It advocated the abandonment of physical restraint and an appeal to the will of the patient. It aimed to restore the dignity of the patient and to enlist him as an ally in the treatment process. Two requirements of moral management were the early detection of insanity and separation of the patient from the circumstances precipitating his attack, usually his home.

Both these requirements, together with claims of a near 100 per cent recovery rate, favoured the growth of the asylum. Moral management also contributed towards the recovery of lunatics from workhouses. The lunacy reformers deplored the indiscriminate intermingling of lunatics with other destitute persons.

By 1844 the abuses within madhouses had been made public and the need for improvement was clearly established. Despite the recommendation of the 1808 Act only twelve county asylums had been built. The 1844 report of the metropolitan commissioners in lunacy provides a landmark. One of the most influential commissioners was Lord Shaftesbury. The report was comprehensive: it included domestic details of the running of asylums, information on the nonrestraint system, a discussion of the nature of insanity, and comments on the admission of pauper lunatics from workhouses. It was based on 166 visits to public and private asylums.

One of the less wellknown themes of the report concerned the dangers of clogging up asylums with incurable patients, thereby 'converting them into a permanent refuge for the insane instead of hospitals for their relief and cure'. By the middle of the nineteenth century the paradoxical situation had arisen where asylums were not able to cure because of the large numbers of incurable patients. One major reason for the asylums' lack of success was that the problems which confronted them were not specifically medical, but had a large social component. The problems of lunacy were closely related to the problems of pauperism, as 75 per cent of the insane came under poor law authorities. The year following the report two acts were passed, one making compulsory the erection of county asylums and the other providing a more comprehensive system of asylum inspection. By 1847, 36 of the 52 counties had complied with the Act and built asylums of their own. However, within a short space of time it was found that the demand for asylum beds far exceeded supply. The size of the lunacy problem grew to fit and then exceed the provisions made for it. Interestingly, the vast increases in the lunatic population occurred among pauper and not private patients: between 1844 and 1870 the number of private patients increased by about 100 per cent whereas the number of pauper lunatics increased

by about 365 per cent. Alongside this growth in asylums the numbers of curable patients declined. Superintendents of asylums estimated that roughly 90 per cent of their patients were incurable. No matter how many new beds were provided the promised cures never materialized. When the asylum failed to fulfil its initial promise a cheaper asylum system and a return to the workhouse were advocated, precisely the state of affairs which had earlier aroused so much horror.

Lunatic asylums deteriorated from being small familybased units to becoming large, custodial institutions offering little hope to their inmates. Emphasis moved from early detection and treatment to illegal detention. The next major piece of legislation, the Lunacy Act of 1890, was concerned with protecting the individual against wrongful detention rather than with cure and treatment. Physicians of the period already recognized the bad effects of increasing size and routine on the inhabitants of the asylum: 'In a colossal refuge for the insane, a patient may be said to lose his individuality and to become a member of a machine so put together, as to move with precise regularity, and invariable routine; a triumph of skill adapted to show how such unpromising materials as crazy men and women may be drilled into order and guided by rule, but not an apparatus guided to restore their pristine selfgoverning existence. In all cases admitting of recovery, or of material amelioration, a gigantic asylum is a gigantic evil and figuratively speaking a manufactory of chronic insanity.' Despite the pessimism which came to surround the asylum, its population continued to grow. Figures show a steady increase in the asylum population (excluding the two world wars) until its peak in 1954, and thereafter a dramatic decline.

With the introduction and widespread use of the major tranquillizers from the midfifties onwards, the emphasis on community treatment, and the attacks by sociologists on the pernicious effects of institutional care, the asylum population has continued to decrease (see ASYLUMS: ARE THEY REALLY NECESSARY?).

By 1980 the total number of beds in England and Wales for the reception and treatment of patients with mental illnesses had declined to about 92,000, of which some 4,360 were in psychiatric units in general hospitals. These beds are intended for shortstay patients, and the majority of psychiatrically ill persons are still admitted and treated in the old county mental hospitals. The asylum buildings remain as a robust testimony to the Victorian faith **Table 1**. Total number of patients in public asylums in England and

ASYLUMS: ARE THEY REALLY NECESSARY? The odium surrounding our mental hospitals, or asylums—a synonym fallen into disrepute but worthy of resurrection in the light of the present situation—is best understood as a chapter in the continuing and complicated history of the care of the mentally disordered (see ASYLUMS: A HISTORICAL SURVEY).

During the nineteenth, and early part of the twentieth centuries, Britain's asylums underwent many vicissitudes. From time to time there were scandals leading to inquiries similar in many ways to those that take place all too frequently today and for the very same reasons. However, in the period between the two world wars the trend towards a more liberal approach was established, culminating in the Mental Treatment Act, 1930, the outstanding feature of which was the provision made for the admission of voluntary as opposed to certified patients. The same liberalism permeated the hospitals themselves and was reflected in the more imaginative decoration and furnishing of the wards, and an improvement in the clothing and diet of the patients. Of even greater importance was the evolution of the concept of the

'open door', thus acknowledging that the majority of mental patients are not dangerous, and that a prisonlike regime is not necessary to contain them. The spirit of enlightenment was crowned with such success that Britain easily led the world. Visitors from far and near came to see what had been achieved.

But the pendulum swung too far. An extraordinary wave of optimism flooded the psychiatric scene in the 1950s, triggered off no doubt by the introduction of the phenothiazines, claimed by some to be as specific for the treatment of the *schizophrenias as, say, insulin is in diabetes, or thyroxine in myxoedema. In a way which is difficult to understand, the mental hospitals, so recently declared Good Objects, became, almost overnight, Bad Objects. Consonant with this changed attitude, a most seductive slogan, 'community care', was conjured up; but unfortunately adequate fieldwork had not been done to make quite sure that the community in fact did care.

Nevertheless, the policy of 'discharge and be damned' prevailed, a policy which was to be given administrative blessing in the Mental Health Act, 1959. Then, stimulated by the statistical forecasts of Tooth and Brook (1961), the then Minister of

Page 55

Health, Enoch Powell, in his Hospital Plan (1962), declared that there would be a very substantial reduction in the number of beds in mental hospitals, some of which would be razed to the ground and their function divided between psychiatric units in general hospitals and 'community care'. The local authorities were to provide certain facilities, such as hostels for discharged mental hospital patients, halfway houses, sheltered workshops, home visits, and so on. Unfortunately, no date was given for when these facilities had to be made available, and it is generally accepted that with a very few

exceptions the overall response left a great deal to be desired.

The policy of discharge continued, however. In the twenty years 1960-80 there was a reduction of over 44,000 in the number of beds in British mental hospitals. This might in itself be an achievement if it could be guaranteed that the quality of life of those who might have occupied those beds was at least as good as it was when they enjoyed the 'asylum' offered by the hospitals. But is it? An examination of some of the evidence might lead one to believe that it frequently is not.

Failing adequate support in the community in general and from their families (if any) in particular, discharged patients may become vagrants and by one avenue or another return to the mental hospital. Berry and Orwin (1966) report on the steep rise in the number of patients of no fixed address admitted to their hospital in Birmingham since the Mental Health Act came into being. Their summary is worth quoting:

Their plight is evidence that the initial enthusiasm evoked by the new Act for the discharge of chronic psychotics into community care was premature in view of the resources available and has resulted in the overwhelming of existing community services.

The doss-house is, of course, another alternative focus of redistribution. Edwards, Williamson, Hawker, Hensman, and Postoyan (1968), in their study of inmates of Camberwell Reception Centre, London, showed that of a population of 279, 24 per cent had previously been in a mental hospital for reasons other than drinking, and of these 7 per cent had been out of hospital for six months or less. Other studies of 'dossers', for example Lodge Patch (1970) and Scott, Gaskell, and Morrell (1966), paint equally gloomy pictures.

But of all the loci of redistribution perhaps the most socially undesirable is the exchange of a bed in a mental hospital for a cell in a prison. Mental disorder may and does at times manifest itself in offences against the criminal law. Such offences are for the most part trivial, but they are not necessarily so by any means. Criminal statistics show that the number of cases remanded for psychiatric report rose from 6,366 in 1961 (Home Office Report) to 11,057 in 1976 (Home Office Report), nearly doubling. It is known that 16 per cent at least had been discharged from mental hospitals less than one year before their arrest. Furthermore, it is safe to say that if the period were extended to two years since discharge the number would be in the neighbourhood of 50 per cent. But of paramount importance in this context is the angry comment contained in the 1976 prison report referring to the growing difficulty in finding accommodation for mentally abnormal offenders in National Health Service psychiatric hospitals: '... mentally ill people are entering prisons and borstals in increasing numbers and people of previous good personality, whose offences frequently stem solely from their illnesses, are now being refused admission to psychiatric hospitals and are, instead, being received and detained in establishments'.

Furthermore, the same report refers to an assessment made by prison medical officers of the number of prisoners in custody who were suffering from mental disorder within the meaning of the 1959 Act. It emerged that 'the prison system was then holding some hundreds of offenders who were in need of and capable of gaining benefit from, psychiatric hospital care, management and treatment in

psychiatric hospitals'.

Moreover, the official statistics quoted give an account of mentally abnormal offenders dealt with after prosecution (Part V of the Act). But there is also a steep rise in the number admitted, or readmitted, to mental hospitals without prosecution. Of special importance in this respect is the use of Section 136 (Part IV of the Act), a method whereby the police can deal expeditiously with social crises occasioned by the mentally disordered and remove them to a place of safety, in practice almost invariably a mental hospital. For example, in the twelve mental hospitals administered until recently by the SouthWest Metropolitan Regional Hospital Board the number rose from 308 (1.9 per cent of all admissions) in 1965 to 709 (4 per cent of all admissions) in 1972, an increase of well over 100 per cent. Investigations by the writer (Rollin, 1969) indicate that no less than 66 per cent of unprosecuted mentally abnormal offenders have previously been treated in mental hospitals.

From what has been said thus far it would appear that it is those who have no homes, or whose homes are unsatisfactory, who are the ones worst affected by the inadequacies of 'community care'. But are expatients who are more fortunate in this respect necessarily better off? A leading article in the *British Medical Journal* (4

May 1974) reads:

As a corollary it might be assumed that a warm, welcoming home would offer optimum conditions for the returning expatient. 'No place like home for rehabilitation' could be another seductive slogan and mean as much or as little as its counterpart 'community care'. But even under optimum conditions the major psychoses usually persist in following their predetermined course. Schizophrenia in particular, still one of the major scourges of mankind, characteristically is a chronic disease with alternating remissions and relapses, producing in about half the cases evidence of everincreasing damage to the personality. The potential for serfsufficiency or 'rehabilitation' will vary inversely with the degree of damage and directly with the support from the family and the community. If the family burden is too great or the community support

inadequate, then not only will the patient suffer but the family may go under too.

Precisely these points have been made with telling and poignant effect in the first report of an organization—the National Schizophrenia Fellowship—which has the support of the Department of Social Psychiatry of the Institute of Psychiatry, London (*Living with Schizophrenia*, 1974). In his foreword John Pringle, the honorary director of the Fellowship, does not pull his punches. He castigates those whose duty it was 'to provide the community support, in replacement for custodial care, which many chronic sufferers [from schizophrenia], unable to fend for themselves, cannot do without'. He goes on: 'The closure of mental hospital wards, which at least provide the basic minimum shelter and life support, goes ruthlessly on, leaving nothing in their place.'

The body of the report contains a series of accounts of relatives, mainly parents, of what it is like to live with schizophrenia. The burning desire to do what is right shines through the pages, but if there is a common theme it is that there are promises and more promises of help from innumerable agencies

but in the end the relatives must go it alone. 'The effect of having George at home on our home life has been disastrous' typifies several examples of the way one schizophrenic can wreck the social life of an entire family. 'I do not think "the community" exists' is the sad reflection of a mother whose daughter has encountered 'the sneers, no job, cold shouldering, impatience and general feeling of being out of step'. 'I have found that every hospital wants to discharge my son at the first opportunity' is a wry comment on the administrative policy obtaining in so many mental hospitals today. 'There is, therefore, virtually nothing available in the way of after care, rehabilitation or training for the schizophrenic in this immediate area' is a further caustic statement requiring no further comment.

The Mental Health Act 1983, which consolidated the provisions of the 1959 Act and those of the Mental Health (Amendment) Act 1982, has focused attention even more sharply on the divide between what may be described as the psychosocial as opposed to the medical model. The principal change in the legislation has been new provisions concerning patients' rights, in particular when compulsory detention is involved. The District Health Authority and local social services are charged as a mandatory duty with provision of treatment, care, and support for patients living in the community, employing a cadre of approved social workers with appropriate competence. However, at the time of writing there are few signs that adequate community care under the new Act is likely to be more of a reality than in the past.

Isolated experiments, such as those accompanying the closure in 1986 of Digby Hospital, Exeter, may give some cause for hope for the future; but in the main the political will at local level to implement all of the requirements of the Act has been in as short supply as the necessary finance in a time of economic stringency.

It has been necessary to condense a very considerable body of evidence to substantiate the plea made by a not inconsiderable number of psychiatrists that the mental hospital—or asylum in the true meaning of the word—should be retained for the foreseeable future, or at least until satisfactory alternatives for the care of its patients are available. If we go on as we are, sacrificing the wellbeing of sick people for doctrinaire reasons, or for reasons of economic or political expediency, then we will have turned the wheel full circle and be back where we were at the beginning of the nineteenth century. There is this difference, however, that in our present industrialized, urbanized, heterogeneous society, the family may not be prepared to shoulder the burden of the psychotic in their midst, nor may the

'community' (analogous to the parish of bygone days) be prepared to shoulder the burden of adequate community services.

As a footnote it could be added that Britain is not alone in reaping the bitter harvest of policies which are both illconsidered and precipitate. In Italy, for example, laws were introduced in 1978 which, *inter alia*, forbade the admission of further new patients to mental hospitals which were themselves to be run down and eventually closed. This has led to a new class of vagrants—the *abandonati*—a host of homeless, mentally sick expatriates who roam the streets and public places. The situation in the USA, where comparable policies have been put into effect, is no better. Dr Alan A. Stone, Professor of Law and Psychiatry at Harvard, writes in 1984: 'Yet madness has not gone out of the world as was

hoped, in fact madness is more visible than ever before in this century. One can see chronic mental patients in the streets of every major city in the United States.'

ATAXIA. The lack of coordination between muscles that causes unsteadiness in body posture and movement and affects eye movement and speech. Sensory (or proprioceptive) ataxia results

Page 57

from an impaired sense of joint position (proprioception). It is aggravated when the patient shuts his eyes, as some of the proprioceptive defect is compensated for visually. Motor ataxia results from cerebellar disorders.

ATTACHMENT. It is characteristic of human beings to make strong affectional relationships with each other and for some of their strongest emotions to depend on how these relationships are faring. Whereas stable relationships are a source of enjoyment and security, separation, loss, or threatened loss arouse*anxiety or anger, or else sadness and*depression.

There is much controversy about how the urge to form such relationships, or bonds, is to be best understood. Until the mid 1950s only one explicitly formulated view of their nature and origin was prevalent, and in this there was agreement between psychoanalysts and learning theorists. Bonds between individuals develop, it was held, because a person discovers that, in order to reduce certain drives, for example for food in infancy and for sex in adult life, another human being is necessary. The theory postulated two kinds of drive, primary and secondary; it categorized food and sex as primary and 'dependency' and other personal relationships as secondary.

Studies of the ill effects on personality development of deprivation of maternal care led the writer to question the adequacy of this traditional model. Early in the 1950s Konrad Lorenz's work on imprinting, which had first appeared in 1935, became more generally known and offered an alternative approach. At least in some species of birds, he had found, strong bonds to a motherfigure develop during the early days of life without any reference to food and simply through the young being exposed to and becoming familiar with the figure in question. Arguing that the empirical data on the development of a human child's tie to his mother can be understood better in terms of a model derived from ethology, the present writer outlined a theory of attachment in a paper published in 1958. Simultaneously and independently, Harlow published the results of his first studies of infant rhesus monkeys reared on dummy mothers. A young monkey, he found, will cling to a dummy that does not feed it provided the dummy is soft and comfortable to cling to.

As a result of these findings many behavioural scientists now believe that affectional bonds are better understood in terms of what has come to be known as attachment theory. Attachment theory deals with the phenomena hitherto explained in terms of 'dependency need' or of 'object relations'; and although it incorporates much psychoanalytic thinking, it differs from traditional theorizing by adopting a number of principles derived from ethology, control theory, and cognitive psychology.

An affectional bond is conceived as being the consequence of certain preprogrammed patterns of behaviour becoming focused on another individual. Their effect is to bring the first individual close to the other and to maintain him there—hence the inclusive term 'attachment behaviour'.

While especially evident during early childhood, attachment behaviour is held to characterize human beings from the cradle to the grave. It includes crying and calling, which elicit care, following and clinging, and also strong protest should a child be left alone or with strangers. With age, the frequency and the intensity with which all these forms of behaviour are exhibited diminish steadily. Nevertheless, all of them persist as an important part of man's behavioural equipment. In adults they are especially evident when a person is distressed, ill, or afraid. The particular patterns of attachment behaviour shown by an individual turn partly on his age, sex, and circumstances, and partly on the experiences he has had with attachment figures earlier in his life.

As a way of conceptualizing proximity keeping, attachment theory, in contrast to dependency theory, emphasizes the following features†: 1. *Specificity*. Attachment behaviour is directed towards one or a few specific individuals, usually in clear order of preference.

2. *Duration*. An attachment endures, usually for a large part of the lifecycle. Although during adolescence early attachments may attenuate and become supplemented by new ones, and in some cases are replaced by them, early attachments are not easily abandoned and they commonly persist.

3. *Engagement of emotion*. Many of the most intense emotions arise during the formation, the maintenance, the disruption, and the renewal of attachment relationships. The formation of a bond is described as falling in love, maintaining a bond as loving someone, and losing a partner as grieving over someone. Similarly, threat of loss arouses anxiety, and actual loss gives rise to sorrow; while each of these situations is likely to arouse anger. The unchallenged maintenance of a bond is

experienced as a source of security and the renewal of a bond as a source of joy. Because such emotions are usually a reflection of the state of a person's affectional bonds, the psychology and psychopathology of emotion is found to be in large part the psychology and psychopathology of affectional bonds.

4. *Ontogeny*. In the great majority of human infants, attachment behaviour to a preferred figure develops during the first nine months of life. The more experience of social interaction an infant has with a person, the more likely is he to become attached to that person. For this reason, whoever is principally mothering a child becomes his principal attachment figure. Attachment behaviour remains readily activated until near the end of the third year; in healthy development it becomes gradually less readily activated thereafter.

5. *Learning*. Whereas learning to distinguish the familiar from the strange is a key process in the development of attachment, the conventional rewards and punishments used by experimental psychologists play only a small part. Indeed, an attachment can develop despite repeated punishment from the attachment figure.

6. *Organization*. Initially, attachment behaviour is mediated by responses organized on fairly simple lines. From the end of the first year, it becomes mediated by increasingly sophisticated behavioural systems organized cybernetically and incorporating representational models Page 58

of the environment and self. These systems are activated by certain conditions and terminated by others. Among activating conditions are strangeness, hunger, fatigue, and anything frightening. Terminating conditions include sight or sound of the motherfigure and, especially, happy interaction with her. When attachment behaviour is strongly aroused, termination may require touching or clinging to her and/or being cuddled by her. Conversely, when the motherfigure is present or her whereabouts well known, a child ceases to show attachment behaviour and, instead, explores his environment.

7. *Biological function*. Attachment behaviour occurs in the young of almost all species of mammal, and in a number of species it persists throughout adult life.

Although there are many differences of detail, maintenance of proximity by an immature animal to a preferred adult, almost always its mother, is the rule, which suggests that such behaviour has survival value. By far the most likely function of attachment behaviour is protection, mainly from predators.

Thus attachment behaviour is conceived as a class of behaviour distinct from feeding behaviour and sexual behaviour, and of at least equal significance in human life.

There is nothing intrinsically childish or pathological about it.

The concept of attachment differs greatly from that of dependence. For example, dependence is not specifically related to maintenance of proximity, it is not directed towards a specific individual, it does not imply an enduring bond, and it is not necessarily associated with strong feeling. No biological function is attributed to it.

Furthermore, in the concept of dependence there are value implications the exact opposite of those that the concept of attachment conveys. Whereas to refer to a person as dependent tends to be disparaging, to describe him as attached to someone can well be an expression of approval. Conversely, for a person to be detached in his personal relations is usually regarded as less than admirable. The disparaging element in the concept of dependence is held to be a fatal weakness to its clinical use.

It was remarked that when mother is present or her whereabouts are well known, and she is willing to take part in friendly interchange, a child usually ceases to show attachment behaviour and, instead, explores his environment. In such a situation mother can be regarded as providing her child with a secure base from which to explore and to which he can return, especially should he become tired or frightened. Throughout the rest of a person's life he is likely to show the same pattern of behaviour, moving away from those he loves for everincreasing distances and lengths of time, yet always maintaining contact and sooner or later returning. The base from which he operates is likely to be either his family of origin or else a new base which he has created for himself. Anyone who has no such base is roofless.

The behaviour of parents, and of anyone else in a caregiving role, is complementary to attachment behaviour. The roles of the caregiver are, first, to be available and responsive as and when wanted, and, secondly, to intervene judiciously should the child or older person who is being cared for be heading for trouble.

Evidence suggests that there is a strong causal relationship between an individual's experiences with his parents and his later capacity to make affectional bonds, and that certain common variations in that capacity, manifesting themselves in marital problems and trouble with children as well as in neurotic symptoms and personality disorders, can be attributed to certain common variations in the ways that parents perform their roles. The main variables are the extent to which a child's parents (i) provide him with a secure base, and (ii) encourage him to explore from it. Especially important is the extent to which parents recognize and respect a child's desire for a secure base and his need of it, and shape their behaviour accordingly. This entails, first, an intuitive and sympathetic understanding of a child's attachment behaviour and a willingness to meet it, and, secondly, recognition that one of the commonest sources of anger is the frustration of a child's desire for love and care, and that anxiety commonly reflects uncertainty whether parents will continue to be available. Complementary in importance to a parent's respect for a child's attachment desires is respect for his desire to explore and gradually to extend his relationships both with peers and with other adults.

ATTAR, FARIDUDDIN (abuTalib/Abu Hamid Muhammad ibnAbuBakr Ibrahim, ibnMustafa ibnSha'ban FaridalDin Attar, 'The Druggist', d. 1220/1230).

Born at Kadkan, near Nishapur, Persia, one of the major*Sufi teachers, and acknowledged by *Jalauddin* Rumi* as one of his inspirers, Attar wrote at least thirty books. The most famous is the classical *Mantiq atTair* (the Bird Discourse, or Parliament), thought by some to have influenced Chaucer in his *Parliament of Fowls*.

A major authoritative compilation is his *Tadhkirat alAwliya* (Recapitulation of the Saints), with biographies of Sufi teachers down the centuries, partially translated by A. J. Arberry. Also highly esteemed is his *PandNama* (Book of Counsel) and the *AsrarNama* (Book of Secrets). *The IlahiNama* he composed while working at his pharmacy, where he had 500 patients; and it was this work which he presented to Rumi when, as a small boy, he passed through Nishapur with his father in 1212. The *Mantiq* is an allegory of human psychological reactions to the problems encountered on the Sufi way, with each individual bird in turn displaying his hopes, fears, and inadequacies. The birds of the world have elected

Page 59

the hoopoe as their leader in the spiritual quest, and he has to deal with their reactions, in the manner of a Sufi teacher. The purpose of the journey is to seek the king of the birds, the immortal Simurgh (Persian homonym for 'thirty birds'). Ultimately the pilgrims reach the throne and find, when a curtain is drawn aside, that they are looking into a mirror: the collective (human) soul is seen to be the divine one, which differentiation conceals from ordinary consciousness.

ATTENTION. The nervous systems of living creatures are subjected to far more stimulation than can be used. On the one hand, the sense organs receive stimuli of great variety. On the other, memories, images, and ideas arise internally and must be considered from moment to moment. Yet it is a commonplace that we are consciously aware of only a limited amount of this information at any moment. The operation by which a person selects information in attention, and its study, have twice been seen as central to research on our understanding of how information is processed by humans and animals.

The first great period was around 1900, when*James,*Titchener,*Wundt, and Pillsbury all wrote of attention at length. William James, on this as on so many other topics, described the main characteristics of attention with precision. Attention was, for him, 'the taking possession by the mind, in clear and vivid form, of one of what seem simultaneously possible objects or trains of thought'. Titchener and his students, in particular, carried out an extensive experimental programme into such

topics as 'prior entry' and the conditions of binocular rivalry and fluctuations of attention. The first of these was the observation that of two simultaneous events, the one to which attention was diverted appeared to occur earlier than the other.

The fundamental property of attention was, for those workers, to make the contents of*consciousness appear clearer. It would have made little sense to them to discuss effects of attention of which the observer was not aware. Pillsbury's book *Attention*, published in 1908, contains many observations which modern work has confirmed, and is a remarkably insightful volume in many respects.

With the rise of*behaviourism, attention was relegated to the status of a mental function which could not be admitted as a suitable object for research. Indeed, for some thirty years it disappeared from indexes and reviews. The second golden age of attention research dates from the early 1950s, and received a particular impetus with the publication of *Perception and Communication* by Donald Broadbent in 1958. A major reason for the renewed interest was the need for the solution of new practical problems, such as the design of control towers and communication networks in the Second World War. A controller might receive several messages at once from different aircraft or ships, and be required to make appropriate responses to each. With an attempt to understand how humans behaved in such situations, modern work on attention began. It was aided by the invention of the tape recorder, which for the first time allowed the ready control and replicability of speech signals, while the phenomenon of stereophony provided an easy way of varying the content and amount of information in competing messages.

Broadbent's Filter theory tried to explain how the brain coped with the information overload caused by having many sense organs receiving information simultaneously.

Drawing an analogy with electronic communication theory, he proposed that there is in the brain a single central information channel whose rate of informationprocessing is rather limited. This channel could select only one sensory input channel at a time, and could switch no more than about twice a second between input channels. To accept an input was equivalent to paying attention to that source of information, and information on unattended channels could be held in a*shortterm memory for a few seconds. Broadbent called the selection mechanism 'the Filter'. While he drew on many fields of research, the most direct line of evidence was the

'split span' experiment. If three digits are read, at a rate of two per second, to the left ear of a listener, and another three to the right ear, so that the listener receives three synchronous pairs, he will recall them ear by ear, not pair by pair. Broadbent interpreted this to mean that the listener attended to one ear first and then switched to the memory trace of material in the other ear. By finding the fastest rate at which the listener could repeat the message as pairs, he believed he had measured the rate of switching of auditory attention. This concept of a singlechannel, limitedcapacity information processing system was central to much research in the next twentyfive years.

From about 1953 to 1963 'speech shadowing' was widely used by Broadbent, Neville Moray, Anne Treisman, and others. This technique had been introduced by Colin Cherry, and required a listener to repeat aloud a prose message in the presence of one or more distracting messages. It was found that

major factors which aided selective attention included separation in space of the speakers, difference in voice timbre, and the statistical structure of the messages. In a series of elegant experiments Anne Treisman greatly extended our knowledge. Certain features of a distracting message proved to be potent sources of distraction, including emotional words (such as a listener's own name), contextually probable words, and—for bilingual listeners—the presence of a translation of the message to which they were listening.

However, these experiments also showed that some material, such as emotionally important words and contextually probable words, was perceived even when in the 'rejected' message.

Page 60

This led to a series of modifications to Broadbent's Filter theory, notably by Anne Treisman, Anthony Deutsch, and Don Norman. Although differing considerably in detail, they all attempted to account for the fact that the Filter apparently did not block all information from the rejected channels, and that selection could be not only of sensory inputs, but of such features as language, class of word, colour (in the case of visual stimuli), and even classes of responses. Attention came to be seen as acting in a variety of ways, at a variety of levels, and on a variety of operations in the nervous system.

By the middle 1960s interest had grown greatly, and a wide variety of experimental techniques were developed. In addition to speech shadowing, simultaneous auditory messages were used, requiring much simpler responses than speech. In a series of studies Moray showed that, contrary to what the early shadowing experiments seemed to indicate, attention acted in the same way on nonlinguistic as on linguistic material. Robert Sorkin and his coworkers in America explored attention to nonlinguistic auditory material. Others, like Alan Allport and Peter McLeod in Britain, and Richard Shiffrin and Walter Schneider in America, found conditions where little or no interference between two messages occurred. These arose especially when messages were presented in different sensory modalities, where long practice had made performance almost automatic rather than conscious and voluntary, and when no competition between responses was required.

Visual attention was investigated by means of eye movements in such tasks as reading, by Paul Kolars, and in car driving and piloting aircraft, by John Senders. Very spectacular results were found using the 'Stroop test', in which attentional and perceptual conflict is induced by the nature of the stimulus. If the word 'red' is written in green ink, the word 'blue' in yellow ink, and so on, it is possible to read the word rapidly without the colour of the ink causing interference, but almost impossible to name the colour of the ink. Analogues of this effect provide a way of discovering which 'analysers' in the brain can be selectively biased by voluntary attention. (The word 'analyser' originated in a theory of learning and perception due to Anthony Deutsch, but its use in attention theory is largely due to Anne Treisman.) Some attempts were made to investigate the physiological mechanisms underlying attention. For example, the 'Expectancy wave', or CNV, was discovered in electroencephalographic records, a change in electrical brain activity which appears when the observer is concentrating on the imminent arrival of a signal he knows is probable. In the late 1970s

Emmanuel Donchin and his colleagues began work on the 'P300' component of the brainevoked potential, and this seems very likely to be intimately connected with attention in the sense of decisionmaking. But to date our understanding of the physiological basis of attention lags a long way behind behavioural research.

More than a dozen theories of attention have been proposed since 1958, most of them strongly influenced by communication theory and computer technology. Their variety to some extent is due to the variety of phenomena which may be subsumed under the heading 'attention'. In addition to our ability to listen selectively to one message and ignore another, or to look at a picture in one colour in the presence of other colours, one may cite *vigilance* (or watchkeeping), in which an observer looks for very rare events, such as detecting the presence of a sonar or radar target. Some studies have been made of mental concentration on cognitive problems.

The interference between internal images and incoming stimuli has been investigated, as has the ability of the brain of a sleeping person to respond selectively to the sleeper's name, even though the sleeper is not aware of the response.

Although no single theory has emerged as completely dominant, the influence of Broadbent's Filter theory remains strong, and what follows is a conflation of theories based on his suggestions. He assumed that an observer can block or weaken the strength of incoming messages to the brain, and there is ample evidence that this can happen. It is not known whether this is done by reducing the intensity of the messages or by switching them on and off rapidly. But some such blocking definitely occurs. In vision it can be done by closing the eyes or averting the gaze. In hearing the mechanism is not so clear. It seems probable that all information which impinges on the receptors of the sense organs reaches the patternanalysing mechanisms of the brain. The Filter perhaps acts to prevent the output of these analysers from reaching consciousness, although behaviour may still be produced, as when we become aware that we have driven for some time 'without being aware of it' (see TIMEGAP EXPERIENCE). It seems likely that information from different sense modalities, or from different dimensions within a modality (such as colour and shape), can be attended to simultaneously, at least after practice; while tasks which are very similar (such as judging the loudness of two tones) cannot. One should note that in making these assertions we are far from William James's definition. Very often the observer is conscious of only one message, but it can be shown that the second is producing behaviour simultaneously with that produced consciously. (See also SUBLIMINAL PERCEPTION.) A second way in which attention can operate is by biasing the interpretation of information proceeding from pattern analysis to consciousness. Thus a person expecting to see a bull in mist will see one, while a person expecting to see a rock will see a rock. This kind of bias is set by the probability of events, their subjectively perceived value, and contextual information derived from recent inputs and from memories. In earlier days this kind of bias was called 'mental set'.

The contents of consciousness as filtered by

attention are very limited: attention is frequently modelled as a 'limitedcapacity information channel'.

But with practice, quite dramatic increases in performance are seen, and some writers, among whom Daniel Kahneman is particularly influential, have proposed a 'parallel processing' model of attention, in which the main limit is on the total effort available, rather than on competition between separate analysers. Such models make extensive use of the concept of*arousal.

Recently, renewed interest in applications of attention has become apparent. Most of the laboratory research has been directed to understanding the internal mechanisms of attention in the brain. But as large and complex manmachine systems appear, and more and more automation is introduced, there is a tremendous need for a good understanding of man as a monitor of complex systems. How should the latter be designed so as to optimize the use of attention? (It is fairly clear that in reallife tasks attention is never switched more than about twice a second.) How should a man be trained so as to combine to best effect his limited conscious attention with his unconscious control of*skilled behaviour? The solution of such questions is necessary if accidents in power stations, aircraft, and industry are to be avoided. Attention theory has advanced to a point where it can give a real insight into the solution of practical problems, and there is likely to be a third age in which the precise experimental work of the 1950s to the 1970s is extended in more complex ways to solve the problems of manmachine system design in the 1980s and 1990s. We have come to see attention not merely as a single process concerned with enhancing the clarity of perception. Rather, it is a complex of skills. These include selecting one from several messages, selecting one from several interpretations of information, selecting one from several plans of action, and selecting one from several actions. But in our interactions with the rich dynamics of the world in which we live and to which we adapt, attention also models that world, and provides us with strategies and highlevel control of our tactics of information sampling, optimizing our informationprocessing in the face of our limited processing capacities.

Developments in research since Donald Broadbent's work in the 1950s have emphasized both the conceptual richness of the concept of attention, and the practical importance of an understanding of its properties. One cannot do better than conclude with an early claim of Edward Titchener's: 'The doctrine of attention is the nerve of the whole psychological system, and that as men judge of it, so shall they be judged before the general tribunal of psychology.'

ATTENTION, LAPSES OF. There are quite frequent short intervals of loss of*attention, technically called Bills' blocks after A. G. Bills. Their cause is unknown, but the explanation is possibly that brain circuits have multiple functions and so are not always available when multiple tasks are being carried out—much as fingers or tools cannot be used for more than one task at a time.

AUDIOMETER. Electronic instrument used for testing*hearing. A simple audiometer is an oscillator having about ten preset frequencies in the range 500 to 8,000

hertz, and a stepped attenuator so that tone detection thresholds can be measured in decibels. More elaborate instruments combine noise masking (for measuring recruitment, which is associated with sensory neural deafness). The most sophisticated is the*Békésy audiometer, in which the patient, or subject of an experiment, tracks a continuously changing tone, his responses being recorded with an automatic plotter. Audiometry may test for word recognition, and it may introduce more or less normal confusing sounds. It can be most useful for distinguishing various kinds of hearing impairment.

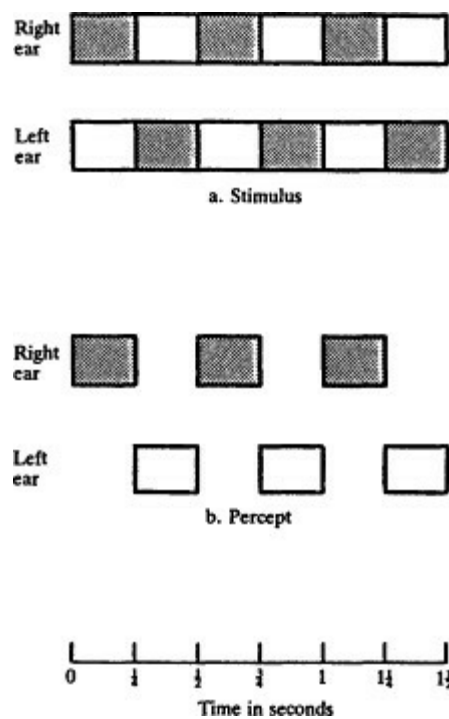

AUDITORY ILLUSIONS. Although many visual*illusions were discovered in the nineteenth century, interest in auditory illusions has developed only recently. Some of these illusions are paradoxical. Apart from their subjective interest they provide valuable information concerning the mechanisms that our auditory system (see HEARING) employs to interpret our environment.

One illusion demonstrates that separate and independent brain mechanisms exist for determining what we hear, and for determining where the sound is coming from.

The combined operation of these two mechanisms may lead to the perception of a sound that does not exist, i.e. with its characteristics taken from one source and its location from another.

The configuration that produces this illusion is shown in Fig. 1a. This consists of two tones that are spaced an octave apart and repeatedly presented in alternation. The identical sequence is presented to both ears simultaneously through earphones; however, when the right ear receives the high tone the left ear receives the low tone, and vice versa. So in fact the listener is presented with a single, continuous twotone chord, but the ear of input for each component switches repeatedly.

It can be imagined how this sequence should sound if perceived correctly. However, with very rare exceptions an illusion is always produced. The type of illusion obtained varies from listener to listener, but the most common one is shown in Fig. 1b. This consists of a single tone that switches

Page 62

Fig. 1.

a. Pattern giving rise to the first illusion. Two tones

that are spaced an octave apart are repeatedly presented in

alternation. When one ear receives the high tone the other

ear simultaneously receives the low tone. The filled

squares indicate the high tone and the unfilled squares the

low tone. b. Illusion most commonly obtained. This

consists of a high tone in one ear alternating with a low tone in

the other ear.

from ear to ear; and as it switches its pitch simultaneously shifts back and forth from high to low. That is, the listener hears a single high tone in one ear alternating with a single low tone in the other ear.

There is no simple way to explain this illusion. We can explain the perception of alternating pitches by assuming that the listener processes the input to one ear and ignores the other. But then both of the alternating pitches should appear localized in the same ear. Alternatively, we can explain the alternation of a single tone from ear to ear by supposing that the listener suppresses the input to each ear in turn. But then the pitch of this tone should not change with a change in its apparent location.

The illusion of a single tone that alternates simultaneously both in pitch and in localization is

paradoxical.

The illusion is even more surprising when we consider what happens when the listener's earphones are placed in reverse position. Now, most people hear exactly the same thing: that is, the tone that appeared to be in the right ear still appears to be in the right ear, and the tone that appeared to be in the left ear still appears to be in the left ear. So it seems to the listener that the earphone which had been producing the high tone is now producing the low tone, and that the earphone which had been producing the low tone is now producing the high tone!

Experiments have shown that this illusion is based on the operation of two independent mechanisms; one for determining what pitch we hear, and the other for determining where the sound is coming from. To provide the perceived sequence of pitches, those arriving at one ear are heard, and those arriving at the other ear are suppressed. However, each tone is localized in the ear receiving the higher pitch, regardless of whether the higher or the lower is in fact heard. So, given a listener who hears the pitches presented to his right ear when a high tone is delivered to the right ear and a low tone to the left, this listener hears a high tone since this is the tone delivered to his right ear. Further, he localizes the tone in his right ear, since this ear is receiving the higher pitch. But when a high tone is delivered to the left ear and a low tone to the right, this listener now hears a low tone since this is the tone delivered to his right ear; but he localizes the tone in his left ear, since this ear is receiving the higher pitch. So the entire sequence is heard as a high tone to the right alternating with a low tone to the left. Reversing the position of the earphones would not alter this basic percept (though the identities of the first and last tones in the sequence would reverse); but given a listener who hears the pitches delivered to his left ear instead, keeping the localization rule constant, the same sequence would be perceived as a high tone to the left alternating with a low tone to the right.

Another auditory illusion demonstrates the importance of unconscious inference in auditory perception. This illusion also involves presenting two different tonal sequences through earphones. The configuration consists of a musical scale, presented simultaneously in ascending and descending form. When a tone from the ascending scale is delivered to the left ear, a tone from the descending scale is delivered to the right ear; and successive tones in each scale alternate from ear to ear.

This sequence is repetitively presented without pause.

This configuration also produces various illusory percepts, which fall into two main categories. Most listeners perceive the correct set of pitches, but as two melodic lines, one corresponding to the higher tones and the other to the lower tones. Further, the higher tones all appear to be emanating from one earphone and the lower tones from the other. When the earphone positions are reversed there is often no change in what is perceived. So it appears to the listener that the earphone that had been producing the higher tones is now producing the lower tones, and that the earphone that had been producing the lower tones is now producing the higher tones!

Other listeners perceive only a single melodic line, which corresponds to the higher

tones, and they hear little or nothing of the lower tones.

How can we account for the first type of illusory percept? It must have a different basis from the illusion described earlier, since here all the tones are perceived; they are simply localized incorrectly. There are strong cognitive reasons for expecting such an illusion. In everyday life similar sounds are likely to emanate from the same source, and different sounds from different sources. Our present sequence consists of tones drawn from closely overlapping pitch ranges which are continuously emanating from two specific locations in space. So the best interpretation of this sequence in terms of the real world is that an object which emits sounds in one pitch range is located in one place, and that another object which emits sounds in a different pitch range is located in another place. This inference is here so strong as to override our actual localization cues, so that we perceive the sequence in accordance with this interpretation.

AUTHORITY. See OBEDIENCE.

AUTISM is a very rare condition that was first named by Leo Kanner, an American psychiatrist, in 1943. It occurs in perhaps four out of 10,000 live births (for comparison, severe subnormality occurs about four times out of every 1,000 births); and the diagnosis is made four times more frequently among boys than among girls. The word means selfconcerned, or independent, and the social withdrawal which is commonly associated with the condition resembles*schizophrenic withdrawal in adults. Despite its rarity and sexselective quality, the condition may arise from several disorders masquerading as one. Although far more autistic children are of below normal*intelligence than would be expected if it occurred equally often at all levels of intelligence, none the less a small number of highly intelligent autistic people have been observed.

The autistic child characteristically appears to go through his or her early development normally, but a break in development occurs usually before two and a half years of age. At this stage, the development of speech may stop and social response does not develop. Bizarre behaviour may show itself, and stereotyped selfoccupying movements may become more obvious. This characteristic pattern of arrest of growth generally results in a relatively poor intellectual development; more than twothirds of autistic children have an IQ within the subnormal range (see SUBNORMALITY). Sometimes social response never develops at all, and a mother may notice that her infant does not cuddle normally from the beginning.

In later years some of the more marked disturbances of behaviour may become less marked and less bizarre. In this phase the children may become more like the mentally subnormal children whom they may match in intelligence. However, their speech may continue to be even more markedly

handicapped.

In the past, certain investigators suggested that autism might have psychological origins, and parents classified as schizophrenogenic because of their supposed emotional coldness were caused unnecessary pain, through fear that they might have been responsible for the handicap of their autistic child. Such psychogenic hypotheses no longer win informed support, and psychiatrists now more frequently identify physical disorders as precipitating autism. As J. K. Wing (1966) pointed out, early onset with signs of brain damage, screaming, and feeding difficulties, the high male:female ratio, histories of complications of pregnancy or at delivery, and the nature of speech and perceptual difficulties, all point to an abnormality of the central nervous system.

The nature of this abnormality is undetermined, but one investigator, G. R. De Long (1978), has suggested a bilateral hippocampal lesion; and J. G. Small (1975), reviewing recent papers on electroencephalography (EEG) and reports of studies of evoked potential in autistic children, states that there is a high incidence of abnormal EEGs and that the evoked potential studies showed the children to be less than normally responsive to stimuli. She pointed out that the high incidence of lowered intelligence may be indicative of central nervous damage. It has been suggested also that abnormalities in the limbic system and vestibular nuclei might be the basis for some elements of autistic behaviour. Tests of vestibular function and EEG sleep studies give some support for these theories and so favour an organic rather than a predominantly psychological cause of childhood autism.

While De Long pointed to the probability of a bilateral hippocampal lesion in these children, P. T. White *et al.* (1964) first noted the relatively high incidence of epilepsy in adolescence. S. Folstein and M. Rutter (1977) also noted epilepsy in association with autism, but added their own observations on the genetics of autism. They reported complex findings that indicated a genetic contribution but also showed the importance of environmental factors, by which they meant the occurrence of brain injury, in a majority of cases. De Long has made some detailed studies of the effect of cortical lesions on cognitive development in children and has found considerable hippocampal deficits, especially when language deficits and certain autistic features of behaviour are present. Some evidence has suggested cortical atrophy, especially of the left temporal lobe. However, any serious and longterm reduction of language ability in children must involve bilateral damage to speech areas, because otherwise the

Page 64

undamaged hemisphere of the brain would probably take over the speech function—compensation which could occur in the developing nervous system at any time before ten years of age, that is before neurological development presumably becomes complete.

This conclusion, however, is uncertain, because it has been claimed that left unilateral hippocampal lesions even in adults may result in peculiarities of language and social behaviour without affecting visuomotor learning.

One point concerning autistic features of behaviour that has not received as much attention as it probably deserves is the occurrence in children of nearly normal or even superior intelligence of a type of social behaviour closely resembling autism. M. Bartak and L. Rutter (1976) reported a clinical study comparing subnormal and normal groups aged eight and a half years, both of whom had difficulty in social relationships and showed little eye contact. Both groups withdrew from adults and did not make friends with other children. They did not adapt easily to new situations and seemed obsessive in their behaviour, being strongly attached to favoured objects.

Both groups showed stereotyped hand movements and facial grimaces. The significance of this report is the large IQ difference between the groups, suggesting that we may be dealing with two different causes of autism, or perhaps the same cause in mild and severe forms. Bartak and Rutter do not discuss their findings in relation to Asperger's finding of autistic children with high IQs, but presumably they have identified a group of children of a similar kind (Asperger, 1944, Wing, 1981).

L. Wing and J. Gould (1979) on the other hand, in a very thorough population study, produce evidence in favour of an association between low intelligence and autistic symptoms, finding increasing percentages of children showing autistic behaviour towards the bottom end of the intelligence scale. Their results do not contradict those of Bartak and Rutter, but they do suggest a common cause for social and cognitive deficits. This common cause, if it exists, must, however, be differential in its effects because it seems from clinical observation that Down's syndrome (mongol) children, although often of very low intelligence, are frequently sociable and certainly not withdrawn, although like autistic children they often have a severe language handicap.

Wing and Gould have made an interesting contribution to the study of autism by suggesting a classification or subgrouping of social as distinct from cognitive impairment. They find that many children other than those classified as autistic have social disabilities, although they regard these latter as associated with cognitive disabilities and low intelligence. The essence of their social classification is in terms of severity—from severe aloofness to social passiveness to oddity (mild)—and of course not all subnormal children are socially inept, although 'associated language and behavioural problems accounted for more than half of all children in the study with intelligence quotients below 50'.

Autistic children might be regarded as having especially severe social handicaps if some recent work of P. Hobson (1981) is confirmed. In this work autistic children matched with subnormals for their capacity to solve objective cognitive tasks proved much inferior to nonautistic subnormals in their capacity to classify representations of emotional displays, or even to classify the displays by the sex of the actor presented in them.

Study of this problem of social incompetence, and its relationships with (or independence of) intelligence, has gone through three historical phases. Leo Kanner first noticed the social withdrawal of certain children and called them autistic. Several authors—B. Hermelin and N. O'Connor (1970), V. Lotter (1974), and M. Rutter—

noted the cognitive deficit associated with autism and interpreted autism in terms of this deficit. More

recently attention has turned again to the social incompetence of autistic children, as distinct from their purely cognitive deficits. Whether, finally, this social incompetence will be shown to be independent of cognitive deficit or strongly associated with it remains to be seen. Recent research suggests that social withdrawal and social incompetence can occur in both more and less severe forms and may to some degree be independent of the intelligence level of the people in whom they are found.

The presence of a disability such as autism in a child inevitably presents society, but more especially the parents, with a very demanding problem. In the United Kingdom provision exists for the special education of autistic children, and the National Society for Autistic Children will inform members of schools available within their area.

Fewer educational than diagnostic studies have been carried out, because the educability of autistic children presented an initially daunting problem. Some technical approaches involving*behaviour therapy have been tried, such as those of O. I. Lovaas, B. Schaeffer, and J. Q. Simmons (1965) in the United States, but in a number of such studies diagnosis has been in doubt, and the method employed, sometimes using electric shock, would be thought highly undesirable in the UK. Bartak and Rutter investigated three schools in or near London, where each school was using a somewhat different educational approach. Rutter (1979) summarized the results of comparing Unit A (psychotherapeutic), Unit B (permissive), and Unit C (organized and structured), as he called the three approaches, as follows: The followup findings showed that whether assessed in terms of educational attainment, ontask behaviour in the classroom or cooperative play with others, the autistic children at C had made most progress and those at Unit A the least. However, there were no differences between the units in terms of the children's behaviour at home, and although the children at C tended to have made more

Page 65

progress in language than those at the other two units, the difference fell short of significance.

In all three units the level of intelligence considerably affected progress made. While children profited educationally from a structured environment, they learned without generalization or understanding, that is, mechanically. Studies of homebased education have also been made, and although the results are uncertain, the effect of intelligence on learning progress is again seen as highly relevant.

To summarize, our present knowledge concerning autism is scanty. It is a rare condition that occurs mainly in boys and shows itself before the age of two and a half. It is marked mainly by social withdrawal and poor speech development, together with stereotyped behavior patterns. It is associated with low intelligence, although exceptions occur, and may be associated with brain damage, which is most likely bilateral; there is also likely to be a genetic component. Such children, if they are of low intelligence, are unlikely to attend a normal school except as special pupils, but proper training can improve their social behavior and elementary scholastic knowledge. The best educational approach is probably that of sympathetic but formal instruction.

AUTOMATION. The development and use of machines to replace human labour, wholly or in part, has ancient origins. Water and windmills for grinding corn and other uses are long-established examples, and early in the Industrial Revolution many machines, such as Arkwright's water frame, Crompton's mule, Hargreaves's spinning jenny, and Kay's flying shuttle loom, were introduced into the manufacture of textiles. Printing with movable type started just before 1450 and was probably the most important single invention that might at least loosely be labelled 'automation'.

Automation in this broad sense has immensely increased the wealth of societies and individuals, and has freed people from the bondage of repetitive work, allowing time for recreation. However, the use of automation in manufacturing led to large industrial units, and these tended to be grouped together to form urban areas. They created a regimented working environment, with the discipline of time being enforced by shift work. The gains and losses from the immense effects of automation are incalculable.

Psychologically there is always resentment at jobs or skills being taken over by machines, and there are harrowing stories of strong men dying while trying to compete with steam saws, for example. In our own time automation by computers is producing some decentralization of work with, in some cases, a relaxation of timekeeping and the opportunity of working at home which, as before the Industrial Revolution, greatly helps women. On the other hand, highly skilled and responsible jobs like those of air traffic controllers and radar operators cannot easily be automated, even when this is technically possible, because the controllers and operators lose both prestige—affecting their morale—and their skills, so that they may be unable to cope in an emergency. As automatic machines become more sophisticated, it may be that prestige will be attached to those who mind the machines.

R. L. G.

AUTOMATISM may be defined as a state in which the individual performs simple or complex actions in a skilled or relatively uncoordinated manner without having full awareness of what he is doing.

Page 66

Such a definition excludes purely reflex motor responses but includes well-developed skills, such as playing a musical instrument, where the individual carries out highly complex movements without detailed awareness of what he is doing. This kind of normal automatism increases with practice and the more expert the performer is, the greater will be the degree of automatism displayed.

Automatism is also associated with psychopathological conditions such as sleepwalking (see SOMNAMBULISM) and posthypnotic states, when the subject may respond to signals in a manner suggested to him during the hypnotic trance (see HYPNOSIS). Of greater importance are postepileptic automatisms. The term was introduced by Hughlings*Jackson to describe 'all kinds of doings after epileptic fits'. These are most often witnessed following psychomotor seizures and may take the form of continuing an action being performed before the onset of the fit, or of new behaviour, simple or complex, which may, although very rarely, be of such violence that serious harm is done to bystanders or anyone going to the patient's help. In cases where homicide has been the outcome of a postepileptic automatism, a plea of noninsane automatism may be accepted in place of insane automatism (a circumstance when an individual, suffering from a disease of the mind, does not know the nature and quality of the act of which he is accused). With a plea of insane automatism, the accused is likely to be found not guilty on the ground of insanity, and sent to a special hospital. (See DIMINISHED RESPONSIBILITY for a discussion of the McNaghten Rules.) Sane automatism might be adduced in persons committing offences following an epileptic fit or during a postconcussional state. It would have to be shown that the defendant was not suffering from mental illness—disease of the mind in legal parlance.

But in a recent case the accused, an epileptic, attacked an individual who came to his help when he was recovering from a seizure. He inflicted injuries sufficiently severe to warrant a charge of causing grievous bodily harm. A plea of not guilty on the basis of his automatism was offered, but the judge directed the jury to the effect that on the evidence given a verdict of not guilty on the ground of insanity would be appropriate. In this instance the judge considered that psychomotor epilepsy had to be classed as a disease of the mind. Although his ruling was challenged it was upheld by the higher Court of Appeal. The case was further considered by the House of Lords (*R. v. Sullivan*, [1983] 3WLR 123), which concluded that a person who committed an offence while in a state of postictal confusion, so that he did not know what he was doing and had no recollection of the event on recovering, was insane at law. This seems to rule out pleas of sane automatism in the future but one might surmise that more will be heard of this decision as it hardly makes sense to insist that a brief disorder of brain function as in epilepsy, is equivalent to a 'disease of the mind' in the McNaghten sense of the words.

F. A. W.

AUTONOMIC NERVOUS SYSTEM. Also known as the involuntary nervous system, it involves the smooth (rather than the striated) muscles, and is essentially the regulatory mechanisms of digestion, respiration, circulation of the blood, and so on (see NERVOUS SYSTEM). These processes are not normally under voluntary control, though they may be brought under control by*conditioning or by*biofeedback. The fact that much behaviour is involuntary and unconscious raises such questions as: why is some behaviour *voluntary*, and under conscious control? It seems that high rates of informationprocessing in unusual situations require consciousness, and are voluntary. The recent appreciation that many involuntary processes (such as heartrate) can be brought under voluntary control is strengthening the claims and widening the range of*psychosomatic medical practice.

AUTOSCOPY. See DOPPELGÄNGER.

AVERSION THERAPY. Applying, or showing, situations or objects which frighten, or disturb, with gradually increasing nearness, or frequency of presentation, as a way of alleviating*phobias by gradually increasing familiarity with the frightening object or situation. See also BEHAVIOUR THERAPY.

AVICENNA (Abu Àli alHussein ibnÀbdallah ibnSina) (9801037). *Islamic philosopher and eminent physician, born at Afshana, near Bukhara, called by the Arabs *AlSheikh alRais*, 'Chief and Leader (of thinkers)'. His *Canon of Medicine* was the standard work, in Europe as in the East, until the seventeenth century. He was a royal physician at the age of 17.

Avicenna's philosophy exercised, through twelfthcentury translations, a considerable influence upon Western thinkers, his major work being the eighteenvolume *Book of Recovery*, written in eighteen months. He follows*AlFarabi in ideas, though his work is regarded by scholars as more lucid, dealing with the distinction between necessary and possible being. Among the terms and concepts that he bequeathed to human thought is *intentio (màqulat)*, the intellectually intelligible. His theme is that the entire universe is constituted of*essences: all existing things have specific essences. 'A horse', he says, 'is a horse.' He holds that all the senses are secondary, being divisions of an inner sense, which is common to all. All reality as we know it derives from one ultimate, unitary reality: God—but not directly. There are agencies which, in a series of actions, cause the apparent differences between phenomena.

AXIOM. When, in any intellectual discipline, a theory is proposed, there will be some propositions that are regarded as fundamental, or first, principles of the theory.

This is in contrast to other propositions which, although part of the theory, are consequences of, or follow from, these fundamental principles. According to*Aristotle, first principles will take the form of either definitions, postulates, or axioms. The Aristotelian definition of an *axiom* is that it is a principle common to all sciences, which is selfevidently true (and thus knowable*a priori) but incapable of proof. Thus we have as one of*Euclid's axioms, or Common Notions, 'The whole is greater than the part.' A *postulate* on the other hand is a principle specific to a given science which is assumed without proof and whose truth may not be selfevident. Thus we have Euclid's postulate that 'if a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which the angles are less than the two right angles'. In modern deductive formalizations of theories this distinction between axioms and postulates is retained, but in a slightly modified form as a distinction between logical and

nonlogical axioms. The nonlogical axioms contain terms specific to the science in question. Where these terms are not explicitly defined, the set of axioms adopted is sometimes regarded as providing an implicit definition of the terms involved. Sets of axioms are also used, particularly in mathematics, as ways of characterizing, and hence providing a definition of, a kind of structure. Thus a group is defined as any structure of which a particular set of axioms, the .group axioms, are true. (See also GEOMETRY and DEDUCTION.) M. E. T.

AXON. A nerve fibre that transmits signals, sometimes over distances of a metre or more. The signals are action potentials from sense organs (*afferent fibres) to muscle (*efferent fibres). Axons transmit with a wide range of velocities up to about the speed of sound, the largest diameter fibres having the fastest conduction rate.

Myelinated axons transmit fastest. The myelin sheathing, formed of the myelinproducing Schwann cells, serves not only to increase the conduction rate but also to isolate fibres from each other. This is important where axons run in bundles, which in the extreme case of the optic nerve contain as many as a million nerve fibres. See NERVOUS SYSTEM; NEUROTRANSMITTERS AND NEUROMODULATORS.

B

BABBAGE, CHARLES (17921871). British mathematician and inventor, born in a wealthy West of England banking family and educated at Trinity and Peterhouse colleges, Cambridge. Babbage became Lucasian Professor of Mathematics at Cambridge (182339). He was not, however, a traditional academic: he was a gentleman of private means and he spent a large proportion of his own money, and funds he received from the government of the Duke of Wellington, developing and building the first programmable computing machine. In the 1830s he conceived the essentials of modern computers, realized by mechanical means. His Difference Engine was designed to compute tables, with its own printsetting to avoid human error. In his efforts to get it built, Babbage became a pioneer in developing both modern methods of machine drawing and the precision mass production of components. Much of the Difference Engine is preserved in the Science Museum in London, but it was never completed, as he conceived a far more ambitious project: the Analytical Engine. This was to have contained the essentials of the modern programmable digital computer, though it would, by comparison, have been extremely slow. It also was never completed.

We owe much of our understanding of Babbage's ideas to the account given by Ads, Lady Lovelace, who was Byron's daughter and Babbage's close friend and collaborator over many years. She was a mathematician in her own right. How much she contributed to the design of the calculating engines is uncertain but she was undoubtedly the first to understand the concepts they represented. As Babbage recognized, these concepts depended in part on earlier ideas, including binary arithmetic, of George Boole.

Babbage also invented the ophthalmoscope (anticipating*Helmholtz by two years), and the railway

cowcatcher! He was also a pioneer in actuarial calculations. He ended his life a disappointed man; but the technology of his time was not quite adequate for his ideas to be fully realized in practice. His autobiography, *Passages from the Life of a Philosopher*, appeared in 1864 and was reprinted in 1969.

Hyman, A. (1982). *Charles Babbage*, Oxford.

BABBLING. The utterance or hearing of incoherent speech sounds. It is thought that the Greeks heard all other languages as 'babble', giving the word an onomatopoeic origin. Indeed unfamiliar languages do sound formless, with no clear demarcation between words. In a familiar language, word units are identified not by breaks in speech but from the continuous 'babble' of speech, much as separate objects are seen from the mosaic pattern of stimulation of the eyes.

It is believed that babies produce all the speech sounds of any language in their babbling, and that speech sounds or phonemes of the language of their environment are gradually selected, according to use (see LANGUAGE DEVELOPMENT IN CHILDREN).

BABINSKI REFLEX. The involuntary raising of the big toe upon stroking the side of the foot. The reflex is present in adult apes and in human infants, but disappears in humans at about eighteen months, when it is inhibited by higher centres. The inhibition is lost in tabes dorsalis (the degeneration of the posterior ascending fibres of the spinal cord that occurs in tertiary syphilis) and in other diseases of the brain and spinal cord. It is believed that the reflex is useful for grasping the branches of trees with the toes, and that the inhibitory mechanism was developed late in primate evolution, when apes forsook the trees to walk on the ground. It is a useful diagnostic reflex, and was discovered by the French neurologist Joseph Babinski (1857-1932).

BACON, FRANCIS (1561-1626). British statesman and philosopher, born at York House in the Strand, London, the younger son of Sir Nicholas Bacon (1509-79), who was Queen Elizabeth's Keeper of the Great Seal—which office Francis later held. He became Baron Verulam, Viscount St Albans, a mark of his highly distinguished legal career culminating in his appointment as Lord High Chancellor in 1618. His public career ended sadly in 1621 when he was convicted on charges of bribery, charges that were probably unfair, given the contemporary professional morality.

Bacon is distinguished for setting out what was to be considered the technique and philosophy of modern science. He developed, from Aristotelian beginnings, inductive principles for amassing and interpreting data—especially for establishing causes. Whereas Aristotle saw causes as the essence of things, to be discovered by descriptive analysis, Bacon stressed the importance of enumerating instances where characteristics and events occur, or do not occur, in association. By setting out methods of induction, which included looking for exceptions and refutations of hypotheses, he separated science from philosophy. He saw his inductive methods as instruments for

generating knowledge. The Royal Society was founded in London in 1660, essentially on the basis of

Bacon's *The Advancement of Learning* (1605) and *Novum Organum* (1620). In his *Essays*, written throughout his life, Bacon appears as a highly literate and wise man. He was thus a philosopher in the fullest sense of the word, as well as having the vision to set out principles that greatly influenced the development of modern science.

The standard edition of Bacon's *Works* is edited by Spedding, J., Ellis, R. L., and Heath, D. D. (1857). London. Quinton, A. (1980). *Francis Bacon*. Oxford.

BAIN, ALEXANDER (18181903). British psychologist, born in Aberdeen, where he spent most of his life. His books *The Senses and the Intellect* (1855) and *The Emotions and the Will* (1859) remained, with revisions, standard texts of psychology for half a century. They are still useful reference sources for their historical comments, and their structure remains as the skeleton of modern textbooks of psychology. Bain linked psychology with physiology; paid attention to reflexes; and discussed instinct and belief. Most important, he developed sophisticated views on the still difficult questions of voluntary action, or the will. His discussions of this topic are still worth reading.

BAJJAHA, IBN (110638), Islamic thinker, poet

and musician, scientist and mathematician. See IBN BAJJAHA.

BALINT, MICHAEL, British psychoanalyst. See FREUDIANISM: LATER DEVELOPMENTS.

BÁRÁNY, ROBERT (18761936). Austrian physiologist, educated at the University of Vienna. He was appointed lecturer in otology at Vienna in 1905, and, after being captured by the Russians during the First World War, he moved to Sweden, where he ran the department of otology at Uppsala. His most valuable work was in unravelling the functions of the labyrinth of the ear (see HEARING), and in designing tests, still widely used, to check labyrinthine function. He was awarded a Nobel prize in 1914 for this work.

BARTLETT, SIR FREDERIC CHARLES (18861969). Born at StowontheWold, Gloucestershire, where his father owned a small boot and shoe business.

He read for an external London University degree, through the University Correspondence College, and took logic as one of his subjects. His success led to an appointment as tutor in philosophical subjects for the College, whose headquarters were at Cambridge. There he became an undergraduate at St John's College, and gained a First in the moral sciences tripos examinations.

At Cambridge he met the philosopher James*Ward, whose article on 'Psychology' in the *Encyclopaedia Britannica* (1886) had great influence on British psychologists and influenced him in turn. He also met C. S.*Myers and W. H. R.*Rivers. In his own account of the development of psychology in Cambridge from 1887 to 1937 (Bartlett, 1937) he gives a most interesting account of these three men and of their influence on him and on psychology in Cambridge. Ward, who foresaw the future psychology could and ought to have, did his best to advance it. Myers had a major influence in the establishment of experimental psychology in Cambridge, and Rivers brought to the university an outstanding and unique combination of sensory physiology and social anthropology, and later of

social psychology.

At first Bartlett had wanted to work on social anthropology with Rivers, but joined with him, Ward, and Myers, who had been able to establish a laboratory for experimental psychology at 16 Mill Lane, Cambridge, under Myers's direction. Cyril*Burt assisted Myers with the laboratory work at first, and, when Burt left, Bartlett took his place. Rivers, who had done extensive pioneering work on sensory measurements in the course of his anthropological studies, considered that experience with psychophysical methods would be an advantage to Bartlett if he ever did social anthropology in the field. In due course the development of the Cambridge University psychological laboratory became Bartlett's lifework. The University chair of experimental psychology was established in 1931 and Bartlett became its first occupant.

The inspiration given by Ward, who developed a psychology altogether opposed to the atomistic associationist psychologies such as that of Herbert*Spencer, must have strengthened Bartlett's discontent with associationist theories of sensation,*perception, learning, memory, and thinking prevalent in experimental psychology at the time. He also chimed in with William*James and the Würzburg school in their different ways. His discontent with the orthodoxy of the day no doubt led towards his extensive empirical research on perceiving,*imaging, recognition, and recall (see REMEMBERING), using definite (and sometimes not so definite) picture material, and also stories derived from folk tales instead of the usual and supposedly meaningless nonsense material (see EBBINGHAUS, HERMANN). The outcome of many years of research was published in his celebrated book *Remembering* (1932). In this he shows that perceiving, recognition, imaging, and recall are to be understood as the expression of active or dynamic processes dealing with the current situation of the organism and its current needs, always based on and related to its past experiences. To avoid the somewhat overmechanical notion of 'memory traces', he used the concept of flexible '*schemas' which had been used by Henry*Head in connection with earlier work on*aphasia. Bartlett also used the expression 'effort after meaning' to good purpose in his studies of perceiv

Page 70

ing and the other psychological functions mentioned above.

The influence of Myers, apart from experimental psychology itself, is to be seen in Bartlett's keen interest in applied and industrial psychology throughout his life. This was apparent in his studies during the First World War, when submarine warfare was of paramount significance, of the problems of perceiving changes in underwater sounds which might indicate the presence of an enemy submarine approaching a ship.

During the 1920s and 1930s Bartlett continued to work on social psychology. His book *Psychology and Primitive Culture* (1923) was an interesting and original work. This and *The Study of Society* (1939), which was compiled during meetings of an informal group of which he was the mainspring and leader, never gained the attention they deserved. Bartlett once told a student that he always enjoyed committee, faculty, and senate meetings because of the fascinating opportunities they gave for the study of leadership, social and personal interactions, and the processes of group decision.

Two important factors then appear to have combined to bring about a change. One of these was the coming of the Second World War, with its tremendous demand for a better understanding of aircraft design and control, and the many problems of the flying personnel themselves and their training, and here Bartlett's interest in applied psychology came to the fore again. The other factor was the coming to Cambridge of Kenneth* Craik, Bartlett's most outstanding pupil, who combined an exceptional gift for theoretical work—seen, for instance, in his concept of the human operator viewed as a link in a control system, clearly relevant to the problems of aircraft control—with an equally astonishing skill in experimentation and the design and use of apparatus and equipment. He and Bartlett fused their powers in a way that made the applied psychology of wartime problems such as they dealt with a major force for success. Craik's sudden death, two days before the end of the war, must have been as severe a blow to Bartlett as Rivers's death had been more than twenty years before.

Myers had gone to London in 1922 to establish the National Institute of Industrial Psychology there. Bartlett then became the leading figure in psychology in Cambridge, a position which he filled at least until his retirement from the University chair of experimental psychology and the directorship of its psychological laboratory thirty years later.

In 1944 the Medical Research Council had established an applied psychology unit in Cambridge under Craik's direction, and Bartlett continued his association with it after his retirement. In later years he extended his earlier work on perceiving and remembering to the psychology of thinking, with the production of a book (Bartlett, 1958) in which he showed that the thinker, whether by interpolation or by extrapolation, deals with a present problem in terms of his past experience, and by a flexible activity brings about the completion of an openended situation. So thinking is a kind of skill, comparable with the skills seen, for instance, in ball games (which had always interested Bartlett); and it was thus brought into line with perceiving and remembering, which can also be regarded as kinds of skill.

Bartlett had very exceptional intellectual powers, sharpened and expanded by logic and philosophy. He could see to the heart of any problem and realize the many ramifications it might have. He could understand and express other people's ideas clearly alongside his own, and weigh their relative merits with illuminating impartiality, sometimes gravely but always with an engaging smile. Students felt that he treated them as equals, much to their astonishment, just as he tells us Rivers treated him.

With Ward, Rivers, and Myers at his back, Mary Smith, an animal psychologist, as his wife, and Craik as his lieutenant, it is not surprising that he occupied the major position in British psychology for some forty years. He received numerous honours, including a knighthood and in 1922 fellowship of the Royal Society.

BASAL GANGLIA. Large masses of grey matter embedded deep in the white matter of the cerebral hemispheres and the midbrain (see NERVOUS SYSTEM).

The basal ganglia have very complicated connections with the central nervous system and are concerned with the control of movement. Degeneration of the basal ganglia can disturb the motor function of the body, as occurs, for example, in *Parkinsonism and *Huntington's chorea.

BEDLAM. A term used initially to describe a lunatic *asylum or madhouse, but now used figuratively to describe a general state of uproar. The word is derived from the Hospital of St Mary of Bethlehem (later the Bethlem Royal Hospital), which was founded in London in 1247 as a priory and which became a hospital specifically for the mentally ill in 1402. In the eighteenth century, the public, as an entertainment, could view the inmates, and the use of the word bedlam (from Bethlehem) arose at this time.

Page 71

BEHAVIOUR GENETICS. See GENETICS OF BEHAVIOUR.

BEHAVIOURISM. The central tenet of behaviourism is that thoughts, feelings, and intentions, mental processes all, do not determine what we do. Our behaviour is the product of our conditioning. We are biological machines and do not consciously act; rather we *react* to stimuli.

In 1913, John B. *Watson argued that human psychology could do without the concept of *consciousness and the technique of *introspection. Instead, people could be studied objectively, as are cats, monkeys, and rats, by observing their behaviour. Watson claimed that research on consciousness had led nowhere because investigators who contemplated consciousness could never really agree about what was going on 'in the mind'. Behaviour was public. Two scientists could time how long it takes a rat to get to the end of a maze or how much of an evening John spends dancing with Jane. This approach came as a shock because, in its early days, psychology was linked closely to philosophy. The assertion that human beings were observable like animals jolted many pioneers who assumed that humankind was a cut above the rest of nature. Watson, furthermore, did not want behaviourism to be just an academic theory. Its goal ought to be 'the control and prediction of

behaviour'. If you could predict behaviour, it would show psychology was a science, just like physics; and if you could control behaviour, you could improve life.

The history of behaviourism has had its ironies. Though Watson was forced out of psychology because of a divorce scandal and temporarily reduced to selling rubber boots, behaviourism came to dominate Anglo-American psychology from the early 1920s to the mid 1950s. Moreover, though it came under increasing attack for neglecting not just consciousness but feelings, it has shaped much of psychology this century. We are all behaviourists now, it could be said. Even a psychoanalyst, Anna*Freud, explained in a late interview that it was well worth observing how children used toys, responded to tests, or ate meals. 'The analyst as behaviourist', she pointed out, 'can use pieces of behaviour to infer for example how a child deals with anxiety or frustration.' It is a mark of the success of behaviourism that even those who were radically opposed to it conceded that psychology has to involve studying actual behaviour. Watson and his followers were remarkable in claiming that psychology should study nothing else. Watson himself, however, did not quite stick to this extreme position: he was always willing to listen to what people said about what they did and, in *A Balance Sheet of the Self*, he suggested that psychology students ought first to analyse their own behaviour, reactions, and fears before being allowed to practise on anyone else.

Behaviourism has featured in political literature. Two nightmares and one Utopia were inspired by the notion that it is possible to condition people's behaviour. Aldous Huxley's *Brave New World* and George Orwell's *1984* both feared that advances in psychology had given the state the technology with which to control individuals.

In B. F. Skinner's *Walden Two*, psychology is also in power. But Skinner, a behaviourist, firmly believed that its insights could be used to make people better and happier. In his community, there is harmony, love, cooperation, and creativity because human beings have been reinforced to behave that way to each other. Many critics of behaviourism have argued that *Walden Two* is, in its cloying, apple-pie harmony, just as oppressive as the Orwell and Huxley nightmares. Be that as it may, these three books bear witness to the cultural importance of behaviourism. The only other school of psychology to have impressed the twentieth century as much was*psychoanalysis.

Though it is now unfashionable to credit one man with a discovery, Watson was very much responsible for the initial success of behaviourism. He was born in Greenville, South Carolina, in 1878. His mother, Emma, was a zealous Baptist; his father, Pickens, was a misfit who enjoyed bourbon whiskey and eventually ran away from his pious wife to live with two Indian women. Religious Greenville was shocked and vitriolic; this helped make Watson detest religion, and was to prove important in his development—and that of behaviourism. After a difficult adolescence during which he was arrested for 'nigger bashing' and for firing a gun in the middle of Greenville, Watson went to Furman University; there 'I cut my teeth on metaphysics'. Having graduated, he went to the University of Chicago to study under the philosopher John*Dewey. But Watson soon became disillusioned with Dewey and turned to the study of animal behaviour. His doctoral thesis, 'Animal learning', looked not at how rats run mazes but at how they learn a variety of tricks including getting out of a box and opening a drawbridge.

In 1903, psychology was very young. Before the start of its first laboratories in 1879, it had often been called experimental philosophy, and in many universities psychologists still worked under the department of philosophy. It is not surprising that much of the discipline was rather abstract. Much effort was devoted to introspection and the unravelling of consciousness. In 1903, introspecting did not mean brooding on one's*psyche but rather trying to dissect what was going on inside one's mind. Psychologists believed that a trained observer could report on what was going on in his consciousness when he saw dots, waited for a tone, or was asked to respond to a picture by pressing a button. Taking their models from chemistry and physics, they hoped to work out what were the 'atoms' of consciousness; but different subjects reported very different mental processes.

Introspection made Watson acerbic. 'I hated to serve as a subject,' he wrote in an autobiographical note in 1936; 'I didn't like the stuffy artificial

instructions given to subjects. I always was uncomfortable and acted unnaturally.... More and more the thought presented itself. Can't I find out by watching their behaviour everything the other students are finding out by using *O's*.' *O's* were introspective observers. Evidence that he began to be highly critical of orthodox ideas does not depend only on his memory. He raised the possibility of studying humans like animals with James*Angell, his doctoral supervisor. Angell told him to stick to animals. This dismayed Watson and, with the pressure of finishing his doctorate, it led to a short breakdown. But he did not abandon his critique. He vowed to a friend that he would remodel psychology.

By 1908, Watson had a national reputation as 'an animal man'. He took the professorship of psychology at Johns Hopkins University and began to read widely in human psychology. He tested some of his ideas in letters to Robert Yerkes, an animal psychologist. Yerkes warned that Watson was too extreme; yet, in 1912, in a series of summer lectures at Columbia University, Watson outlined his critique. The lectures were well attended, and Watson, given the radical nature of his ideas, was nervous about how they would be received. Angell, he had heard, 'thinks I am crazy. I should not be surprised if that is the general consensus of opinion.'

The lectures, published in 1913, remain the text for behaviourism. Psychology 'as the behaviourist views it is a purely objective branch of natural science. Its theoretical goal is the control and prediction of behaviour.' Introspection was no help and psychologists should not judge the value of their data by whether it shed any light on the intricacies of consciousness. The behaviourist 'recognises no dividing line between man and brute'. Watson's dislike of religion, learned in Greenville, made him hostile to the idea that human beings were superior organisms with souls.

He made much fun of the failure of introspection. 'If you can't observe 39 states of clearness in attention, your introspection is poor. If, on the other hand, a feeling seems reasonably clear to you, your introspection is again faulty.' Sweeping such mystical nonsense away would enable psychology to become a proper science linked to biology rather than to metaphysics.

Rejecting introspection was easy; developing a coherent theory of how human beings behaved was rather harder. Watson drew heavily on the work of*Pavlov, who had shown that you could condition dogs to salivate not just at the sight of food but at the sound of a bell that preceded food. A reflexlike

salivation was malleable.

Watson argued that human behaviour is built on just such conditioning. He claimed that almost all behaviour is learnt: if one gets up every time a lady enters the room, one is acting not out of politeness but because behaviour is a chain of wellset reflexes. Watson claimed that what determined the next item of behaviour a person

'emitted' was *recency* and *frequency*—what had occurred just before and what, in the past, had been the response a person made to that particular stimulus: if one usually gets up when a lady enters the room, one is very likely, if a lady enters the room now, to get up again. The behaviour may be explained as a polite action, but it is a reaction that could have been predicted. In Watson's scheme, rewards find punishments were not crucial.

In 1916, Watson began to study how children develop. He wanted to isolate the most important early reflexes on which conditioning could build. He also examined the idea of applying such ideas to psychiatry. In the early 1920s, he reported a study of Little Albert, a child who was taught to fear rats and then not to fear them entirely through manipulating. This paper (whose integrity has been disputed) was an inspiration to behaviour therapists who aim to train people out of their phobias and neuroses.

The historian John Burnham has warned against being romantic about Watson. Other psychologists were inching towards behaviourism, too. Burnham stressed T. S.

Kuhn's theory of scientific revolutions which states that scientific revolutions occur when the field is ripe for a new paradigm. According to this view, Watson prevailed because the prevailing mood was right. But Kuhn's theory may not fit psychology too well. In arguing for behaviourism, Watson wasn't so much making a new discovery as offering a new philosophy and methodology. Behaviourism was a selfconscious revolution against consciousness. Some traditional psychologists grasped its dangers very well and reacted with hostility: James Angell said privately that Watson should be 'spanked', while Watson said of E. B. Titchener that he 'roasted me'.

There is some dispute about how quickly behaviourist ideas spread through American psychology, but by 1920 Watson was recognized as one of the leading American psychologists.

In the 1930s and 1940s, behaviourism became very much laboratorybased. B. F. Skinner (see next entry and SKINNER BOX) made his name through his studies of how to reward pigeons and other creatures; Clark*Hull, perhaps the leading behaviourist of the 1940s, devised immensely complicated models of animal behaviour.

These developments make it easy to imagine that Watson was bent not only on making psychology scientific but on imprisoning it in the laboratory. Nothing could be further from the truth.

In *Psychology from the Standpoint of a Behaviorist* (1919), Watson argued passionately that psychology should be relevant to real life. Scientists should analyse what people did in the factory, the office, the home, and even the bedroom. He initiated studies on subjects as varied as how well

one can throw darts while drunk and the effects of anti-VD propaganda on the sex lives of GIs. Behaviourism was to be a psychology of real life. But after the divorce scandal he had to resign from Johns Hopkins and could not see his programme

Page 73

through. Following his job as a travelling salesman, the advertising firm J. Walter Thompson employed him. Advertising was to benefit from his psychological skills—

he pioneered many modern advertising techniques—but he was lost to serious psychology. He was only 42 at the time of his divorce, an age at which many psychologists begin doing their best work.

Behaviourism as it developed between 1913 and 1920 had many problems. It was a fluid theory. Watson tended to ignore the power of reinforcement. There was no convincing account of language, let alone of thought. B. F. Skinner later attempted to remedy this with his *Verbal Behavior* (1957); further research showed conclusively, however, that we do not just learn language but that we are innately 'wired' to speak. Then, from 1920 and into the 1930s, American universities expanded quickly and many new departments of psychology were set up. Behaviourism was in an attractive position because it seemed to ensure that psychology could be scientific. Most psychologists accepted Watson's methods though not his vision of applying psychology objectively to all of life. Behaviourism became narrower than it might have been if he had remained active.

The three major figures among those who developed behaviourism through the 1930s and 1940s were Edward Guthrie (1886-1959), Clark Hull, and Skinner.

Guthrie followed Watson most closely but dropped frequency as an important determinant of behaviour. For Guthrie, 'a combination of stimuli which has accompanied a movement will on its recurrence tend to be followed by that movement'. He tried to show that all learning could be explained on this principle, ignoring rather how it might explain novel combinations of movements.

Clark Hull proposed a more systematic total behaviourist theory. He tried to link the external circumstances (such as the intensity of a pain stimulus or the size of a reward) with internal body states (hunger and thirst) and with specific behaviours such as the speed with which an animal will run a maze for a food reward. Hull wanted a theory of behaviour as formal as Euclid's theory of geometry, and he introduced theorems and postulates which could account for all behaviour. The scheme was a grand one, and defined precisely some internal states such as drive, and strength of habit. For example, a rat who had been deprived of food for seven hours was likely to be hungrier than a rat deprived of food for three hours, unless the seven-hour rat had been used to going without food for longer. Hull perfected his system over some twenty years, but it had its problems. First, some experiments had inconvenient results. For example, Hull argued that habit strength built up slowly.

It could therefore be expected that, for an animal used to doing X for reward Y, if the reward was reduced it would still tend to do X because of the habit strength attached to X. In fact, diminishing rewards reduced the behaviour fast. Then, as Hull tried to accommodate such results, internal

inconsistencies in the theory began to creep in. He succeeded in offering a very grand vision of a theory that was precise and quantifiable. His books are full of equations. But by 1952, the year of his death, he knew that he had not quite succeeded, and it may be that his failure to make his system convince affected the ambitions of psychology. Perhaps it was too soon to attempt a comprehensive theory of behaviour.

B. F. Skinner now became the leading exponent of behaviourism. His first major theoretical contribution had tended to go against Watson's ideas. Arriving at Harvard in 1929 to work for his doctorate, Skinner was committed to a scientific and practical psychology. But he grew dissatisfied with basing everything on the reflex. It seemed to him not only that people respond to the environment but also that 'behaviour operates on the environment to generate consequences'. If a rat gets food every time it presses a lever, it is operating on the environment. Skinner argued, therefore, that most behaviour involves operant conditioning. We behave the way we do because of the consequences our past behaviour has generated. If every time a man takes his wife out to dinner, she is very loving, he is likely to learn to take her out to dinner if he wants her to be loving. Though this example (like many of Skinner's) involves description of behaviour in which motives, feelings, and intents appear to matter, Skinner himself was always scathing about what he described as 'the mentalists'. For Skinner, it is the history of reinforcements that determines behaviour.

Consciousness is just an epiphenomenon, and feelings are not causes of actions but consequences. Behaviour can be predicted and controlled without reference to them.

Skinner made famous the notion of *shaping*. By controlling the rewards and punishments the environment offers in response to particular behaviours, you can shape behaviour. Pigeons can be 'shaped' even to play pingpong. Psychiatric patients can be 'shaped' to behave in less anxious and more socially acceptable ways. Much of Skinner's detailed technical work was aimed at discovering the different effects of different schedules of reinforcement. Which are most effective: regular rewards, irregular rewards, or a mixture of the two?

The controversies Skinner has fuelled arise largely because, like Watson, he was not content to see behaviourism merely as a scientific method; rather it offers a way of organizing our lives better. Skinner has been accused of helping to perfect technologies of control, but the truth is more prosaic. In the 1950s and 60s, there was a vogue for trying out 'token economies' in penal and psychiatric institutions. Professionals tried to 'shape' the behaviour of inmates by giving them rewards for behaviour that was deemed good or appropriate. Usually, the inmates were not punished, a point Skinner liked to stress. But Page 74

though some institutions continue to use such methods of 'behaviour modification', as it has been called, it would be an exaggeration to say they are widespread or entirely successful. The individual histories of human beings are too complex for their behaviour to be shaped like that of laboratoryreared birds. Moreover, Skinner claimed, human beings cling to illusions of being free to act because they think, wrongly, that without them they will lose all dignity. We are, in fact, controlled by our past and controlled by our environment. The more we realize that, the more we analyse the nature of that control, the better our situation. Herein there is a paradox that Skinner doesn't really

explore in his enthusiasm to go against the importance of thoughts, intentions, and feelings. Skinner has certainly attracted much respect and fame but his form of classic behaviourism is now less and less in vogue especially as cognitive psychology has, since the late 1960s, suggested that it is possible to be objective about studying mental processes.

Behaviourism has been seen in different lights by different observers. The British psychologist Donald Broadbent argued (1961) that it offers the best method for rational advance in psychology, allowing one to weed out facts from fantasy and to replace armchair speculation about the nature of the soul or the mysteries of consciousness with repeatable results. In contrast, Nehemiah Jorden asked the question (1968), 'can one positive contribution towards any increased knowledge of man be pointed to since Watson wrote his famous paper?' And answered it: 'None such can be found.' Any assessment of behaviourism has to recognize such different opinions, but almost all psychologists and psychiatrists see merit in some of Watson's ideas, while very few are strict behaviourists. One needs to study behaviour objectively. There are close links between human and animal behaviour, and conditioning does play an important part in human development. Many would also applaud the original aim of establishing a scientific psychology of life in the factory, the office, and the home. On the other hand, seventy years of research have shown that consciousness cannot be dismissed as uninteresting in human psychology and that even introspection has its uses as one tool among many.

BEHAVIOURISM, SKINNER ON. The scientific study of behaviour covers many fields, including ethology, psychology, sociology, anthropology, economics, and political science. Behaviourism is not one of these fields; it is a consideration of certain problems which arise in all of them. Behaviour is most effectively studied in relation to the environment—the environment in which the species evolved and the physical and social environments in which the individual lives. It has been traditionally viewed, however, in other ways—for example, as the expression of feelings or states of mind, as the role played by a personality, or as the symptom of mental illness. Behaviourism is in part an attack upon these traditional interpretations. It is a philosophy of behavioural science, the roots of which are to be traced through the writings of J. B.*Watson and I. P.*Pavlov to Ernst*Mach, Henri*Poincaré, and Auguste*Comte, among others.

'Methodological' behaviourists often accept the existence of feelings and states of mind, but do not deal with them because they are not public and hence statements about them are not subject to confirmation by more than one person. 'Radical' behaviourists, on the other hand, recognize the role

of private events (accessible in varying degrees to selfobservation and physiological research), but contend that so-called mental activities are metaphors or explanatory fictions and that behaviour attributed to them can be more effectively explained in other ways. A few examples will be considered here to illustrate the latter position.

Purpose, intention, expectation. Most behaviour is selected by its consequences. For example, we tend to do the things we have successfully done in the past.

Although it is the product only of past consequences, behaviour is useful because it may have similar consequences in the future. We refer indirectly to that future when we say that we act with a*purpose, intention, or expectation. Such 'states of mind' are not, however, the causes of our behaviour. We do not act because we have a purpose, we act because of past consequences, the very consequences which generate the condition of our bodies which we observe introspectively and call felt purpose. Natural selection raised the same issues. Has life a purpose? Is a given species the result of an intentional design? (See EVOLUTION: HAS IT A PURPOSE?) These concepts can be abandoned in both fields when the principle of selection by consequences is understood.

Mental processes. Many aspects of mental life are modelled upon the physical environment. The smell of a rose is said to 'remind us of' or 'bring to mind' the visual appearance of a rose because we associate one with the other. But the odour and the visual properties are associated in the rose. When we have been exposed to two physically associated stimuli, we may subsequently respond to one as we responded to the other, but the environmental association is enough to account for our behaviour. We have no introspective evidence of any internal process of association. Abstraction, concept formation, and many other so-called mental processes are also modelled upon complex arrangements of stimuli, and again the arrangements suffice to

Page 75

explain the behaviour without appeal to mental duplicates.

Sensations, perceptions, and images. Most people believe that when they look at a rose they construct an internal copy, called a sensation or perception, and that later, when they are reminded of a rose, they reconstruct that copy, now called a mental image, and look at it again. They do not observe themselves doing so; they simply see a rose. Under special circumstances, they may, in addition, observe that they are seeing one, but even so there is no evidence, introspective or physiological, of an internal copy. If seeing were simply constructing a copy of the thing seen, we should have to make another copy to see the copy, and then another copy to see that. At some point we must 'see a rose' in some other sense. What that means is not well understood—by anyone. Rather than look for internal representations, we should examine the ways in which a person learns to see things, in both the presence and absence of the things seen.

Reasons and reasoning. Three things must be taken into account in the study of behaviour: the situation in which behaviour occurs, the behaviour itself, and the consequences that follow. The relations among these things can be very complex, and only a careful scientific analysis will then

untangle them. For practical purposes, however, we describe many of them with reasonable accuracy. When we give someone advice, for example, we specify a situation ('When you have a headache...'), an act ('take an aspirin...'), and (possibly only by implication) a consequence ('and you will feel better').

People profit from advice because by following it they can behave in ways which, without help, they would have to learn through a possibly long exposure to the conditions described. The social environment called a culture offers a vast store of rules, maxims, and governmental and scientific laws describing relations among situations, behaviour, and consequences, which enable people to acquire much more extensive repertoires than would otherwise be possible.

In taking advice or following rules we can be said to behave because of reasons rather than causes, and in what is called reasoning we formulate rules for our own use.

Rather than explore a situation and allow our behaviour to be changed directly by it, we analyse the situation and extract a rule which we then follow. We sometimes extract rules from other rules, as in logic and mathematics.

Introspection. The world within a human skin is part of the physical world. It may seem that we should know it better because we are close to it, and we do, indeed, respond to private events with great precision in the normal functioning of our bodies. But *knowing* about our bodies, in the same sense in which we *know* about the world around us, depends upon conditions which cannot easily be arranged with respect to a private world. We learn to tell *P* from *Q* because other people respond appropriately when we say '*P*' or '*Q*' when looking at a letter. Unfortunately they cannot respond as precisely when we name or describe a private event (such as those we call feelings or states of mind), because they lack the necessary contact. As a result, we never know our own bodies with any great accuracy. Moreover, we cannot know much about many important parts of them (for example, the physiological processes which mediate the complex behaviour called thinking) because we simply do not have nerves going to relevant places.

Behaviourism criticizes mentalistic explanations of behaviour in this way only to promote a more effective analysis. By dismissing mental states and processes as metaphors or fictions, it directs attention to the genetic and personal histories of the individual and to the current environment, where the real causes of behaviour are to be found. It also clarifies the assignment of the neurosciences, saving the time that would otherwise be wasted in searching for the neurological counterparts of sensations, stored memories, and thought processes. Behaviour is simply part of the biology of the organism and can be integrated with the rest of that field when described in appropriate physical dimensions.

At the same time behaviourism provides an overview which is particularly helpful in the social sciences. The experimental analysis of behaviour has led to an effective technology, applicable to education, psychotherapy, and the design of cultural practices in general, which will be more effective when it is not competing with practices that have had the unwarranted support of mentalistic theories.

Skinner, B. F. (1974). *About Behaviorism*. New York.

BEHAVIOUR MODIFICATION. See BEHAVIOUR THERAPY.

BEHAVIOUR THERAPY. The term 'behaviour therapy' was coined towards the end of the 1950s by H. J. Eysenck to denote a method of treatment of neurotic disorders that was based on laboratory studies of*conditioning, and on modern*learning theory. Behaviour therapy is derived from a general theory of neurotic disorder which differs profoundly from psychoanalytic or orthodox psychiatric theories. Before presenting this theory (which is basic to the therapeutic application of the various methods comprised under the general term 'behaviour therapy'), it may be useful to distinguish behaviour therapy from *psychotherapy* and from *behaviour modification*, two terms which partly overlap with behaviour therapy, and are partly contrasted with it.

Psychotherapy denotes the use of psychological theories and methods in the treatment of psychiatric disorders; in its generic sense it therefore includes behaviour therapy as one of the

Page 76

methods used by psychologists and psychiatrists, and is partly synonymous with it. However, psychotherapy also has a narrower meaning, namely the use of interpretative (mostly*Freudian) methods of therapy; in this sense psychotherapy and behaviour therapy are antonyms, the former relying on verbal and symbolic methods, the latter on the direct manipulation of motor and autonomic behaviours. Thus psychotherapy in the wider sense can be usefully divided into psychotherapy in the narrower sense, and behaviour therapy. Both psychotherapy and behaviour therapy refer to a whole set of methods; they are not confined to one single method, as the terms used might suggest.

The terms behaviour therapy and behaviour modification are also partly synonymous, partly antonymous. In the United States, particularly, both terms are used indiscriminately to refer to two sets of rather different theories and methods. Both these sets do, indeed, make use of psychological theories of learning and conditioning, and to that extent there is some overlap. However, psychologists make a fairly clear (although probably not absolute) distinction between two kinds of conditioning:*Pavlovian or classical, and instrumental or operant. Behaviour therapy in the narrower sense is concerned with Pavlovian conditioning, behaviour modification with instrumental conditioning. In this sense these methods and theories are antonymous; and we may say that behaviour therapy in the wider sense can be usefully subdivided into behaviour therapy in the narrower sense, and behaviour modification. These complications of nomenclature are bothersome and annoying, but they have become so firmly entrenched that they have to be dealt with; clearly anyone writing about these various therapies should indicate in which sense the terms are being used.

Pavlovian conditioning forms associations between conditioned stimuli (neutral before conditioning) and unconditioned stimuli and responses by simple pairing: the animal or human being conditioned does not perform any act that would affect the outcome. Thus a dog may be conditioned to lift his paw

upon a signal by fixing to his foot a device that delivers an electric shock and activating it shortly after giving a signal (the conditioned stimulus). The shock makes the dog lift his leg, and although this movement does not enable the dog to escape from the shock, nevertheless the movement becomes conditioned. Instrumental conditioning, pioneered by Pavlov's rival Bekhterev, is based on similar associations, but in this case the action performed by the animal or human is the crucial factor. Thus the shock to the leg of the dog may be delivered through a grid on which the foot of the animal rests; if he lifts his foot, in response to the conditioned stimulus, he avoids the shock. This is a profound difference, and E. L. Thorndike, B. F. Skinner (see BEHAVIORISM, SKINNER ON), and other American psychologists have elaborated practical methods of using positive and negative reinforcements (rewards and punishments) in order to modify behaviour. These are usually related to explicit behaviour patterns: for instance they may be used to make schoolchildren less boisterous, criminals better behaved, or psychotic inpatients more responsive to the demands of society. In each case the stress is on segments of largescale behaviour: the child may be required to learn to sit quietly for certain periods of time, the criminal to carry out a series of acts such as making his own bed, keeping his room clean, and working adequately for a certain period of time. The psychotic may be required to come to meals punctually, keep himself tidy, work in the laundry, associate with other people, and so on. Methods have been worked out for the optimum use of rewards ('token economies') according to the laws of operant conditioning, and many practical applications of these methods have been developed, particularly in the treatment of deteriorated psychotics. But little attempt has been made to use these methods in connection with the treatment of the far more widespread neurotic disorders, and in clinical practice there is little doubt that Pavlovian methods are much more frequently used, and much more efficacious.

Operant conditioning applies, for the most part, to motor activities and the performance of integrated activities. Pavlovian conditioning applies, for the most part, to the activity of the autonomic system, i.e. to emotions; thus it is no accident that neurotic behaviour, which is largely characterized by emotional upsets and difficulties, is more closely related to Pavlovian conditioning. (This distinction is not an absolute one, but it is very useful and farreaching; most human activities, as well as most animal activities studied in the laboratory, partake of both operant and classical conditioning, and complex methods of analysis are required to sort out the respective contributions of these two processes.) The theory of neurosis from which behaviour therapy derives states that neurotic disorders are essentially *conditioned emotional responses*; they are acquired through some traumatic emotional event, or a series of subtraumatic emotional events, in which some previously neutral conditioned stimulus becomes linked (perhaps quite accidentally) with a fearproducing unconditioned stimulus. This theory is clearly different from psychoanalytic and other psychiatric theories, according to which the observed signs of the disorder are merely symptoms of some underlying 'complex'; according to Freud and his followers, this 'complex' must be eliminated before any permanent cure is possible. Behaviour therapists deny the existence of these alleged 'complexes', and they assert that the putative 'symptoms' are not in fact symptoms of anything— they *are* the disorder. The aim of behaviour therapy is to eliminate these 'symptoms'; if this can be accomplished, then no 'disease' or 'complex' will remain. Freud predicted that 'purely sympto

matic treatment', which did not eliminate the 'complex' allegedly underlying the outward manifestations of the disorder, would lead to relapse or to symptom substitution, i.e. either the 'symptom' would return, or else another one would arise in its place. Behaviour therapists have been on the lookout for such effects, but although they have succeeded much more completely than others in eliminating the 'symptoms', relapse and symptom substitution have been notable mainly by their failure to occur.

The methods of behaviour therapy (in the narrower sense) derive from this general theory. If the manifestations of neurotic disorder are conditioned emotional responses, then a cure must consist in the *extinction* of these conditioned responses. Fortunately experimental psychologists, following the lead of Pavlov, have elaborated many different methods for attaining this aim, and these have been tried out very successfully in neurotic patients. The methods include *desensitization* or counterconditioning (in which the conditioned stimulus that produces fear/anxiety responses in the patient is conditioned by the therapist to more positive antianxietyproducing unconditioned stimuli, such as relaxation or selfassertion); *flooding* (in which the patient is exposed for a lengthy period to the conditioned stimulus that produces fear/anxiety responses; by preventing the usual reactions of flight or whatever, the therapist forces the patient to face his fears, which then disappear quickly);

and *modelling* (in which the patient is shown a 'model' who copes properly with his own difficulties and fears, and thus learns the absurdity of his conditioned responses). The effectiveness of these, and many other similar methods, is no longer in question; indeed, empirical evidence from clinical and experimental studies has shown that for no other therapy is there anything like as good evidence for speed and efficacy of cure. If we consider that, at the time of writing, these methods have been in existence for less than twenty years, their future development suggests even greater promise of effectiveness.

BÉKÉSY, GEORG VON (1899-1972). Hungarian physicist and physiologist, the son of a Hungarian diplomat. He spent his early years in Munich, Constantinople, Zurich, and Berne. He received his Ph.D. in physics from the University of Budapest, and remained in Budapest until 1946. After a year in Stockholm he moved to the psychoacoustic laboratory in Harvard, where he remained until 1966.

He then moved to Honolulu to become professor of sensory sciences at the University of Hawaii. He continued in active research there until shortly before his death.

Békésy is most famous for his work on the inner ear or cochlea. He was the first to observe directly the patterns of vibration on the basilar membrane inside the cochlea. He found that sound evoked a pattern of wave motion which travelled from one end of the membrane towards the other, increasing in amplitude up to a certain point, and then decreasing. He found that the position of maximum vibration varied systematically with the frequency of the sound, thus providing the basis for the frequency analysing power of the ear. He carried out this work first on models of the cochlea, and later on preparations of human temporal bones and on the cochleas of living animals. Most of his work in this field was carried out in Hungary. (See also HEARING.) In Stockholm Békésy invented a new method for measuring thresholds of hearing, and devised a new*audiometer to go with it. The Békésy audiometer is still widely used in clinical hearing testing and in auditory research.

At Harvard the emphasis of his work shifted from the mechanics of the ear to biophysics, and particularly the mechanism by which mechanical vibration on the basilar membrane is transformed into neural impulses. Later still he conducted perceptual experiments on a number of different senses, including hearing, sight, smell, and taste.

Békésy's work on hearing is summarized in his fine book *Experiments in Hearing* (1962). The quality of his work was recognized by the award of the Nobel Prize for Physiology or Medicine in 1961, for 'discoveries concerning the physical mechanisms of excitation in the cochlea'. The award was celebrated by a special issue of the *Journal of the Acoustical Society of America* in 1962, which contained a series of papers dedicated to his work.

B. C. J. M.

BELL, SIR CHARLES (1774-1842). British anatomist and surgeon, born in Edinburgh, the son of a Scottish Episcopalian clergyman. He was taught anatomy by his brother and was admitted to membership of the Royal College of Surgeons of Edinburgh in 1799, followed shortly by his appointment as a surgeon at the Edinburgh Royal Infirmary. In 1806 he moved to London, where he taught anatomy and surgery to his house pupils and, from 1811, at the Great Windmill Street School of Anatomy. From 1812 to 1836 he acted as surgeon at the Middlesex Hospital. In 1824 he accepted the senior professorship of anatomy and surgery at the Royal College of Surgeons of London, his lectures there forming the text of a book entitled *Animal Mechanics, or Proofs of Design in the Animal Frame* (1828) (see CYBERNETICS). In 1826 he was

Page 78

elected a Fellow of the Royal Society, and in 1828, on the founding of the University of London, he accepted the chair of anatomy and physiology, but after two years he resigned. On the accession of William IV he was knighted, and in 1836 he became professor of surgery at Edinburgh, where he remained until he died, while on a journey to London.

Bell's first claim to fame rests on his contributions to physiological psychology, of which the law beating his name is the cornerstone. Throughout his published work he has much to say about the mind, and especially in his two favourite books, *The Hand* and *The Anatomy and Philosophy of Expression as Connected with the Fine Arts*, which testify to his capacity for shrewd observation. He delved into the art of antiquity, examined theories of the beauty of the human form, and critically studied the laws governing the expression of feeling, emotion, and passion in the movements of face and figure.

For nearly two thousand years no one had seriously ventured to question Galen's conception of brain and nerves. Many anatomists, it is true, had suspected that the nerve fibres serving sensation and movement, though joined in the same sheath, might be distinct, and Thomas Willis (1621-1703) had stated that some nerves were exclusively sensory and others exclusively motor. But, as Bell says in his preface to *The Nervous System of the Human Body* (1830), 'the (ancient) hypothesis that a nervous fluid was derived from the brain, and transmitted by nervous tubes, was deemed consistent with anatomical demonstration'. Furthermore, his contemporaries took it for granted that one and the same nerve fibre could serve the twofold function of conducting sensory messages and of transmitting the 'mandate of the will'.

Why, Bell asked himself, should sensation remain entire in a limb when all voluntary power over the action of the muscle is lost? And why should muscular power remain when feeling is gone? In seeking to answer these questions, he demonstrated the separate functions of the anterior and posterior roots of the spinal nerves.

Some time between 1812 and 1821, his surgical and clinical 'experiments' led him to believe that movement is served by the anterior or ventral, and sensation by the posterior or dorsal, roots of the spinal nerves (Bell-Magendie law); the respective fibres are distinct but bound within the same trunks, and terminate separately, both centrally and peripherally.

From this discovery, Bell moved to the suggestion that sensory and motor functions might be served by different parts of the brain. He recognized (before Johannes Müller) the specificity of sensory nerves; identified (before C. S. Sherrington) the muscle sense; and understood the facts of reciprocal innervation (relaxation of extensor muscle while the flexor contracts). No one before him had acquired such an understanding of the human hand, and of the manner in which it reveals its superiority over the homologous organs of other animals. By dwelling on the delicate musculature of the fingers, and on the sensibility of the skin, he came to see the hand as the special organ of the sense of touch, while in the 'muscular sense' he detected a sixth sense which we now recognize as that which serves our powers of haptic perception. He saw the function of the hand as adapted to the arm and shoulder. In studying their comparative anatomy, he drew striking comparisons with the shoulder of the horse, elephant, and camel, and with corresponding organs of the mole, the bat, the anteater, and other species, including many now extinct.

Bell felt that he was continuing in the tradition of what he called 'the English School of Physiology', in contrast to the French School, which represented life as 'the mere physical result of certain combinations and actions of parts by them termed Organization'. This was an oblique reference to the

Cartesian conception of 'animal as machine' (see DESCARTES), which culminated in*La Mettrie's *L'homme machine*.

A simple principle governed his work, namely 'that design and benevolence were everywhere visible in the natural world'. The 'different affections of the nerves of the outward senses' were, for him, 'the signals which the Author of nature has willed to be the means by which correspondence is held with the realities'. Perfect symmetry of form and function, continuous renewal of the 'material particles', and the integrity of the body amidst the ceaseless changes to which it is subject, convinced him of the existence of a 'principle of life' which governed bodily structure and change.

Charles Bell must be counted among the leading men of science of the nineteenth century, and the most versatile of that illustrious group of men who raised Scottish medicine to preeminence. He combined a surgeon's intimacy with the human body with a profound understanding of its anatomy and physiology. To all this he brought considerable gifts as a writer, and as a consummate medical artist.

BENHAM'S TOP. Quite intense colours can be produced by pulsing coloured or white light. Flashing coloured lights can produce other colours: for example, flashing monochromatic sodium yellow light may produce any spectral hue (and brown,

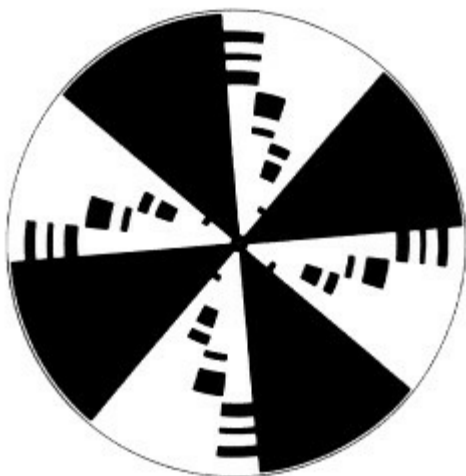

Fig. 1.

which is not in the spectrum), though not usually with very high saturation. These phenomena are most easily seen with a spinning disc, or top, having black and white sector rings (as in Fig. 1). This gives intermittent stimulation to retinal regions as it is rotated, quite slowly, to give a flicker rate below the fusion frequency. The colours seen depend on the widths and arrangement of the black sectors and the rate of rotation. There are considerable individual differences for what is seen under given conditions.

Although generally called 'Benham's top', after C. E. Benham (1894), the basic effect goes back to a French monk, Benedict Prévost, who, in 1826, observed colours—like a heavenly light on his fingers—when he waved his hands about in the cloisters. Finding that this also happened with white cardboard, he realized that it has a physiological origin, in the eye, and attributed it to different rates of action of specific colour mechanisms of the retina. He was essentially correct. It is remarkable that Prévost's discovery was forgotten, and the effect was rediscovered no less than twelve times: by Gustav Fechner in 1838 and then by others. John Smith, in 1859, thought that the effects were 'objective' by changing the light itself, and so he (incorrectly) challenged Newton's account of light and colour. The third rediscovery was made by Sir David Brewster in 1861. (The history is given fully in Cohen and Gordon, 1949). Hermann von Helmholtz carried out systematic observations, noting that a white rotating sector is red on the leading edge and blue on the trailing edge, and in dim light the red becomes yellow and the blue violet. In very bright light the red becomes pinker and the blue greenish. Further observations were made by S. Bidwell, who discovered a related effect, Bidwell's ghost.

These subjective colours have been shown successfully on black and white television, but they are a little too weak for commercial uses. They are due to different timeconstants of the colour receptor systems of the eye, but they are rather too variable for precise measurements. The effects are interesting but not particularly useful.

BENTHAM, JEREMY (17481832). Born in London and educated at Westminster School, he entered the Queen's College, Oxford, at the age of twelve.

Although he studied law at Lincoln's Inn and was called to the Bar in 1772, he never practised law;

but he wrote on its theory. He held that laws should be socially useful and should not merely reflect custom, that men are hedonists (pursuing pleasure and avoiding pain), and that desires may be classified into self and otherregarding: the function of law is to provide punishments and rewards to maintain a just balance between them. His famous dictum is that all actions are right and good which promote 'the greatest happiness of the greatest number', this principle being the basis of utilitarianism.

Bentham was a founder of University College, London, where his mummified body may still be seen, dressed in his own clothes. He collaborated closely with James*Mill, whom he met in 1808. He also founded the *Westminster Review*.

BEREAVEMENT is a common cause of grief, that 'fierce or violent sorrow' which Robert*Burton in his *Anatomy of Melancholy* referred to as 'the epitome, symptom and chief cause of melancholy'. The relationship between mourning and melancholia was explored in more detail by Sigmund*Freud who, in 1917, suggested that depressive illness (melancholia) differs from grief in the prominent part played by feelings of guilt and in the symbolic significance of the loss which preceded it.

Subsequent research has confirmed the frequency of guilt and selfreproach among those who develop depressive illnesses after bereavement.

Despite Freud's claims, little attention was paid to bereavement by psychiatrists until Eric Lindemann described the symptomatology and management of acute grief following the Coconut Grove nightclub fire in Boston, Massachusetts, in 1944. Lindemann showed that people who do not 'break down' and express feelings appropriate to a bereavement may suffer from delayed or distorted grief. Such pathological forms of grief, said Lindemann, could be restored to a more normal form in the course of six to eight weekly interviews in which the bereaved person was encouraged to give vent to the feelings of sadness, anger, or guilt which they had repressed. A recent development of this

Page 80

approach has been the use of 'flooding', a technique derived from*behaviour therapy in which bereaved people are pressed to vivid recollection of the sight, smell, sounds, and feelings associated with the dead person. R. W. Ramsay (1977, 1979), the originator of this method of treatment, has subsequently toned down the intensity of the approach, which, in its original form, could only be safely carried out in a psychiatric inpatient setting.

While there is now much agreement regarding the efficacy of Lindemann's approaches to delayed or avoided grief, their use in the treatment of the severe and protracted grief which sometimes follows the dissolution of relationships characterized by ambivalence or dependency is more controversial. Alternative strategies have been developed by C. M. Parkes, who has also advocated the introduction of bereavement counselling during the early phases of grief as a means of preventing later difficulties in those who are thought to be at risk. Recent randomallocation studies have confirmed the effectiveness of some counselling services of this kind (Parkes, 1972, and Raphael, 1984).

The application of Freud's libido theory to grief has been challenged by John Bowlby (1969), whose

studies of the development of attachment between mother and child led him to explain the intense pining or yearning of acute grief as a frustrated form of the urge to search for any loved person from whom one has become separated. This urge to search is thought to be an instinctually derived behaviour pattern which conflicts with the awareness of the older child or adult that such a search is useless and bound to disappointment. Consequently attempts to avoid reminders of the loss, seek distraction, and inhibit thoughts of loss coexist alongside contrary impulses to cry aloud, to drop everything, and to focus one's mind upon the search for the lost person. Individuals, families, and cultures vary in the extent to which one or other aspect of the conflict is permitted, but some form of expression of sorrow is allowed for in the religious ceremonials of all cultures which have been studied (Rosenblatt *et al.*, 1976). G. Gorer (1965) has claimed that the decline in ritual aspects of mourning which has taken place in industrialized countries since the First World War has removed an important source of support for the bereaved and encouraged pathological reactions to bereavement.

In most bereaved people the urge to search for the lost person is reflected in thoughts, actions, and perceptions. Thoughts about the dead person return repeatedly, and the bereaved tend to pine intensely and to go over in the mind the events leading up to the death as if, even at this time, they could find out what has gone wrong and put it right again. The search is reflected in acts concerned to 'keep alive' the memories of the dead, to visit graves or places associated with them, and to treasure possessions which will act as reminders. Clear visual memories of the dead person are kept in mind, and sights and sounds are commonly misperceived as evidence of his or her return.

In the normal course of events the intensity and duration of episodes of pining (the so-called 'pangs' of grief) grow gradually less, and attachment behaviour is extinguished. As this happens, people become more fully aware of the extent to which their basic assumptions about themselves and the world will have to change.

The psychosocial transition which results necessitates lengthy revision of the individual's view of the world (world model), and, in the interim, the bereaved remain insecure and relatively helpless. Many withdraw from social relationships and become disengaged from their wider circle of interests and acquaintances. The elderly bereaved may never become reengaged with the outside world. Younger people more often find their way through to a new identity which may be more mature than the one which preceded it.

Factors which predispose to a successful outcome of this transition include appropriate anticipation and preparation for bereavement, emotional support from friends and others (permitting expression of grief), psychological resilience and confidence in oneself, opportunities for personal growth, and faith in a religious or philosophical system of belief that gives meaning to death. Conversely the process of grieving may be impaired by sudden, unexpected, and untimely deaths, by the dissolution of relationships characterized by ambivalence or dependence, by social isolation or the presence of others who will block attempts to grieve or distract the griever, by the failure of previous attempts to cope with major loss (particularly in childhood), by lack of self-confidence, by physical or other obstacles to self-fulfilment, and by the absence of a system of belief that gives meaning to death.

Although bereavements are commonest in old age, their frequency and predictability reduce the

chance that the bereaved will be unprepared for them. Also there is less need for old people to compete for a place in the world that remains to them, and many come through the stress of bereavement without experiencing the lasting distress which characterizes younger bereaved people.

Although most of the published work on bereavement has focused on bereavement by death, the phenomenon of grief follows many of the 'slings and arrows of outrageous fortune'. Hence an understanding of the psychology of bereavement is important to all those involved in the care of people who are undergoing psychosocial transitions.

BERGER, HANS (1873-1941). German psychiatrist who spent most of his career at the University of Jena where, in 1929, he discovered the human*electroencephalogram. Influenced by his father, a physician, and his mother, the daughter of the poet Friedrich Rückert, Berger's interests spanned medicine, science, and philosophy. He sustained a lifelong preoccupation with the*mindbody problem and saw the electrical activity of the brain as a means of clarifying that relationship.

After a brief study of astronomy and an equally brief time in the German army he studied medicine. In 1897 he received his doctorate at Jena and was subsequently appointed to the University psychiatric clinic there. During the period up to 1910 he published work on the spinal cord, cranial bloodflow, and brain temperature changes. Underlying the physiological investigations were always questions of psychological state. He had also in this period attempted, less successfully, to record electrical

activity from the cerebral cortex of a dog. In 1911 he married his technical assistant, Baroness Ursula von Bülow, with whom he had carried out work on the psychogalvanic reflex (see ELECTRODERMAL ACTIVITY).

During the First World War, Berger served on the Western Front as an army psychiatrist. On his return to Jena after the war he was appointed professor of psychiatry at the University and director of the *clinic*, where his duties also encompassed neurology. He resumed his research, but not until 1924 did time permit him to begin in earnest his search for cortical currents in the human brain which might relate to consciousness. In that year he observed from the head of a patient very small oscillations on his string galvanometer, although for a long time he retained serious doubts about their cerebral origins. However, by painstaking research he systematically eliminated most of the possibilities that they were due to extracerebral artefact. In 1929 he was sufficiently satisfied With their authenticity to publish his first paper 'On the electroencephalogram in man' in the *Archiv für Psychiatrie und Nervenkrankheiten*.

The world of neurophysiology remained unimpressed by the claims of this little known professor of psychiatry, who had only begun his serious investigations at the age of 51 and who seemed more at home in philosophy than in electrophysiology. Contemporary animal evidence provided little support for the human findings. It was not until 1934, when*Adrian and Matthews published their replication of Berger's findings, that neurophysiologists felt obliged to take account of their significance.

Once Berger had satisfied himself that the electroencephalogram (EEG) was a genuine brain phenomenon, he used it as a tool to study psychophysical relationships.

The two main features of the EEG were termed 'alpha' and 'beta' waves. The former were represented by regular oscillations of about 10 hertz, seen when the eyes were closed and in states of relaxation. The latter were less synchronous forms of faster activity which replaced the alpha waves when the eyes were open or when the individual was engaged in mental activity such as arithmetic calculations.

For Berger, alpha waves represented a form of automatic brain functioning, a state of electrical readiness which exists when the individual is conscious, but inattentive.

The desynchronous blocking of this activity was held to occur when attention was focused on one idea or sensory input. This was considered to result in a localized activation of the specific sensoryreceiving area in the brain, coupled with a more generalized inhibition of the surrounding areas, manifesting itself as a blocking of the alpha waves. He postulated that consciousness depended upon the potential gradient between the localized active area and the surrounding area of inhibition. Although he made little attempt to utilize his findings in clinical contexts, he described abnormal patterns of EEG activity in a number of pathological conditions, most notably in epilepsy.

In his thinking Berger was much influenced by the notion of the conservation of energy. He regarded*dualism as inconsistent with that principle, but could not reconcile its alternative, materialism, with his belief in volition. His solution was a form of psychophysical parallelism which

accepted transformation of physical energy to 'psychic energy' and vice versa, thus permitting causal interaction between the physical and mental domains.

He retired in 1938 at the age of 65. During his last years in Thuringia he developed a severe depression, and in May 1941 he took his own life.

W. C. M.

BERGSON, HENRI LOUIS (1859-1941). French philosopher, born in Paris. He was professor at the Collège de France (1900-24), elected an Academician in 1914, and awarded the Nobel Prize for literature in 1927. Bergson follows Heraclitus in arguing that change is the stuff of reality. He contrasts the everchanging and yet unified world of consciousness with the world of things in space. He stresses the immediacy of experience, given by perception, with the structure of things known only intellectually. His most important books are *Essai sur les données immédiates de la conscience* (1889), translated as *Time and Free Will* (1910), and *L'évolution créatrice* (1907), translated as

Page 82

Creative Evolution (1911), in which he discusses the place of man in nature and his notion of *élan vital* as the force of evolution (rather than natural selection). He also wrote on aesthetics and the particularly interesting *Le Rire* (1900), translated as *Laughter: an essay on the meaning of the comic* (1911). Bergson's philosophy, which at best is poetical, is critically discussed by Bertrand Russell in *The History of Western Philosophy* (1946).

BERKELEY, GEORGE (1685-1753), was born in Ireland, went to school at Kilkenny College, and in 1700 proceeded to Trinity College, Dublin, where he graduated in 1704 and became a Fellow in 1707. He retained his Fellowship, though with long periods of absence, until 1724, in which year he became Dean of Derry.

His intellectual development was strikingly precocious, and he was fortunate in his education. In 1700, although Ireland had so recently been the scene of prolonged turmoil and civil war, the state of learning at Trinity College was much livelier and more progressive than at either of the English universities at that time. It is clear that Berkeley was early and thoroughly acquainted with John Locke's *Essay concerning Human Understanding* (published in 1690) and with the physical theories of Isaac Newton and others which underlay that work. He learned much also—perhaps more than he afterwards cared to admit—from Malebranche's *Recherche de la vérité*. His own first book, *An Essay Towards a New Theory of Vision*, was published in Dublin in 1709, when he was 24; and his most important work, *A Treatise Concerning the Principles of Human Knowledge*, followed in 1710. He first visited England in 1713, and the third major work of his youth, the *Three Dialogues between Hylas and Philonous*, was published in London in that year. These are the works on which his fame securely rests, all written and well established before he was 30.

Berkeley was, with the zeal and confidence of youth, in a sense a reactionary figure. He rightly discerned, in the writings of Locke and his scientific mentors, the steady progress towards general acceptance of a certain scientific 'worldview', which he hated and believed that he could utterly

confute. This was the idea that mathematics and mechanics are the keys to the understanding of nature—that all matter is fundamentally atomic, or 'corpuscular', in structure, and that its properties, on both the largest and the smallest scale, are ultimately a matter of mechanical interactions. Berkeley believed this idea to be fatal to religion and dangerous to morality; he thought also that he could show it to be philosophically absurd and untenable. His own sweeping solution, by which he believed that all could be set right at a stroke, was his denial of the existence of matter. For if there is no matter, there is nothing that mechanistic materialism can even pretend to be true *of*, and the pretensions of the physical scientist are completely undermined. Not surprisingly, a major theme of Berkeley's writings is his struggle to persuade his readers that, by the denial of the existence of matter, no one—other than the sinister physicist—need be surprised or disturbed. At no time was this struggle particularly successful. Berkeley's contemporary readers, to his chagrin and surprise, were inclined to praise him for his dialectical ingenuity, but to dismiss his conclusions as the paradoxes of an amusing Irishman.

Berkeley's middle years, from about 1722 until late in 1731, were almost wholly given over to a project for founding a college in Bermuda, intended for both indigenous and white colonial Americans. For this project he secured a charter from the king, the promise of a large grant from the public revenues, and wide support from individuals—on this topic at least, his powers of persuasion, supported by what all observers agree to have been great personal charm, proved most efficacious.

In September 1728 he set sail for Newport, Rhode

Island, where he built himself a house (which still stands) and waited for his project to mature. But he was disappointed. The pragmatic Sir Robert Walpole had always regarded the scheme as visionary, and, once Berkeley's persuasive presence was withdrawn, he worked quietly against it. The crucial grant was found at last not to 'suit with public convenience', and after three years in America Berkeley returned, emptyhanded, to London.

In 1734—in spite of having, as it appears, never once visited the Deanery he had held for ten years—he was appointed Bishop of Cloyne, in the extreme south of Ireland. Here in 1744 he published his strange work *Siris*, a disquisition on the supposed medicinal virtues of 'tarwater', decked out—in a manner astonishingly unlike that of his graceful, rapid, and lucid early writings—with an oppressive bulk of miscellaneous scientific, medical, and philosophical learning. It has been held that his enthusiasm for tarwater was eccentric enough to catch the professional eye of the psychoanalyst; but it must be remembered that, if Berkeley's medical opinions were somewhat wild and uncritical, they differed little in that respect from those of many of his contemporaries.

Berkeley died in January 1753, while visiting Oxford to supervise his second son's entry to Christ Church. The memorial tablet erected in the cathedral there is noteworthy in that, presumably on his widow's authority, it records his date of birth as six years earlier than it actually was.

THE MIND.

The complete and definitive modern edition is *The Works of George Berkeley* (ed. Luce, A. A., and Jessop, T. E.) (1949/57), 9 vols. London. The authoritative biography is Luce, A. A. (1949), *Life of George Berkeley*, London, published uniformly with the *Works*.

Bennett, J. (1971). *Locke, Berkeley, Hume*. Oxford. (An able, selective commentary on 'central themes'.) Foster, J. and Robinson, H. (eds.) (1985). *Essays on Berkeley: a Tercentennial Celebration*. Oxford. (A valuable

Page 83

able collection, issued to mark the tercentenary of Berkeley's birth.)

Luce, A. A. (1945). *Berkeley's Immaterialism*. London. (The work of a learned but somewhat uncritical partisan.) Pitcher, G. W. (1977). *Berkeley*. London. (An unusually detailed scrutiny, step by step, of the particular arguments by which Berkeley sought to support his conclusions.)

Tipton, I. C. (1974). *Berkeley: The Philosophy of Immaterialism*. London. (A notably careful and scholarly work, particularly useful on those topics, for instance Berkeley's theory of the mind, which other commentators have tended to neglect.)

Warnock, G. J. (1969). *Berkeley*, 2nd edn. London. (A general analytical survey, perhaps overstressing Berkeley's 'defence of common sense' and underplaying his very curious metaphysical and religious views.)

BERKELEY ON PERCEPTION. The principal sources for Berkeley's views on*perception are *An Essay towards a New Theory of Vision* (1709) and *A Treatise Concerning the Principles of Human Knowledge* (1710). The doctrines set out in these two works are not the same. But the explanation of that, according to Berkeley's own statement in the *Principles*, is not that he had changed his mind, but that in the *Essay*, the topic of which was specifically vision, he had deliberately suppressed—even misrepresented—his views on other matters, so as to avoid introducing too many novel doctrines all at once. The explanation seems odd, but there is no good ground for not accepting it.

In the *Essay* Berkeley has two principal aims. The first is negative. Raising the question how and why we make by vision—as on the whole we make pretty successfully—our everyday judgements of the sizes, distances, and positions of objects, Berkeley first contends—contrary to much current theorizing of his day—that such judgements are not made on the basis of a knowledge of optics. It may for example be true that, as an object recedes from us, the angle at which the optic axes converge upon it decreases; but since we do not see those axes or the angle at which they converge, that cannot explain why we judge the object to be receding. His point here, surely a correct one, is that the everyday visual judgements we all make of distance and size must be in some way based on how things look to us, not on theorems of optics which, however sound in their own sphere, cannot constitute direct visual evidence and for that matter are often totally unknown to persons of perfectly sound visual competence.

Berkeley then turns to the question of how it comes about that 'how things look' does enable us to make, on the whole, reliable judgements as to how things are. And here he offers the double contention that the connection between visual 'clues' and actual states of affairs, first, is learned only by experience, not calculable*a priori;

and second, is completely*contingent, and indeed arbitrary. In support of this contention he argues that objects are, strictly speaking, tangible objects only; they are not, strictly, literally seen—or, for that matter, heard. The 'proper objects' of hearing are sounds, and only indirectly or by inference the things that make sounds.

Similarly, he holds, there are purely visual 'proper objects' of vision; and we learn only by experience to make inferences from these 'proper objects' to states of (tangible) things. States of things are, as we learn by experience, fairly reliably correlated with the occurrence of distinctive purely visual objects; but these correlations, however reliable, are fundamentally quite arbitrary—like, for instance, the link between the word 'red' and the colour red. God maintains these correlations for the benefit of his creatures, so that the objects of vision can be said to constitute a 'divine visual language' by which, once we have learned it, we are 'told' about the tangible things in our environment.

Readers of the *Essay* must have been struck, even in 1709, by one conspicuous omission from it. John*Locke's many admirers, for example, would have agreed with Berkeley that the direct objects of vision were purely visual 'ideas', and that these were properly quite distinct from what they would have called 'external bodies'. But why say that the connection between visual ideas and states of things is *arbitrary*, maintained purely at God's pleasure? For surely it is *causal*. Was there not a well-established, or at any rate widely accepted, theory as to the causation of perception, according to which visual ideas, and for that matter all 'ideas of sensation', were the causal products of states of things and of their action upon our sense organs? Why is this theory, which at least appears to offer a unified, nonarbitrary explanation of the connections between our ideas of sensation, not even mentioned by Berkeley?

Berkeley's total rejection of that theory—Locke's so-called 'causal' or 'representational' theory of perception—is made clear in the *Principles*. The theory was that the universe is, fundamentally, a system of solid bodies in mechanical interaction; that the objects of everyday experience are themselves systems of 'corpuscles',

'insensible particles', in mechanical interaction; and that, in perception, these bodies act mechanically upon our various sense organs, causing ultimately, by way of causal chains in nervous system and brain, 'ideas of sensation' to occur 'in the mind'. Such ideas are the 'immediate objects' of perception, and inform us—or, so Locke held, in some cases *mis* inform us—to the existence and character of the 'external' bodies that are their originating causes.

Berkeley's chief grounds for rejecting this theory were these. First, he took it to be selfdefeating—if true, it could not be known to be true. For if the contents, the

'immediate objects', of perception are all, and only, *ideas*, what ground could there be in perception for supposing the existence of anything else? Second, and for much the same reason, he regarded the theory as ontologically redundant. Given observers ('spirits') and the ideas that they have, that actually

Page 84

constitute their experience, why add a supposedly distinct 'external' world which forms no actual part of anyone's experience at all? *Experience* would be just the same if no such world existed: why, then, suppose that it does exist? Now the answer to that question was supposed to be that the existence of 'external bodies'

causes and therefore *explains* the occurrence of ideas in our experience; but Berkeley's third contention is that that cannot be so. For, he asserts, only an active, animate being can be a cause; the only true case of causation is volition, intelligent agency, so that the mere mechanical happenings postulated in Locke's theory could in principle neither cause nor explain anything.

Berkeley's own views in the *Principles* could be said to take the form of a generalization, to all sensory modes, of the account of vision put forward in his *Essay*. He had held there that the 'proper objects' of vision are purely visual ideas 'in the mind', generated by the direct action of God so as to 'tell' us about tangible objects 'in circumambient space'. In the *Principles* he dispenses with those objects. Every sense, he now holds, even the sense of touch, has its own 'proper objects', all 'ideas', all 'in the mind'; there are (besides minds or 'spirits') *only* ideas; and God's work is now said to be, not merely that of informing his creatures by 'visual language' of independent things, but of so maintaining the complex correlations between *all* ideas, of *all* the senses, as to sustain in the experience of us all the apparent unity, continuity, and coherence of a common world. He claims for this extraordinary doctrine, first—surprisingly enough—that it accords with common sense. Locke, with his 'scientific' theory, had been obliged to shock us by concluding that the world is in many ways not as it appears; Berkeley holds that, on his view, the world is exactly as it appears—for, in fact, it *is* 'what appears', no more and no less. Then his doctrine is also, he claims, ontologically economical, nonredundant: to describe our experience we need nothing more than 'spirits' and 'ideas'; and Berkeley makes no further, gratuitous existential assumptions. Then, since the cause of ideas, in Berkeley's doctrine, is the will of God, he has, he claims, a real cause, a truly explanatory agency—and, last but for Berkeley not least, one that firmly entrenches theism in the nature of things, as the ground of all being.

What then of the 'scientific' theory of perception, according to which 'particles' acted on sense organs to cause sensation? Berkeley was at first inclined to dismiss all such talk as mere rubbish, to be simply abandoned. But later he contrived to accommodate this theory also, as not a genuinely causal theory, not really explanatory, and indeed not true, but a possibly *useful* purely theoretical construct to assist us in predicting how the true cause—God's will—was likely to operate in our experience. This was, indeed, his general account of all scientific theories which postulated entities not accessible to direct observation.

G. J. W.

BERKELEY ON THE MIND. The task of outlining Berkeley's theory of the mind is complicated by the fact that the work in which he was to treat at length of this topic was never published. His major work, *A Treatise Concerning the Principles of Human Knowledge*, as we now have it, was issued in 1710 as 'Part I'.

Apparently its account of perception and our knowledge of the external world was to be followed by a second and even a third volume, one dealing with the mind, and another with the principles of morality. It seems that the second volume was at least partly written; for in a letter of 1729 Berkeley says that 'the manuscript was lost about fourteen years ago, during my travels in Italy'. But that manuscript was never rewritten, and Berkeley's views on the mind have consequently to be collected, partly from brief passages in his published works, and partly also from his surviving private notebooks of 17078, which give many clues to what 'Part II' of his *Principles* was intended to contain.

We may consider first a certain view of the mind by which Berkeley was, not surprisingly, tempted, though he eventually rejects it. His term—shared with John*Locke—for the successive actual contents of experience is, of course, 'ideas'; and early in his notebook he had laid down (with his theory of perception in mind) the general principle that 'Language and knowledge are all about ideas, words stand for nothing else'. If so, then clearly language and knowledge about the mind must be 'about ideas'; and accordingly in later entries we find Berkeley saying that 'the very existence of Ideas constitutes the soul.... Mind is a congeries of Perceptions....

Say you the Mind is not the Perceptions but that thing wch. perceives. I answer you are abus'd by the words that & thing: these are vague empty words without a meaning.' These remarks of course suggest a theory of the mind resembling that later put forward by David*Hume—and much later by William*James and Bertrand*Russell—in which the mind is, not a persistent entity distinct from the contents of experience, but a 'logical construction' out of those contents themselves.

Such a view, however, is directly and flatly contradicted in the second paragraph of the *Principles*, where Berkeley writes: 'But, besides all that endless variety of ideas or objects of knowledge, there is likewise something which knows or perceives them; and exercises divers operations, as willing, imagining, remembering, about them. This perceiving, active being is what I call MIND, SPIRIT, SOUL or MYSELF. By which words I do not denote any one of my ideas, but a thing entirely distinct from them, wherein they exist, or, which is the same thing, whereby they are perceived.'

It is perhaps clearer why Berkeley rejected the Humean 'logical construction' view than what the view actually was with which he sought to replace it. He held—and this was indeed crucial in his criticism of Locke's 'causal' theory of perception—that ideas, and indeed any other nonanimate enti

ties if any others exist, are essentially 'inert', inactive, incapable of *doing* anything; and he no doubt took it, reasonably enough, that a 'congeries' of such inactive elements could not but be itself inactive. He came to regard it, by contrast, as the fundamental truth about the mind that it is essentially active—

and uniquely as well as essentially so, for he came to hold that mental agency was in fact the *only* case of real activity, of actual doing. That is why, in the passage quoted above, he was careful to speak of MIND as 'this perceiving, active being'; and it follows of course that he must regard such 'active beings' as 'entirely distinct' from ideas or any other inanimate items. It should be added that he does not mean to say that MIND is active in addition to perceiving; for he came to hold that perceiving, 'taking notice', is itself an act, not merely passive receptiveness. In one notebook entry he goes so far as to say, 'The soul is the will properly speaking', and in another asks 'Whether Identity of Person consists not in the Will'.

Since Berkeley held without question that we could speak intelligibly about, and have knowledge of, minds, then, since minds are 'entirely distinct' from ideas, he naturally had to modify his simple empiricist's maxim that 'language and knowledge are all about ideas'. He does little more, however, than concede that the case of minds is an evident exception to that principle. Though we have no idea of the mind, he says, we have—from our own case—a 'notion' of it; but what it is to have a

'notion' of the mind he then elucidates no further than to insist that 'we understand the meaning of the word'—which, though doubtless true, is unilluminating.

There is one further point, however, on which Berkeley is clear and explicit. While insisting that the mind is 'entirely distinct' from its ideas, he insists no less that it is *not* distinct from its 'acts'. Just as the existence of an inanimate thing consists in, *is*, its being perceived—just as its being perceived and its existing are not to be distinguished—so the existence of 'mind, soul, or spirit' is its acting, and so its acting and its existing are not to be distinguished. Hence Berkeley boldly asserts in the *Principles*, as if it were the most natural thing in the world, that 'it is a plain consequence that *the soul always thinks*'. Since the very existence of 'the soul' is thinking, the very notion of a mind not thinking, not active, is selfcontradictory.

Now this conclusion, as Berkeley was of course aware, at least appears to fly in the face of very obvious facts: for it at least appears to be a fact of common experience that, in the history of 'myself', there are intervals of complete unconsciousness in which the mind is inactive. Remarkably, of the possible ways of attempting to get round this difficulty Berkeley seems quite deliberately to choose the most extraordinary of all. In theory, he might have argued that, while my mind does not exist continuously through periods of complete unconsciousness, *I* do; it is, however, not realistic to suppose that Berkeley could have taken that line, since it requires a distinction between 'myself' and 'my mind' which (however wrongly) he would never have thought of making—like*Descartes, he took it for granted that a person is, and is only, a mind or 'spirit', a 'thinking thing'. Again, he might have argued that, through periods of what is commonly called unconsciousness, the mind is really in some way active after all; but that line has a decidedly *ad hoc*, unempirical look about it, and Berkeley seems never to have found it tempting. What he held at one time, boldly embracing the paradox, was that persons actually do not exist continuously; since the mind is active only intermittently, 'men die or are in state of annihilation oft in a day'. But that too he rejects; and the doctrine he finally adopts is the very extraordinary one that there can be in a person's life no periods of unconsciousness, since the passage of time itself is nothing but the succession of his 'perceptions'; we cannot ask what the position is *during* the mind's unconsciousness, for if the mind is not active there is no duration. It is

clear that, in this strange doctrine of 'private times', with its evident rejection of any public, objective timeordering, desperate paradoxes lurk; and one can only speculate how Berkeley might have tried to deal with them, or alternatively how he might have so modified his theory of the mind as to avoid them, if his projected second volume of the *Principles* had ever been completed.

See also LOCKE ON THE MIND.

G. J. W.

BERNSTEIN, NICHOLAS (Nikolai Alexandrovich, 1896-1966). Russian physiologist and founder of the school of the physiology of coordination and the

'physiology of activity'. Born in Moscow, the son of a well-known psychiatrist, Bernstein was a rare case of a scientist who practically devoted his whole life to one problem: the physiological mechanisms of human movements and motor actions.

A man of outstanding abilities, he started his work, when twenty years of age, with studies of human movements (gait, movements included in the process of work, etc.). The invention of a precise method for the recording of movements (a system of photographing lights fastened to the extremities, and interrupted by a rotating sector disc) made it possible to establish not only the trajectory of the movement but also changes of speed. These observations brought Bernstein to the statement that human movements have structures, and, though not repeating their form, always preserve their basic *scheme*, and that this scheme (clearly seen in writing movements) remains preserved, independently of which organ is involved in its production.

These studies of man's movements were followed by a careful analysis of the process of the development of motor skills. Bernstein observed that motor skills go through at least two basic developmental stages. In the first stage, motor

Page 86

action sometimes results in an inadequate movement, which is only secondarily corrected. During the second stage these 'secondary corrections' become 'primary corrections', when an adequate scheme of the movement is centrally elaborated and does not require a secondary correction of motor mistakes. As to the mechanism of regulation and coordination of movements underlying motor skills, Bernstein concluded that motor actions are based on the extremely complex apparatus of joints and muscles, which have practically infinite degrees of freedom, so that they change every moment according to changes in the position of the limbs and the density of muscles. Such complexity cannot be controlled by efferent impulses only; it requires a permanent system of afferent impulses, which give continual signals from the moving extremities and provide the basis for a self-regulatory movement system. This assumption, formulated by Bernstein in 1935, provided the starting point for the development of the theory of self-regulated motor systems and different levels in their organization (see CYBERNETICS). It was found that the 'afferent fields' could be arranged at different levels of the nervous system—beginning with the reflex or spinal level, going through the thalamostriatum level, or level of

coordination, and ending at the cortical levels required for the changeable spatial, or objectlinked and symbolically determined movements. These levels of organization of movements were described in Bernstein's *On the Construction of Movements* (1947), which gained him one of the highest prizes in the USSR.

The last part of Bernstein's work led him to a more complicated problem. As a physiologist, he had studied well-determined, reactive movements. However, the question of how to provide a scientific approach to man's *active* movements remained unanswered. Was a physiology of active processes possible?

Bernstein dedicated the remainder of his life to this problem and to creating a 'physiology of activity'. He supposed that feedback mechanisms are only a part of the regulating system, that 'feedforward mechanisms' have to exist, and he tried to explain their origin and their place in the organization of movements (see FEEDBACK

AND FEEDFORWARD). Every movement starts with a *goal*, and that goal provides a model of the future result, or, as Bernstein called it, a '*SollWert*'; the present position of the movement is reflected in an image of actual position—an '*IstWert*'. The whole sequence of the movements required emerges from the comparison of both, and can be designated as '*Wert*'. This '*Wert*' is a leading factor in the determination of the further sequences of the movements.

Bernstein's attempts to create a 'physiology of activity' were only the first steps in this field, the first attempts to move physiology from elementary theory of passive (reactive) processes to a theory of man's active processes. Although he could not, in

the short time left to him (he died before reaching 70), come to decisive conclusions on this very complicated problem, his attempts were highly regarded, and his ideas not only remained influential but became increasingly so among scholars of other countries.

' **BESIDE ONESELF** ' (with anger, grief, etc.). An English phrase suggesting that the individual is temporarily not, or is separated from, his usual self. The implication is that there are limits to how far the self can be different from or change from its usual character—before another self takes over. This is a possible basis for the notion of being *possessed*; and also of multiple personalities, as in the remarkable case of Sally Beauchamp, who was supposed to have several alternating selves or personalities. See DISSOCIATION OF THE PERSONALITY.

BIDWELL, SHELFORD (1848-1909). British physicist and barrister, born at Thetford, Norfolk, and

educated at Cambridge. After practising as a barrister for a number of years he devoted himself to scientific research, especially in electricity and magnetism and physiological optics. He was elected a Fellow of the Royal Society in 1888 and was President of the Physical Society (1897). In 1899 he published *Curiosities of Light and Vision*, enlarging a series of lectures he gave at the Royal Institution. The so-called Bidwell's ghost is a visual phenomenon associated with afterimages produced by alternating flashing lights.

BILINGUALISM, or polyglossia, refers to a person's ability to communicate in two or more languages. The phenomenon is found commonly in border regions, especially in those whose geographical boundaries change from time to time. Southeastern Poland, for example, was formerly part of the AustroHungarian Empire, making Austrian the official language for a population whose native language was Polish but which was in contact with neighbouring Ukrainian, Belorussian, and Slovakian communities, and whose religious groups included Orthodox, Roman Catholic, and Jewish. Thus Church Slavonic, Greek, Latin, Hebrew, and Yiddish were all likely to be used to varying degrees by inhabitants of the region, in addition to the Slavic languages. The phenomenon is also found in small countries that participate extensively in international relations: the Netherlands and Switzerland are especially wellknown examples. In the Netherlands, children characteristically have instruction in Dutch as a first language, begin a second, third, and fourth (English, French, or German) within a few years of each other, and, if they plan to go to university, add

Page 87

several years of Latin and perhaps some Greek. Most highschool graduates can manage to communicate in two foreign languages; fluency in three or four is common among university graduates. Bilingualism is encountered also in small countries experiencing substantial immigration or made up of disparate groups. It is estimated that peoples from more than ninety different language communities have emigrated to Israel since the 1930s. It is encountered in large countries also. In the Soviet Union, as in Iran, China, and India— countries comprising people of many different ethnic, linguistic, and religious backgrounds—a single 'national' language is inculcated as a unifying device, while the separate groups use their own languages for local communication. Even in a country where the languages share a common root, such as Italy, the regional variants may be almost mutually unintelligible. In all of these cases people who wish to communicate with others not in their immediate linguistic community are obliged to learn another language. The fact of two languages in a single person is commonplace in most parts of the world, but is still thought of as an oddity in many others. Most Englishspeaking countries seem to be among the latter group.

Bilingualism is actively studied by linguists who are interested in the way that speakers of one language accommodate the impact of another on their own; by sociologists and sociolinguists who trace change in social custom as a function of change in language; by teachers concerned to minimize the interfering effects of one language upon the learning of another; by psychologists who are interested in bilingualism as a natural laboratory for the study of the way the mind represents its knowledge; and of course by many others. The psychological issues are the most pertinent here.

One longstanding query has been whether instruction in a second language helps or hinders the

student. The question seems not to have been asked when several years of Greek and Latin were customary constituents of the young scholar's programme. It has come to be asked largely following the development of linguistic nationalism. Although first undertaken in the context of educating children in Welsh or Irish, the studies have been extended to the education of many groups in their native language. The findings have been that educating a child in one language interferes with his or her ability to pass examinations in a second, and the interference is greater the more 'minor' the one language and the more elaborate the second. Initially interpreted as evidence that bilingualism interfered with or lessened intellectual capability, the data are now seen as supporting the view that particular skills acquired through one language may not be wholly available for transfer to a second, especially if the two languages are quite different. No evidence has been accumulated to suggest that intelligence is lessened or heightened by instruction in one language or another; what has been shown is that skill in manipulating the dominant symbols of the culture is better acquired one way than another.

Languages are said to differ in their ability to express information in one or another area or on one or another topic. The classic examples have to do with the vocabulary for varieties of snow among some Eskimo, and for varieties of camel in Arabic. A considerable philosophy has been built on related observations. The term 'linguistic relativity' marks the view of the linguists E. Sapir and his student B. L. Whorf, which in its dogmatic form is called the Sapir-Whorf hypothesis: the language one uses controls the way one thinks about the world. This extends well beyond differences in vocabulary items of Eskimo and Arab—or of a vintner for wines, or a perfumer for smells, or any other specialized terms or jargon: the claim is that the mind works differently. In this claim Whorf seemed to identify language with thought—an equation few linguists, psychologists, or philosophers accept at present—and went on to confuse the ability to learn to make a discrimination with the readiness with which it is made. That is, Whorf used lexical and syntactic aspects of a language as evidence for procedures of mind, and in so doing seems to have used faulty reasoning to arrive at a plausible conclusion. The conclusion is that the symbols the mind uses in its activities actually affect the way the mind works. The interaction of symbol systems and mental operations is under present active study.

Languages do seem to differ in the ease with which they lend themselves to certain topical areas. Italian and French are rich and subtle in the areas of interpersonal relations, German lends itself easily to metaphysics, English dominates modern science—to name a few related languages. The structure of language, it has sometimes been suggested, also influences the way the mind works, perhaps in the way that speaking a particular language tends to shape the face. Whether a language requires many qualifications of the action before the action is named, or whether it is named first and then qualified; whether disparate items are stuck together to make new composites or whether features are analysed out and put into contrast; whether word order is a fixed or a free variable—these and other questions have been related to 'national character' and to mental activity. The topics are rich in speculation and poor in data.

They attract the psychologist's attention because of their relation to the topic of representation. Psychologists not only study the fact of behavioural change as a function of experience, but also try to give a plausible account of the means by which behaviour is controlled. Since what a person knows somehow affects what he or she does, some formalism is sought by the psychologist to accommodate the knowledge. That is, how knowledge is represented in mind and how best to represent it can be taken as important aspects of the psychologist's

Page 88

study. In this respect bilingual individuals are interesting test cases, for they can learn something through one of their languages and be tested for the knowledge through another; changes in performance as a function of changes in language can then sometimes be used to make plausible inferences about the mental operations underlying the behaviour. The findings suggest that knowledge is often situational and specific and that something learned through one language is not known to the person generally but is available to him or her only through that language. Recent evidence on the effects of stroke and related cerebral accidents upon language performance tends to bear out the supposition that knowledge and skill may be interfered with selectively, according to interference

with the means by which the knowledge or skill were acquired.

BILLS' BLOCKS. See ATTENTION, LAPSES OF.

BINARY DIGIT. See BIT.

BINAURAL HEARING. The use of both ears in order to locate the direction of sound sources. For frequencies lower than about 1,500 hertz the location is given by phase, or time, differences between the ears. For higher frequencies it is given by the different amplitudes of sound in the ears, as the head masks high-frequency sound from the further ear (see HEARING). (It is remarkable that the low-frequency phase detector resolves time differences between the ears of only a few microseconds.) The use of the two ears is important for understanding speech where there is an echo, as there is even in a normal room, the echo being suppressed by some unknown mechanism depending on binaural signals. For this and other reasons, binaural hearing aids can be significantly better than the more usual monaural aids, and are especially useful for blind people with impaired hearing, who make much use of binaural location of the direction of sounds. (See also AUDITORY

ILLUSIONS.)

BINET, ALFRED (1857/1911). French psychologist, born at Nice. He became director of the department of physiological psychology at the Sorbonne in 1892.

With Theodore Simon, he was responsible for the design and standardization of the first formal intelligence tests—the 'Binet scale'—originally devised at the request of the French Government in order to establish which children were or were not worthy to benefit from education.

He instigated the concept of intelligence quotient (IQ), i.e. chronological age divided by mental age, multiplied by 100, which has been widely used ever since to

'measure' the intelligence of children and, in somewhat modified form, that of adults too. Indeed, the notion that individuals are born with all potential ability assessed along a single continuum is widely

regarded as one of the most notable achievements of modern psychology; and yet it may be both conceptually and socially misguided and has led to race and sex rivalries. In spite of extensive research, it still remains unclear how far the IQ score represents actual ability and whether it is genuinely predictive of intellectual accomplishment. At all events, the recent tendency is to interpret the results of intelligence tests only with extreme caution.

Binet's most important book was *L'Étude expérimentale de l'intelligence* (1903). But he also wrote books on many other psychological subjects, including hypnosis and suggestibility, and the psychic life of microorganisms.

O. L. Z.

BINOCULAR VISION. The use of the two eyes, which in many animals and in man gives*stereoscopic or 3D vision. Sensitivity to very dim light is also improved with two eyes instead of one, just as though the second eye belonged to another observer. The increased probability of capturing photons precisely describes the increase in visual efficiency. Stereo depth is given by neural computation of the slight shift in position of corresponding points in the retinas due to the separation, and so slightly different viewpoints, of the two eyes. This combining of the different signals from the two eyes to give a single (stereoscopic) perception is remarkable, and from recent experiments is now coming to be understood (see VISUAL SYSTEM: ORGANIZATION).

When the differences between the eyes' images are too great, fusion fails, and there is either 'rivalry' or rejection altogether by one 'lazy' eye.

BIOFEEDBACK, It is selfevident that many of our physiological processes are not under our voluntary control. We cannot, for instance, decide to alter our bloodpressure or our heartrate and successfully accomplish the change in the direction and to the extent desired. One of the reasons why voluntary control is not possible in such cases is that we do not consciously sense their current state.

Biofeedback is a term used to describe a series of techniques that aim to provide us with such information, and hence enable us to exercise some degree of voluntary control over the particular physiological function under consideration. What these techniques have in common is that relevant information about the process involved, e.g. muscle tension, heartrate, and bloodpressure, is monitored, usually by an electronic device of some

sort, and displayed to the person himself, usually in a visual or auditory form, or less usually in some other modality.

The general term '*feedback' was coined by Norbert*Wiener, who defined it as 'a method of controlling the system by reinserting into it the results of its past performance'. Such feedback is common in biological systems and, indeed, no creature would survive were it not for such selfregulation. Through feedback we come to learn to coordinate and control our limbs, through sight and kinaesthesia for example, and to coordinate hand and eye by means of visual and proprioceptive feedback, and, at a higher level, to solve problems mentally from the*memory systems without which

we could not process linear inference. By means of equipment such as transducers, amplifiers, and visual and auditory displays, we can artificially extend such a principle to parts of the biological system that do not have such conscious feedback, in the expectation that the subject can learn to control a particular physiological function in a manner similar to the way he can in those parts of the system with integral feedback loops. How such control is achieved is still a matter of considerable controversy.

The beginnings of biofeedback go back to the late 1960s. As with other so-called departures in psychology, there were earlier examples. The work of Alexander Graham Bell (1847-1922), the inventor of the telephone, with the deaf, and his interest in using the visible display of speech sound, either by means of 'manometric'

flames or by an early form of kymograph, in order to help the deaf to reproduce correct sounds, would seem to utilize feedback principles (Bruce, 1973). However, it needed a dramatic event to focus attention on the area of feedback control. This event took place at the 1967 annual meeting of the Pavlovian Society of North America in the form of a report by Neal Miller (1968). He introduced a technique that his colleague, Jay Towill, had first devised. This involved immobilizing animals with D-tubo curarine, artificially respirating them, and with electrodes placed in the so-called 'pleasure-centres' in the brain, operantly conditioning various physiological systems. For example, it was reported that the animal could learn, through operant conditioning, to increase or lower blood pressure, increase or decrease heart rate, kidney flow, and so on. The reward was, in each case, a brief electric pulse delivered to the pleasure centres. The use of D-tubo curarine to produce paralysis of skeletal muscles was an attempt to avoid the possibility that the animal was modifying its autonomic responses via voluntary activities, such as changes in muscle tension or breathing pattern or rate. Research papers soon followed, and in a series of studies carried out with Leo DiCara on the curarized rat, the instrumental conditioning of heart rate, blood pressure, renal blood flow and—in collaboration with A. Banuazizi—contraction of the intestines, appeared to be demonstrated. Reports from other laboratories seemed to support Miller's findings.

These results conflicted with a prevailing bias in experimental psychology of learning that divided learning processes into two classes: Pavlovian, classical or respondent conditioning, and instrumental or operant conditioning. The former applied to autonomic and visceral learning and the latter only to the external behaviours mediated by skeletal muscles. Miller's work, and that of others at the time, led to a less rigid distinction between classical and instrumental conditioning, and the different order of control of the skeletal nervous system and the autonomic nervous system. Hence it paved the way for an acceptance of the idea that autonomic functions could be brought under voluntary control.

Miller (1974) subsequently found that he could not replicate the results he had previously reported of operant autonomic control under curare, and finally admitted that he was uncertain as to whether he had ever genuinely demonstrated the instrumental conditioning of autonomic function in the rat.

From the time of Miller's early reports there has been an escalation of research work in, and clinical applications of, biofeedback techniques, together with a growing public interest. Three main factors

have contributed to this: (i) the potential practical clinical application of biofeedback; (ii) the development of technical means for investigating biofeedback effects and for displaying feedback; and (iii) a belief among certain sections of the community, even some scientists, that it might provide a route to higher states of consciousness, to greater 'awareness' and 'fulfilment of life', to greater creativity and more efficient cognitive activity. So far, however, in spite of the continuing enthusiasm and the many claims made for its efficiency both as a clinical tool and when applied in normal psychology, as an experimental technique biofeedback has still not been thoroughly evaluated, and studies involving its clinical application have outstripped by far those concerned with fundamental research issues.

A typical example of applied biofeedback, and one which has generally been considered formative in one area, is the early work of Budzynski *et al.* (1973) on electromyographic (EMG) biofeedback and tension headache. It was based on the belief that tension headaches are associated with higher resting levels of frontalis muscle tension (measured by EMG methods). Consequently, since the immediate cause of pain with tension headache is usually sustained contraction of the muscles of the scalp and neck, patients would obtain alleviation of the pain if they could be trained to relax these muscles (the evidence concerning this supposed relationship between tension headache and frontalis muscle activity is equivocal). Volunteer patients who suffered from tension headaches (characterized by a dull 'bandlike' pain located bilaterally in the occipital region, although often

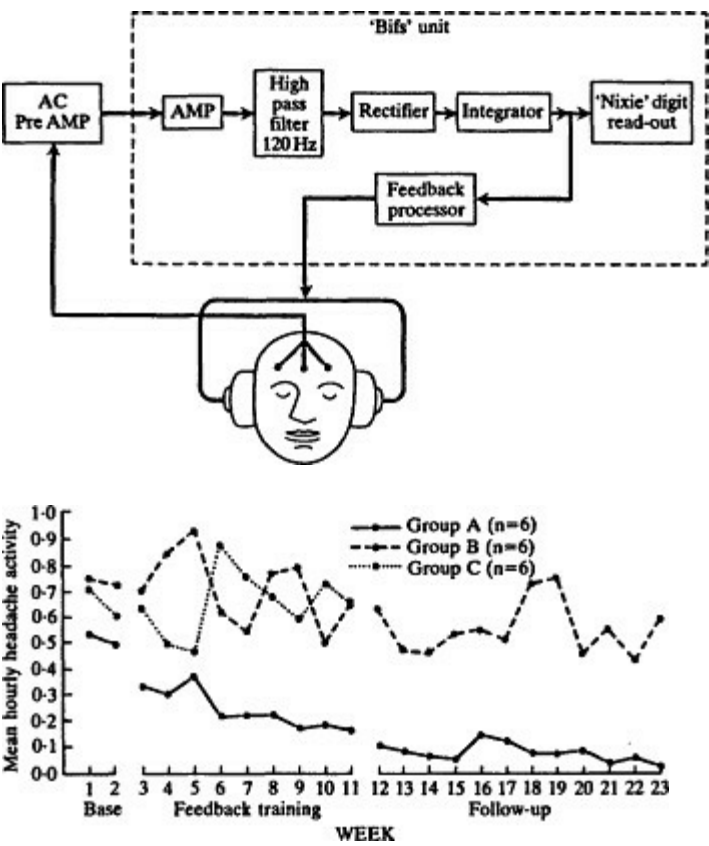

Fig. 1.

Functional diagram of the EMG feedback system.

felt in the forehead region as well, which is gradual in onset and may last for hours, weeks, and even months) were trained to relax their frontalis muscles with the aid of biofeedback. This took the form of a series of clicks in the headphones that the patient wore during training sessions. The clickrate was proportional to muscle tension. The higher the tension in the forehead, the faster the clickrate. The patient had EMG electrodes applied to the skin over the area of the frontalis muscle and connected to an electronic feedback system, which transformed the EMG level as picked up through the electrodes into a series of clicks whose rate was proportional to the measured tension (Fig. 1). He attempted to lower the clickrate by progressively relaxing the muscle.

As this was intended to be a controlled outcome study, there were two other groups of patients included in order to test for placebo or suggestion effects. The members of one of these control groups received false feedback (i.e. clicks from a previous successful patient) which appeared to indicate their success in muscle relaxation; the other control group received no treatment. The results showed that the group receiving real biofeedback experienced a significant reduction both in frontalis muscle tension and in headache activity (Figs. 2 and 3). Followup data reported a dramatic decrease in drug usage, tiredness, and insomnia, and a general increase in wellbeing, in the feedback group—and indeed some changes were also reported in the pseudofeedback group.

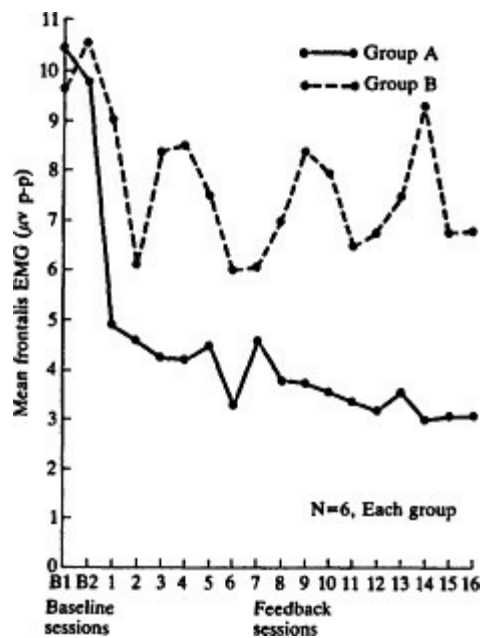

In spite of the reported success of this study, however, there were many theoretical issues which had not been resolved. The supposed causal relationship, e.g.

between frontalis muscle activity and tension headache, had not been conclusively demonstrated, nor had it been shown that frontalis muscle tension reduction training was superior to general relaxation training. Subsequent studies have failed to resolve these issues unequivocally. The relative success of this study and the issues that it fails to resolve are typical of much of the extensive work carried out on biofeedback since the late 1960s. The studies have been very varied. Apart from the work on tension headaches, clinical applications of biofeedback have been used with patients suffering from migraine headaches, peripheral vascular disorders such as Raynaud's disease, insomnia, cardiac arrhythmias, hypertension, asthma, epilepsy, anxiety, neuromuscular disorders, chronic pain, dental disorders, and Fig. 2.

Headache activity during feedback training (all three groups)

and during the threemonth followup (Groups A and B only). Group A,

true feedback; Group B, pseudofeedback; Group C, no treatment.

Page 91

speech, hearing, and reading disorders. They have also been used with hyperactive and learningdisabled children. In most of the areas studied biofeedback therapy appears to work, but no reported study has so far demonstrated that the active element responsible for the observed change, when it occurs, is in fact biofeedback *per se*.

There are several reasons for this state of affairs. First, there is the enthusiasm from clinician and patient alike that greets most innovative therapy, especially if some success is apparent; and, as Miller (1978) has pointed out, there is a wonderful tendency on the part of the body to heal itself, with or without treatment. Thus, as many chronic conditions fluctuate, it is likely that the patient will seek treatment when he feels worse than usual and claim relief, if not cure, when he feels better than usual. Further, many patients show a profound placebo effect and are likely to feel better because they are receiving 'expert' attention. Such nonspecific treatment effects are present in all clinical procedures and are likely to be particularly profound in all psychotherapeutic relationships. In general, in clinical biofeedback, there has been too great an emphasis on the widespread application of biofeedback therapy and too little attention paid to the models and underlying theoretical conceptualizations of the disorders and treatments.

Apart from those already mentioned, biofeedback studies have given rise to a number of theoretical problems. One of these, arising out of the reported evidence of instrumental learning of autonomic functions, is the socalled mediation issue. This is concerned with whether the observed changes in autonomic functions are really learned or whether they are, for instance, mediated reflexively, consequent upon somatic or cognitive change. (It was in order to control for somatic mediation that

Miller used D-tubocurarine to produce paralysis of the rats' skeletal muscles in his original feedback experiment.) With regard to the possibility of cognitive mediation, several studies have shown that cognitive activity, such as internally generated thoughts, and expectations induced by the instructions given to the subject, may play a part in feedback training, although this effect probably varies with the specific function being trained. The relatively small number of studies in which imagery has been used have not as yet confirmed its popularly believed role as a mediator in some feedback learning. Certain logical considerations complicate the issue. These have to do with the direction of the supposed mediation. Is the cognitive state a determinant of the observed autonomic change, or vice versa? Or are they both consequent upon activity elsewhere?

Such complication is pertinent to the possible role of somatic mediation also, and several investigators questioning the legitimacy of the mediation issue as a criticism of studies indicating autonomic learning, have considered alternative models in which autonomic, cognitive, and somatic responses are all mediated at a higher neural level. The question then becomes 'what specific functions can be voluntarily controlled'? The role of muscular and respiratory activity (itself muscular) has been investigated. Biofeedback studies directed towards resolving this issue, in relation to attempts to control heart rate, for example, generally indicate that somatic mediators can be utilized in heart rate control, although whether they are necessary as well as sufficient is not known. This is a general problem.

Apart from the mediation issue, other problems remain unresolved. Does reinforcement play any role in the learning of voluntary control over those physiological functions not normally subject to such control? Does the information fed back to the subject act as a reinforcer which makes the voluntary control of the function more likely in the future, or is the role of reinforcement one of increasing motivation, the subsequent change being attributed to the feedback of information? This issue, like so many others, still remains to be resolved, although the weight of evidence at the moment would appear to support the latter view that there is feedback of information.

Yet another problem, and one related to the mediation issue, concerns the 'control' that biofeedback techniques are designed to help the subject learn. The use of biofeedback equipment which senses somatic changes and displays them to the subject in some form is a temporary device, later to be discarded when the subject has learned how to 'control' the function. In what way does he

Page 92

'know' what to do when the equipment is withdrawn? Neither he nor the therapist or experimenter knows! He cannot say how he is exercising any control, nor can the therapist tell him. In short he appears to be learning some sort of functional body language which defies adequate description.

Perhaps we should not be surprised at this state of affairs because a very similar situation obtains in many of our natural so-called volitional functions. We do not, for instance, know 'how' we are doing it when we retrieve information from our memory store, nor indeed 'how' we are organizing our thoughts into sentences. If, as seems likely, the 'language' we learn involves processing at a higher nervous level (the brain presumably), then we may never completely resolve this issue.

Another difficulty, and one probably inherent in many biofeedback studies, has to do with the possibility of inherent biological constraints. Organisms can only learn to modify functions within possible physiological limits. Some limitations in control may arise because of such constraints. It has been suggested, for instance, that the greater incidence of success in studies aimed at accelerating the heartrate than in those with deceleration as the aim, can be put down to a postulated constraint that works against the production of largemagnitude decreases in heartrate (Schwartz, 1975).

Individual differences undoubtedly play an important role in biofeedback studies—although positive results abound there is a very large variability in the ability of subjects to achieve control. The factors underlying such individual differences have yet to be discovered. Nonspecific or placebo factors undoubtedly play some part and confuse many studies, and they need to be investigated and controlled if the true nature of biofeedback control is to be exposed. Clarification of the issue would enable the clinician to utilize those factors to advantage in treatment—especially as it is unlikely that he will ever be able to remove them.

Finally, although the nature of biofeedback still needs to be elucidated, and the final evaluation of clinical biofeedback is still awaited, work directed towards the former will teach us much about the mechanisms of volitional control and the role of internal systems involved in an organism's adaptation to its environment, and work directed towards the latter may well indicate that in some circumstances biofeedback may become the preferred alternative to other treatments, especially where their efficacy is questionable or their sideeffects undesirable. Further, clinical biofeedback has the great merit that it emphasizes the role of the patient in determining the course of the treatment and in taking an active role in it. This is likely to prove one of its most positive aspects.

Anybody who has crossed the Atlantic in an aeroplane knows about 'jet lag'. After a journey from London to New York it is difficult to stay awake, while after the return journey one tends to wake up late. Man's body is intolerant of changes in clock time and it takes several days to readjust to a new local time.

The same is true of practically all other animals, not very surprisingly, because we all live on the same planet and experience the same 24hour cycle as the earth rotates. Mice, birds, and men eat and sleep at particular times of day, depending on their species, and if they are placed (or choose to place themselves) in unvarying habitats such as laboratories or down a mine they will generally retain these regular habits. The cycle tends to drift a little, with the animal waking a few minutes earlier or later on each succeeding day, but it remains amazingly constant in duration. The rhythm of the body's activities can be reset by a new time of sunrise, or by a series of nightshifts at a factory, but it cannot be substantially altered: man can be induced to live on a 23 or 25hour cycle (by speeding up or slowing down his watch), but a 12 or 18hour day seems impossible.

Shoreliving invertebrates typically show an additional 'tidal' cycle, which has obvious adaptive significance, and many also show longerterm rhythms, coincident with the phases of the moon; species may spawn only at spring tides, or even only at spring tides at a particular time of year. Even annual rhythms may persist in constant conditions: weaverbirds, for instance, build nests and lay eggs at the 'correct' time of year for at least two

Page 93
years when deprived of daylength or temperature cues to the time of year.

There are also much shorter cycles—activities that are repeated every few seconds or minutes. Many sessile, burrowing, and boring animals lead monotonous lives in almost constant conditions and show these shorter rhythms very clearly. As with the circadian (*circa diem*, almost 24hour) cycles, the rhythms tend to persist when all obvious sources of stimulation (even food) have been eliminated; they seem to be generated from within, rather than caused from outside.

The conclusion is that an animal contains one or more 'biological clock' (but the existence of several different rhythms in one animal does not necessarily imply several clocks—it could be a matter of gearing); and a great deal of research has gone into establishing the whereabouts of the mainsprings. A recurrent problem is that because a body's various activities are interrelated, most if not all of its tissues operate to a cycle, and how does one distinguish between the mainspring and the rest of the clockwork? One approach is to determine which of the tissues will continue to perform rhythmically

in isolation, although it is difficult to keep most tissues alive in a testtube, and even if one succeeds it is impossible to be certain that the tissue is behaving normally. The method is useful in the study of shortterm cycles, however, and there are now a number of welldocumented cases in which individual nerve cells have repeated regular patterns of electrical discharge over periods of hours or even days. The matter can be followed further into the cell, which may show cyclic changes in ribonucleic acid (RNA) content.

But where and how does the timing originate? Some argue that there is no endogenous clock and that the rhythms observed are driven from outside. It is impossible to disprove this, although in laboratories it is relatively easy to screen animals and plants (even potatoes show rhythmic cycles in respiration rates) from changes in lighting, temperature, and vibration. It is difficult, however, to screen them from daily changes in weak magnetic fields (and many are known to respond to these) and quite impossible to screen them from cyclic geophysical events such as the varying pull of the moon. Eventually the use of orbiting laboratories may help; in the meantime conventional wisdom holds that truly endogenous clocks are likely, even though it can offer no convincing models of how they may be engineered.

BIT. The binary digit, or 'bit' as it is termed, is the primary unit for measuring information and uncertainty. The bit is a yes/no decision, which may be represented in an information system, or computer, by the two positions of a simple onoff switch.*Digital systems are based on 'bits', and their speed may be specified as their maximum 'bit rate'.

The 'Dictionary Game' illustrates very clearly how dividing a set of possibilities into two, and then this set into two again, then again, can lead very quickly to finding a particular item. Any word can usually be located with a dozen questions of the form: 'Is the word before "G"?' or 'Is it after "D"?' ... But this works only when the items are arranged in some kind of order, such as alphabetical, or numerical. It is, however, just possible that at least some memories may be selected or accessed in this kind of way, by branching search strategies.

In*information theory (Shannon and Weaver, 1949), information is related mathematically to uncertainty; for it takes more information to specify a particular specific alternative item from many possibilities than from few possibilities. As the number of alternatives increases, so more bits are needed to select one of them. The number of bits required is the logarithm, to the base 2, of the number of alternatives. So for dice, there are six possibilities for a die, and the uncertainty for each face or number on the die is $\log 6 = 2.58$. For drawing a card from a pack of 52 cards, $\log 52 = 5.70$. Thus, for the die two or three questions will determine the number, and five or six questions will identify a card.

Many experiments have been aimed at measuring the 'bit rate' for human performance, first defined by W. H. Hake and W. R. Garner (1951). Their subjects identified positions of a pointer on a linear scale, with various possible positions for the pointer. With five positions the subjects lost no information, but with 10, 20, or 50

alternatives the transmitted information was effectively constant, at about 3·0 bits. People can only identify about nine points on a line; increasing the number of alternatives does not increase the amount of information transmitted. The human bit rate for choices along a single dimension is about 3·0 bits, but this rises with more dimensions (for example, recognizing positions of a dot on a square, with a short exposure time) up to about 9 bits. Long practice may raise the bit rate somewhat.

H. Quastler and V. J. Wulff (cited in Attneave, 1959) have estimated bit rates for various human skills. For a pianist playing random notes, the bit rate may be as high as 22 bits per second. The skilled pianist learns to '*chunk' notes into familiar chords—each being a single selection—so his effective performance may be much better. Typing is limited to about 15 bits per second. Speech can be as high as 26 bits per second, though around 18 is normal. It has been estimated that silent reading may be as high as 44 bits per second. Mental arithmetic by a 'lightning calculator' was estimated at about 24 bits per second: about the same as that of a pianist.

Page 94

The pioneering experiment by Edmund Hick (1952), which measured the 'rate of gain of information' by getting subjects to press a key corresponding to a light, with various numbers of keys and lights, showed that*reaction time increases logarithmically as the number of choices (the number of lights and keys, one for each finger) increases. There is, however, a deep problem for this or any other technique for measuring the bit rate for the human nervous system—for we are never quite limited to the alternatives provided by the experimenter. Thus, the subject in Hick's experiment (actually the editor of this Companion to the Mind!) was not deaf, or blind, to everything except the lights to which he was responding, so that his range of possibilities was always greater than the experimenter knew, or could take into account.

Possibly*attention serves, consciously or unconsciously, to limit possibilities to what are likely to be relevant: to make best use of our limited human bit rate.

BLACK. The visual sensation associated with lack of, or sudden reduction in, light. Black is not

absence of visual sensation but is sensationally a colour. If we think of what is behind the head, we experience *nothing*—which is very different from black. (See NOTHINGNESS.) **BLEULER, EUGEN** (1857-1939). Swiss psychiatrist, educated at the University of Zurich, where he became professor of psychiatry. He undertook major studies of schizophrenia and suggested that this term, rather than *dementia praecox*, be used to describe the disorder.

BLINDNESS, RECOVERY FROM. What would an adult who had been blind all his life be able to see if the cause of his blindness was suddenly removed? This question was asked by several empiricist philosophers in the eighteenth century. John*Locke considered the possibilities of such a case in 1690, following the question posed in a letter from his friend William Molyneux:

Suppose a man born blind, and now adult, and taught by his touch to distinguish between a cube and a sphere of the same metal. Suppose then the cube and the sphere were placed on a table, and the blind man made to see: query, whether by his sight, before he touched them, could he distinguish and tell which was the globe and which the cube? ...

The acute and judicious proposer answers: not. For though he has obtained the experience of how the globe, how the cube, affects his touch, yet he has not yet attained the experience that what affects his touch so or so, must affect his sight, so or so....

Locke comments in the *Essay concerning Human Understanding* (1690), Book II, Ch. 9, Sect. 8: I agree with this thinking gentleman, whom I am pleased to call my friend, in his answer to this problem; and am of the opinion that the blind man, at first, would not be able with certainty to say which was the globe, which the cube....

René*Descartes, in a passage in the *Dioptrics* (1637), considers how a blind man might build up a perceptual world by tapping around him with a stick. He first considers a sighted person using a stick in darkness. Descartes must surely have tried this for himself, and perhaps actually tested blind people. He says, of this experiment:

... without long practice this kind of sensation is rather confused and dim; but if you take men born blind, who have made use of such sensations all their life, you will find they feel things with perfect exactness that one might almost say that they see with their hands....

Descartes goes on to suggest that normal vision resembles a blind man exploring and building up his sense world by successive probes with a stick.

George*Berkeley, in *A New Theory of Vision* (1709), Sect. lxxxv, stresses the importance of touch for seeing by considering that a microscope, by so changing the scale of things that touch no longer corresponds to vision, is of little use; and so, if our eyes were '... turned into the nature of microscopes, we should not be much benefited by the change ... and (we would be) left only with the empty amusement of seeing, without any other benefit arising from it' (Sect. lxxxvi). Berkeley goes on to say that we should expect a blind man who recovered sight not to know visually whether anything was high or low, erect or inverted ... for the objects to which he had hitherto used to apply the terms

up and down, high and low, were such as only affected or were in some way perceived by touch; but the proper objects of vision make a new set of ideas, perfectly distinct and different from the former, and which can in no sort make themselves perceived by touch (Sect. xcv).

These remained interesting speculations, until in 1728 an unusually expert and thoughtful surgeon, William*Cheselden, reported such a clinical case. Though generally distinguished as a surgeon his achievements were especially ophthalmic operations for cataract (Cope, 1953). In a celebrated case Cheselden gave sight to a boy aged thirteen or fourteen who was born with highly opaque cataracts. Cheselden reported that:

When he first saw, he was so far from making any judgment of distances, that he thought all object whatever touched his eyes (as he expressed it) as what he felt did his skin, and thought no object so agreeable as those which were smooth and regular, though he could form no judgment of their shape, or guess what it was in any object that was pleasing to him: he knew not the shape of anything, nor any one thing from another, however different in shape or magnitude; but upon being told what things were, whose form he knew before from feeling, he would carefully observe, that he might know them again; and (as he said) at first learned to know, and again forgot a thousand things in a day. One particular only, though it might

Page 95

appear trifling, I will relate: Having often forgot which was the cat, and which the dog, he was ashamed to ask; but catching the cat, which he knew by feeling, he was observed to look at her steadfastly, and then, setting her down, said, So, puss, I shall know you another time. He was very much surprised, that those things which he had liked best, did not appear most agreeable to his eyes, expecting those persons would appear most beautiful that he loved most, and such things to be most agreeable to his sight, that were so to his taste. We thought he soon knew what pictures represented, which were shewed to him, but we found afterwards we were mistaken; for about two months after he was couched, he discovered at once they represented solid bodies, when to that time he considered them only as partycoloured planes, or surfaces diversified with variety of paint; but even then he was no less surprised, expecting the pictures would feel like the things they represented, and was amazed when he found those parts, which by their light and shadow appeared now round and uneven, felt only flat like the rest, and asked which was the lying sense, feeling or seeing?

Being shewn his father's picture in a locket at his mother's watch, and told what it was, he acknowledged the likeness, but was vastly surprised; asking, how it could be, that a large face could be expressed in so little room, saying, it should have seemed as impossible for him, as to put a bushel of anything into a pint. At first he could bear but very little light, and the things he saw, he thought extremely large; but upon seeing things larger, those first seen he conceived less, never being able to imagine any lines beyond the bounds he saw; the room he was in, he said, he knew to be but part of the house, yet he could not conceive that the whole house could look bigger. Before he was couched, he expected little advantage from seeing, worth undergoing an operation for, except reading and writing; for he said, he thought he could have no more pleasure in walking abroad than he had in the garden, which he could do safely and readily. And even blindness, he observed, had this advantage,

that he could go anywhere in the dark, much better than those who can see; and after he had seen, he did not soon lose this quality, nor desire a light to go about the house in the night. He said, every new object was a new delight; and the pleasure was so great, that he wanted words to express it; but his gratitude to his operator he could not conceal, never seeing him for some time without tears of joy in his eyes, and other marks of affection.... A year after first seeing, being carried upon Epsom Downs, and observing a large prospect, he was exceedingly delighted with it, and called it a new kind of seeing. And now being couched in his other eye, he says, that objects at first appeared large to this eye, but not so large as they did at first to the other; and looking upon the same object with both eyes, he thought it looked about twice as large as with the first couched eye only, but not double, that we can in any ways discover.

Evidently the sensory worlds of touch and vision were not so separate as at least Berkeley imagined they would be, and visual perception developed remarkably rapidly. This was discussed in terms of the Cheselden case by the materialist philosopher Julien Offray de*La Mettrie, in his dangerously challenging book, *Natural History of the Soul* (1745), where he argues that only education received through the senses makes man man, and gives him what we call a soul, while no development of the mind outwards ever takes place. A few years later, in his better known *Man A Machine* (1748), he says: Nothing, as any one can see, is so simple as the mechanism of our education. Everything may be reduced to sounds or words that pass from the mouth of one through the ears of another into his brain. At the same moment, he perceives through his eyes the shape of the bodies of which these words are arbitrary signs.

The findings of the Cheselden case (which, though by no means the first, is the first at all adequately reported) are confirmed by some later cases, though in others the development of perception is painfully slow. R. Latta described a case of a successful operation for congenital cataract in 1904, which was broadly similar with almost immediately useful vision; but very often the eye takes a long time to settle down after a cataract operation. This may explain why so many of the historical cases described by M. von Senden (1932) showed such slow development. This is, however, a controversial matter. The Canadian psychologist Donald Hebb, in *The Organization of Behaviour* (1949), attributed the general slowness to see after operation as evidence that a very great deal of learning is needed. This, indeed, is now generally accepted, but it remains a question how far previously gained knowledge from exploratory touch, the other senses, and from the reports of sighted people helps newfound vision.

The case of a man who received corneal grafts when aged 52 (Gregory and Wallace, 1963) has the advantage over previous cases that a good retinal image is immediately available after corneal grafts as the eye is far less disturbed than by a cataract operation. In this case the patient, 'S. B.', could see virtually immediately things he already knew by touch; though for objects or features where touch had not been available a long, slow learning process was required, and in fact he never became perceptually normal. It was striking that he had immediate visual perception for things that absolutely must have been learned while he was blind, and could not have been known innately. Thus, from extensive experience of feeling the hands of his pocket watch, he was able, immediately, to tell the time visually. Perhaps even more striking, as a boy at the blind school S. B. had been taught to recognize by touch capital letters which were inscribed on special wooden plates. This was useful

for reading street names, brass plates, and so on. Now it turned out that he could immediately read capital letters visually, though not lowercase letters, which he had not been taught by touch. These took months to learn to see. The general finding, of this case, was dramatic transfer of knowledge from touch to vision. So S.

B. was not like a baby learning to see: he already knew a great deal from touch, and this was available for his newly functioning vision.

He had difficulties with shadows. When walking on steps on a sunny day he would quite often step on the shadow, sometimes falling. He was remarkably good at judging horizontal though not vertical distances. Thus while still in the hospital he could give the distance of chairs or tables almost Page 96

normally; but when looking down from the window he thought the ground was at touching distance though the ward was several stories high. When he was shown various distortion*illusions it was found that he was hardly affected by them: they were almost undistorted. And he did not experience the usual spontaneous depthreversals of the Necker cube—which appeared to him flat. Indeed, like the Cheselden case, he had great difficulty seeing objects in pictures. Cartoons of faces meant nothing to him. He also found some things he loved ugly (including his wife and himself!) and he was frequently upset by the blemishes and imperfections of the visible world. He was fascinated by mirrors: they remained wonderful to the end of his life. As for most of the cases, though, S. B. became severely depressed, and felt more handicapped with his vision than when blind.

A dramatic and revealing episode occurred when he was first shown a lathe, at the London Science Museum, shortly after he left hospital. He had a longstanding interest in tools, and he particularly wanted to be able to use a lathe.

We led him to the glass case, and asked him to tell us what was in it. He was quite unable to say anything about it, except he thought the nearest part was a handle. (He pointed to the handle of the transverse feed.) He complained that he could not see the cutting edge, or the metal being worked, or anything else about it, and appeared rather agitated. We then asked the Museum Attendant for the case to be opened, and S. B. was allowed to touch the lathe. The result was startling; he ran his hands deftly over the machine, touching first the transverse feed handle and confidently naming it 'a handle', and then on to the saddle, the bed and the headstock of the lathe. He ran his hands eagerly over the lathe, with his eyes shut. Then he stood back a little and opened his eyes and said: 'Now that I've felt it I can see.' He then named many of the parts correctly and explained how they would work, though he could not understand the chain of four gears driving the lead screw.

Many of these observations have been confirmed by Valvo (1971) in half a dozen cases of recovery from blindness by a remarkable operation: fitting *acrylic* lenses to eyes that never formed completely. Tissue rejection of the artificial lenses was prevented by placing them in a tooth, which was implanted as a buffer in the eye. One of these Italian patients, wearing a lens in a tooth in his eye, is a philosopher! It is now possible to implant artificial lenses without tissue rejection, so perhaps more cases of adult recovery from infant blindness will now appear.

BLINKING. When the eye is irritated by a foreign body, such as grit or a fly, we blink to remove it. This is a*reflex, and there is also reflex dosing of the eyes to prevent damage when we sneeze; but everyday blinking is not a reflex activity. A reflex needs an initiating signal; but if, for example, the eyes had to dry up to initiate blink signals, the blink would follow the beginnings of damage, due to the eyes drying, for it would be too late to protect the delicate corneas with a film of tears.

Normal blinking is initiated by signals initiating in the brain, probably from the*basal ganglia. Rather surprisingly, the rate of blinking is a useful index of general attention, as it tends to increase markedly at times of*stress or distraction and it falls below the normal resting rate during extended periods of high concentration. This is possibly related to its early use in conditions such as hunting, when the eye needs to be cleared and the fluid on the cornea smoothed out for maximum visual acuity. During a prolonged task, however, the eyes need to remain open for long periods. Blinking can then be so reduced that damage may result as the eyes dry. This is a hazard in some occupations: draughtsmen, for example, are apt to suffer from inflammation of the eyes, and over time from clinical problems with their corneas if they continue to concentrate for prolonged periods without blinking.

It is interesting that the rate of blinking is also affected by nonvisual tasks, and may increase with anxiety or embarrassment. Most curiously, we are not normally aware of blinking, though the eyes are

closed every few seconds. One might have thought that blinking would occur in one eye at a time so that we are not intermittently blinded; but it turns out that this seldom matters, as blinking is normally inhibited just prior to important anticipated events. It has been suggested that people having unusually high blink rates may be unsuitable as pilots, or be dangerous drivers; but experiments have shown that high individual blink rates are not a significant hazard for skills where shortterm prediction of dangerous events is possible.

BLOOD MYTH. Always man has been fascinated with blood, and he has often associated it with the life force itself. Primitive man noticed that, when an arrow or spear pierced the skin of another human or animal, as the blood flowed out on to the earth so life gradually ebbed away. So he made the simple deduction that blood must be the source of life itself, since when it drains from the body, life also goes away. Blood is the lifesustaining substance.

In accordance with this belief, primitive man often smeared himself with blood, in order to give himself more life. It was thought that those who had a ruddy complexion, the 'bloody ones', had more health than those who were pale and had less blood in them. Today, the use of rouge and lipstick may be regarded as a sophisticated relic of this primitive practice.

In ancient Greece, humans gave blood to the gods of the earth, to heroes, and to the dead in general. The precious blood was spilled on the ground; sometimes there were deeply buried, makeshift pipes to carry it down into the bowels of the earth. The Greeks characterized the dead as 'bloodless' ones who needed blood. In Homer's *Odyssey* there is the famous passage in which blood of newly slaughtered animals is provided for the dead, so that they can drink and become conscious once again. The shades of the dead gather round the blood to drink it; only after they have drunk are they able to think and speak. Virgil, too, mentions how 'holy blood' was poured on Polydor's grave.

Sprinkling the altar with blood to honour the gods in heaven was also a common practice. In the Old Testament, priests had the duty of sprinkling the altar with the blood of victims.

In those civilizations where human sacrifice was customary, blood letting sometimes reached astounding proportions: every year in ancient Mexico, for example, thousands of humans were killed to honour the gods; their blood was smeared on godly images or collected in bowls for libations. Often these rituals were directed towards the sun god.

If one accepts the myth that blood is the source of life, it follows that blood must carry characteristics of the soul. Hence, drinking the blood of some person or animal of strength should communicate this strength to the drinker. In Lapland humans drink the blood of reindeer; in parts of Asia the blood of the tiger.

Whoever gives blood, gives up part of himself as well as life. This is the origin of the belief in the sacred character of blood pacts. A blood pact can be set up with God or with the Devil. Both deities seem to enjoy blood sacrifices, since the soul is in the blood.

In so-called 'higher religions' wine is often substituted for blood, but the symbolism of blood remains. In the Christian ritual the faithful drink the wine which has been changed into the blood of Christ, in order that they may become one with the Saviour. With the blood comes the promise of eternal life: 'Unless a man eats of my flesh and drinks of my blood, he shall have no life in him. But whosoever eateth of my flesh and drinketh of my blood, shall live forever, and I shall raise him up on the last day.'

In everyday language there is an association between the blood myth and life, as in the expression 'he gave his life's blood for his friend'. Blood is the most worthy gift of all. From life is life given. Friendship can be expressed in the blood ritual, in which both prospective friends cut themselves and mix their blood together, in order to become 'as thick as blood brothers'.

Tied up with the blood myth is the belief that there is 'good' blood and 'bad' blood. Until the late eighteenth century illness was often assumed to be the result of 'bad blood'. So the bad blood had to be let out; and medical doctors were often referred to as 'leechers' because of their practice of bloodletting.

In the act of sexual intercourse some humans like to bite their partners on the neck or shoulder. This may be a residue of the human sucking instinct developed while still a foetus. Carried to an extreme, this fixation on seeing human blood is part of sexual pathology. There are some humans who thrill at the sight of flowing blood;

they are classified as 'living vampires'. For most of them it is not enough to draw blood, they must see the blood spurt. Apparently these patients confuse blood and spurting semen. To them the flowing blood is the main attraction, rather than genital pleasure, hence they are sometimes called blood fetishists.

R. T. M

BLUSHING. Uncontrollable reddening of the cheeks, and sometimes the ears and neck, is associated with embarrassment and guilt. Charles*Darwin made the most interesting suggestion: that blushing is a warning that the individual who is blushing is not to be trusted, as he or she has violated the mores of the group or has committed some crime. This notion that blushing is a visible warning sign that an individual is not to be trusted, Darwin puts forward in *Expression of the Emotions in Man and Animals* (1872). Part of his evidence is that children before the age of understanding social rules do

not blush, for 'the mental powers of infants are not yet sufficiently developed to allow of their blushing. Hence, also, it is that idiots rarely blush.' Blushing (and also weeping and sobbing) is found only in man and not in other Primates, who are generally supposed (in spite of some recent contrary evidence) not to have cognitive understanding of social mores or their violation. This is not to say that only humans have social mores, only that we alone appreciate and evaluate them, and act on our assessments of social situations, and monitor our successes and failures and the appropriateness of our behaviour in situations that

Page 98

had no precedence earlier in evolution. It seems that only humans have the understanding to be embarrassed—and so to blush.

For Darwin 'blushing is the most peculiar and the most human of all expressions'. He goes on to suggest a psychosomatic origin: 'we cannot cause a blush by any physical means . . . It is the mind which must be affected.' But this is not the *conscious* mind, for (writing nearly twenty years before Sigmund*Freud was born) Darwin points out that blushing is not under control and that, further: 'Blushing is not only involuntary; but the wish to restrain it, by leading to selfattention, actually increases the tendency.' That it is an innate sign of mental states is confirmed by blushing in blind people.

Women blush more than men. Darwin wished to discover how far down the body blushes extend, so he adopted the ingenious notion of asking his medical friends

'who necessarily had frequent opportunities for observation'. His friend Sir James Paget (1814-99, who wrote the standard texts, *Lectures on Surgical Pathology* and *Clinical Lectures*) reported that: 'with women who blush intensely on the face, ears, nape of the neck, the blush does not commonly extend any lower down the body'. He never saw an instance in which it extended below the upper part of the chest. Darwin considers whether it is the exposure of the face to temperature changes that makes the capillaries specially labile; but derides, rather, that the face is intimately associated with the brain and that the blushing is primarily facial, at least in Englishwomen, because of the 'attention of the mind having been directed more frequently and earnestly to the face than any other part of the body...!'.

What we would now call the psychosomatic basis of blushing was pondered in astonishing depth by Darwin as he considered that its mental effects may be *reversible*.

He refers to the observation that when patients are given nitrite of amyl they blush in the same restricted regions as with embarrassment. 'The patients are at first pleasantly stimulated, but, as the flushing increases, they become confused and bewildered. One woman to whom the vapour had been administered asserted that, as soon as she grew hot, she grew *muddled*.' Although all this was said well over a century ago there is little to add now, apart from its detailed physiology, to Darwin's comments on blushing.

BODY BUILD AND PERSONALITY. The continuing debate on the relation between physical form and mental attributes, which goes back at least to Hippocrates, took on new life with the publication in 1921 of Ernst*Kretschmer's monograph *Körperbau und Charakter* (English translation, *Physique and Character*, 1921). Although the form taken by this debate has varied greatly from one century to the next, the most prevalent belief was that two types of temperament could be distinguished. Thus Shakespeare contrasted 'fat; Slekheaded men and such as sleep o nights' with Cassius's 'lean and hungry look; He thinks too much: such men are dangerous.' In more modern times, C. G.*Jung wrote of extraverts and introverts and William*James contrasted toughminded empiricists with tenderminded rationalists, while*Kraepelin drew the distinction between*schizophrenia and manicdepressive psychosis which still remains a cornerstone in psychiatric classification (see MENTAL DISORDERS: CLASSIFICATION). The question then arose: is there any correlation between these two classes of illness, predispositions to which are inherited individually, and particular features of body build? On the basis of clinical experience Kretschmer reached the conclusion that manicdepressive illness—or predisposition to develop it—and what he called psychotic temperament (i.e. proneness to either undue exuberance or depression) were associated with a roundbodied, so-called *pyknic* physique, whereas schizophrenia—or predisposition to develop it—appeared to be linked with a so-called *asthenic* physique.

Kretschmer was, however, careful to point out that any distinction between the abnormal and the normal, i.e. the pathological and the biologically healthy, is relative;

and that between the main types that he recognized are the average men, those of athletic build and those of harmoniously balanced, so-called *syntonic* temperament.

He recognized, too, that among patients are to be found many of anomalous physique (*dysplastic* types) differing markedly from the types already described and impressing as being 'rare, surprising, and ugly'. Kretschmer worked out detailed schemes for preparing an inventory of the entire body surface from head to foot. This involved systematic measurement with calipers and tape measures, photographing, and drawing. Extensive verbal descriptions of temperament were based on viva voce questioning in a concrete manner in order to get information about the 'simple, colourless psychic life' of his patients. Even so, although his work exhibited both thoughtfulness and care, it is too remote from experimental design and control to justify serious scientific consideration.

More satisfactory methods of classifying physique have since been devised, most notably by W. H. Sheldon, who based his investigation on the premise that the components of physique are normally distributed in the community. He was then led to postulate three supposedly primary aspects of physique for largescale inquiry.

The first, which he called *endomorph*y, refers to relative predominance of soft and rounded tissue throughout the body; the second, christened *mesomorph*y, is concerned with the relative predominance of muscle, bone, and connective tissue; and the third, *ectomorph*y, is marked by a predominance of linear dimensions and a relatively large surface area in relation to bodyweight.

independently in any given physique. In consequence they were chosen as basic variables and, with the aid of specially constructed checklists of their main characteristics, a large number of photographs of young male physiques was arranged in rank order, one for each component. A sevenpoint scale was employed and a numeral assigned to each ordered series: thus the extreme endomorph was designated 711, the extreme mesomorph 171 and the extreme ectomorph 117. The pattern of morphological structure as represented by these three numerals is termed the *somatotype* of the individual. It is important to bear in mind that whereas over seventy individual somatotypes were distinguished, the three extreme types taken together make up only 1 per cent of the entire population sampled in the study.

Sheldon then proceeded to investigate whether significant correlation could be discovered between varieties of physique and qualities of temperament. To this end he selected fifty traits for study, and subjects were rated for each trait on a sevenpoint scale. Ratings were based on a combination of personal knowledge and observations of behaviour. It transpired that twenty of the traits studied fell into three welldefined clusters that were highly intercorrelated, suggesting that there might be three basic temperamental components, which Sheldon christened *viscerotonia*, *somatotonia*, and *cerebrotonia*. The first of these is marked by sociability and love of comfort, the second by selfassertiveness verging on aggression, and the third by selfconsciousness and diffidence, Correlations as high as 0.80 were claimed between viscerotonia and extreme endomorphy, somatotonia and extreme mesomorphy, and cerebrotonia and extreme ectomorphy, though in the light of more recent studies these correlations are generally considered to be too high.

Sheldon's later work was largely concerned with the application of his methods to the study of clinical issues. This has been less successful, partly on account of methodological difficulties and partly through doubts as to how far physical characteristics in adult life reflect inherited constitution and how far they depend on eating habits, physical activity, or illness contracted at various stages of life.

Although there has been a good deal of criticism of the bodybuildpersonality concept, there is some evidence of a correlation between ectomorphic body build and the personality trait of dysthymia. It has also been reported that young schizophrenic patients had a predominantly ectomorphic body build. This is essentially in agreement with Sheldon's findings, although older patients who develop paranoid schizophrenia were more often mesomorphic. As might be expected, delinquent boys in detention centres showed a high degree of mesomorphy, equivalent to measurements recorded on young men attending a physical training college. In spite of these interesting and suggestive findings there is no evidence that possession of a particular body configuration is of aetiological importance, and relatively little interest has been shown in this topic in recent years.

O. L. Z.

BODY LANGUAGE. One important aspect of 'body language' is that people are supposed to exert an enormous degree of precise yet unwitting control over each other's movement in everyday social

interaction. In the mid 1960s William Condon and W. D. Ogston of the University of Pittsburgh studied films (shot at 48 frames per second) of two people conversing. The films were analysed intensively, one frame at a time. When Condon and Ogston (1966) compared the movement flow analysis with the linguistic segmentation, they discovered that there were sustained configurations of body change which occurred isomorphically with the words uttered. They also claimed that the configurations of movement change of one individual were in precise synchrony with those of the other. The form of the behaviour displayed by the two individuals did differ, but the timing was precisely coordinated. Thus, a speaker was found to move his hand in time with his speech while the listener echoed the same rhythm with small head movements. They called the harmony between the speech and body motion of one speaker 'selfsynchrony', and the harmony between speaker and listener 'interactional synchrony'.

In a subsequent study they analysed a segment of a film of a threeperson interaction—a mother, father, and their fouryearold son at dinner. Here again, they identified selfsynchrony and interactional synchrony, the father and son moving in precise harmony with the mother as she spoke. They also found that changes in velocity of movement were to some extent shared by all three individuals and identified the mechanism underlying this synchrony as the rhythmic structure of the speech. Thus, the father was seen to move his fork to and from his plate in precise cadence with the syllabic structure of the mother's speech.

Adam Kendon (1970) followed up this investigation of interactional synchrony using material from a film shot in a London pub. He noticed that other members of a group moved in synchrony with both the speaker and the direct addressee, but that their movements differed either in form or timing from those of the direct addressee. Kendon claimed that the addressee, by exactly mirroring the movements of the speaker, differentiates himself from others present and so heightens the bond that is established between himself and the speaker. He further noted that interactional synchrony occurs when people are not looking at each other, thereby indicating that the coordination of the listener's and the speaker's movements is brought about through the listener's response to the speech rather than through direct copying. Lastly, he claimed that interactional synchrony is not continuous during a period of interaction, and that its intention may be to signal rapport.

A phenomenon somewhat akin to interactional

Page 100

synchrony, which has been described by Albert Scheflen (1964), is postural congruence shown by two or more individuals who adopt identical or mirrorimage postures. This was particularly noted in group sessions and it is of interest that when one member of the group changes his posture, others are quick to follow suit. The outcome is that postural congruence is often maintained despite repeated changes in bodily posture. Scheflen has also reported that in family psychotherapeutic sessions, one child may maintain postural congruence with one parent and the other child with the other. Possible interpretations of such behaviour are easily surmised.

Interactional synchrony and postural congruence are decidedly intriguing and have featured in a

number of popular accounts of 'body language' and cognate phenomenon, of which the best known is undoubtedly that of Desmond Morris (1977). Unfortunately, certain errors and distortions have crept into both this and other popular studies, and too much is frequently claimed on the basis of anecdotal or poorly controlled observations. For example, Schefflen's accounts of his work are often too imprecise to allow replication or direct test. Again, the possibility that some, at least, of the instances of synchrony reported in earlier work may be no more than chance occurrences can seldom be excluded with complete confidence. Postural congruence, too, may in some cases at least be purely coincidental, as Schefflen himself has admitted.

Fortunately, a number of more recent studies have embodied more rigorous methods of investigation. In a carefully designed study by McDowall (1978), for example, microanalysis was carded out on a film shot at 24 frames per second involving a sixperson discussion group comprising both friends and strangers. Two observers each coded three boundary types of movement for each of the six participants. McDowall calculated the chance occurrence of frequency of interactional synchrony with which he compared the observed frequency of such synchrony. The results of this careful test were largely negative, only one pair of subjects displaying interactional synchrony at above chance level. Further, no difference was found in the amount of synchrony shown by friends as compared with strangers. On the other hand, studies of postural congruence, particularly those undertaken in a clinical context, have produced findings more closely in keeping with the results of earlier studies and provide more positive evidence both for the existence of postural congruence and its possible role in signalling rapport. A study by Beattie and Beattie (1981) carded out on a beach provides convincing evidence that postural congruence is definitely not a chance phenomenon.

AND CAUSALITY.

BOGGLE. It is said that 'the mind boggles' (meaning an extreme state of incredulity, or rejection of a situation or idea). Nothing but minds can boggle— except computers? Perhaps this depends on whether computers are accepted as having, or not having, minds.

BONDING. A term from ethology, meaning a special relationship developed by individuals, such as the pairbonding of male and female birds. The ethological theories of bonding have been taken over to describe or explain human relationships. See ATTACHMENT

BORING, EDWIN GARRIGUES (18861968). American psychologist, who became Edgar Pierce professor of psychology at Harvard. He won distinction for his *History of Experimental Psychology* (1929; revised edition 1942), which traces the genesis of experimental psychology from its origins in early nineteenthcentury philosophy and physiology to its general acceptance as an autonomous academic discipline a century later. While placing the major stress on its German origins—more particularly the massive contribution of Wilhelm*Wundt—Boring was fair to the claims of the United States and Britain to have developed important brands of experimental psychology in which introspective analysis was less strongly represented and greater emphasis was placed on objective studies of behaviour in both animals and man. There was also wide recognition of the practical applications of psychological enquiry. Boring's book was, however, criticized in some quarters for its identification of scientific with experimental psychology and its correlated neglect of psychological medicine, in particular the work of Sigmund*Freud and his School (remedied, however, in the 1942 edition). None the less, in spite of some noteworthy limitations, Boring's *History* remains a scholarly record of the early days of experimental psychology.

Boring later published *Sensation and Perception in the History of Experimental Psychology*, a less ambitious though perhaps more satisfactory account of its subject viewed in historical perspective. It is fittingly dedicated to the memory of Hermann von*Helmholtz. A slighter book, owing

BRAID, JAMES (1795-1860), British physician and surgeon. See HYPNOTISM, HISTORY OF.

BRAILLE. A system by which the blind read from patterns of raised dots. The basic 'cell' consists of six dots in two vertical lines of three, from which can be derived letters, numerals, and punctuation marks (see Fig. 1). Most experienced Braille readers use their left index finger rather than their right to read Braille (see HANDEDNESS). The system was developed by Louis Braille (1809-52), simplifying the system of the army officer Charles Barbier, who wanted to use his system to pass messages silently. Braille became blind at the age of 3 and at 10 became a student at the Institution Nationale des Jeunes Aveugles in Paris, where he was later appointed a professor.

BRAIN, ANATOMY OF THE. See NERVOUS SYSTEM.

BRAIN DEVELOPMENT. The fabric of the brain has been discovered within the last 150 years. As recently as Charles*Darwin's day, nerve cells and their delicate connections were almost unknown. Darwin wisely spoke little of the brain, though he assumed it to be the evolved organ of the mind.

About 1870 an Italian psychiatrist, Camillo*Golgi, discovered that single nerve cells could be stained black with silver or gold particles, so that their fine receptor branches (*dendrites) and output fibres (*axons) could be seen in brain slices under the microscope. In Spain, Santiago Ramon y*Cajal used silverstaining to lay the foundations of modern neuroanatomy. By the end of the nineteenth century the tissues of the brains of many animals had been mapped, showing in outline how the main parts had evolved. A common plan, evidence for common principles of growth and function, became clear.

Surgical experiments with animals located regions in the cortex necessary for perception in different modalities, and these researches were soon augmented by controlled electrical stimulation of territories from which movements could be elicited. Strangely distorted sensory and motor images of the body were found. These were evidence for the ordered growth of nerve systems that mapped perceptual and motor skills. Then, about the turn of the century, methods were developed for amplifying the minute electrical impulses by which neurones excite one another. Electrodes could be used to record nerve discharges, as well as to stimulate; and connections were followed with a totally new precision.

During the 1960s and 1970s, much closer inspections of the complex arrangements of brain tissues were made, by staining and by microelectrode techniques capable of identifying inputs to a single cell

and of following its projections to the furthest tips. (See NEUROANATOMICAL TECHNIQUES.) It is possible now to trace where a cell at one point projects to, and backwards, to locate cell bodies which send axons to that point. Microelectrodes can excite a single cell and follow its discharges, Fig. 1.

A Braille alphabet.

Page 102

pick up impulses in a single axon, and inject*neurotransmitters or blocking agents into a minute territory of the brain. With the electron microscope, nervecell membranes and the specialized contact points (*synapses), by which selective chemical communication is established from cell to cell, can be seen. The electron microscope can also reveal the intricately folded macromolecular membranes that control nervecell biochemistry: the synthesis of protein or of transmitter chemicals, and other processes. Biochemical and immunohistochemical methods show up chemical differences between nervecells and reveal the location of chemical communication points on the cell surface. The anatomical patterns revealed by these methods testify to the formation of organized cell systems by a process of development and differentiation more complex than in any other tissue.

Cajal pioneered studies of how the brain develops from undifferentiated sheets of blocklike embryo cells into the most amazing communication system in the universe.

He imagined the growing tip of a nerve fibre probing its way with delicate filaments, like an amoeboid protozoon. He described it as, 'a sort of battering ram, possessing an exquisite chemical sensitivity, rapid amoeboid movements and a certain driving force that permits it to push aside, or cross, objects in its way'. He concluded that formation of the right patterns of connections in development or regeneration depends upon how this growth tip chooses a path through the densely packed tissues of brain and body. He also saw evidence of elaborate mass migrations of nervecells, resembling the manoeuvres of an army for battle. He drew remarkably accurate conclusions about mature brain anatomy by studying the relatively uncluttered tissues of foetal mice and birds.

Recently, the use of radioactive or fluorescent tracers that are drawn into nervecell chemistry and carried throughout the protoplasm, and techniques of microelectrode neurophysiology, have brought a new vitality to studies of brain growth. The brain is seen to lay the foundations of even the higher psychological processes before birth. Such discoveries prove that brain growth is inseparable from mental growth. Notions of how*consciousness, will, and human understanding came about can never be the same.

For most of the modern scientific era, descriptions of the human brain have been faithfully Cartesian (see DFSCARTES). One set of anatomically fixed conduction pathways is imagined to be prewired innately, before birth. These govern essential 'biological' functions. Somehow, inside these pathways, probably at junctions between nervecells, plastic changes allow use and disuse to modify function. New connections make up new combinations of reflexes by*conditioning. This is the familiar theory

of*Pavlov, based on his brilliant experiments on the formation of new connections between stimulus effects and movements or gland secretions in restrained dogs. His work gave the physiological foundation to*behaviourism, the belief that even the higher mental, moral, and cultural attributes of a human being are added by learning to the reflex biology of the brain.

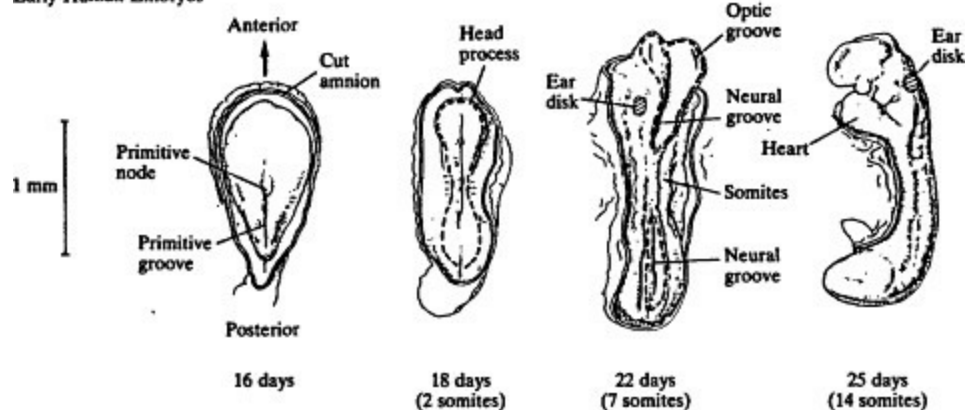

Such a theory of how the mind is formed takes no account of how the brain actually develops. It is impossible to reconcile a simple reflex theory of integrative functions of the brain with the facts of brain growth as they now appear. In the first place, sensory and motor nerve cells are in a minority, even in the spinal cord.

Interneurons that link input to output, and determine changes in the possibilities of such links and how they will be grouped into coordinating systems, are a hundred times more numerous. Everywhere in the brain these intermediate integrative cells, some small, some reaching far in the brain, are organized to form systems that look much more like special machinery for formulating varied central states of nervous activity. Every type of neurone is capable of spontaneously firing impulses that may be transmitted through the nerve net. We have to take this into account in our theories of learning.

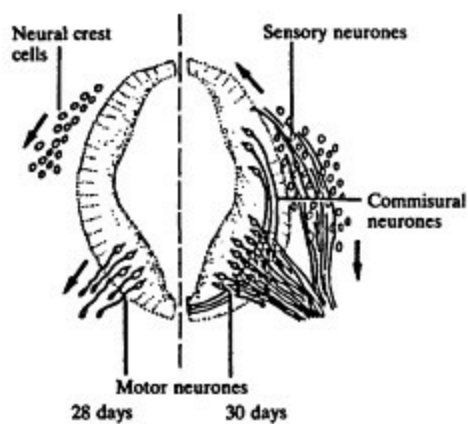

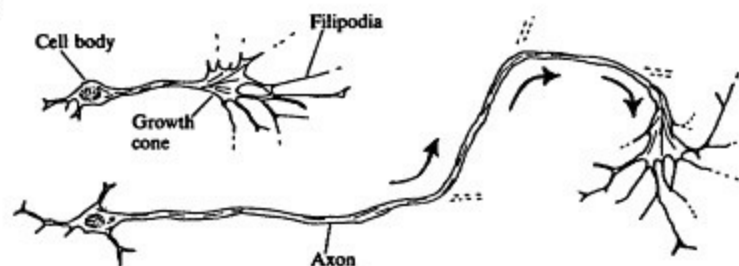

In foetal birds and mammals, varying movements and sequences of action can be formed before sensory cells are connected to the brain or in pieces of the central nervous system that have been cut off from sensory nerves by surgery. The movement programs are set up among the interneurons. On the input side, too, the fine branches of sense cells—from the retina, from the touch cells of the skin, etc.—grow millions of fine branches that end among already organized and active central networks. Then these afferent terminals sort themselves into precisely ordered arrays that map the body and the outside world into the prewired systems of the brain.

In short, the way the human brain parts grow before birth suggests that the interacting nerve cells might make up and coordinate basic rules for object perception, for purposeful movement patterns, and for motive states, without benefit of experience. This is confirmed by the behaviour of infants shortly after they are born (see INFANCY, MIND IN). We are therefore obliged to pay careful attention to the steps by which nerve cells are linked up into communicating systems before birth.

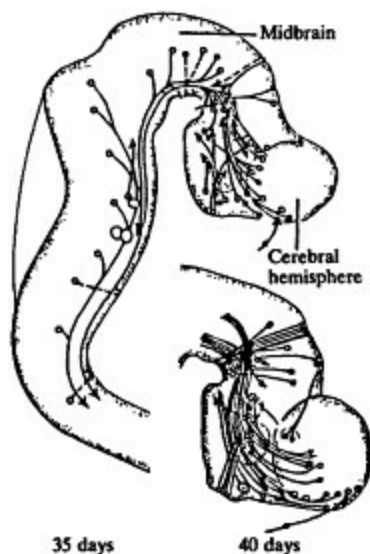

The brain starts as a slab of cells in the upper layer of the embryo, which become irreversibly different from other cells about three weeks after gestation. Different parts are already designated to form specific relations with the body in the future. Both brain and body of the embryo have bilateral symmetry but hidden differences exist between left and right halves. Brain and spinal cord roll into a hollow cylinder, then, in a few days, cell multiplication occurs round the central cavity, and cells migrate outwards to form rudimentary brain nuclei in the wall of the tube. Some cells become neurones and others change into nonneural support cells (glia). Ventral cells in brainstem and cord grow axons out to the muscles of the trunk, limbs,

Growing Neurones

Embryo Spinal Cord

Embryo Brains

Fig. 1.

The human central nervous system develops in the dorsal surface of the embryo (inside dotted line) and rolls up to form a tubular spinal cord and brain.

At one month after conception, nerve cell axons grow out, each headed by a growth cone: first away from the spinal cord, then up and down within the core of the brainstem.

and viscera after four weeks, the anteriormost motor cells innervating the muscles of the eyes, face, and mouth. Sensory cells grow shortly after motor cells, projecting their input to the dorsal half of the central nervous system.

The brain is soon much enlarged relative to the cord; its dorsal lobes receive axons from the special receptors of the head (nose, eyes, ears, and mouth). The hypothalamus, the foremost ventral component of the embryo brainstem, as well as being the 'head ganglion' of the viscera, controlling appetites and aversions, acts as a coordinator between activities of the central nervous system and the endocrine system—glands that secrete hormones controlling growth, metabolic activity, and sexual development. Among the earliest neurones inside the brain to send axons down the embryo brainstem to the cord and upward to the developing forebrain hemispheres are core interneurons, which will transmit a spectrum of messenger chemicals to other neurones and maintain the balance of integrative states in the central nervous system. These substances play a key role in the regulation of nerve cell growth and differentiation everywhere in the young brain. One set of cells from the ventral midbrain reticular system of embryo rats can be injected into adult rats to correct for the attentional and motor deficits that follow particular surgical removals of tissue from nuclei deep in the cerebral hemispheres. The 'brain grafts' penetrate the older brain and 'cure' its fault, rejuvenating nerve axons, finding the right sites, and terminating on cells that had lost input from cells of the same type as the graft. In the mature brain reticular neurones of the brainstem modulate perception, the formation and recall of memories, and motor coordination. By the end of the embryo period (eight weeks), when the cells of the future neocortex of the cerebral hemispheres first appear, the brainstem has an elaborate system of projections that will influence the migration and differentiation of cortical neurones (Fig.

1).

In the forty weeks of gestation a human brain grows to a twothirdssized likeness of the adult brain. Its anatomy at birth is remarkably complete. All the typically human cortical areas and nuclear masses of the brainstem are there, containing a million million nerve cells in total. But this general impression is misleading in one important respect. The formation of intercellular connections, which take up little extra space but upon which the function of the brain depends, is far from complete.

There is, in fact, a huge postnatal manufacture of fine branches where nerve cells seek to form effective contacts with dendrites of other cells (Fig. 2). The number of contact points in the cerebral cortex increases astronomically. Each mature cortical cell is estimated to have, on average, about 10,000 synapses, the greater part of which develop a few months after birth. The total number of synapses in the cortex of one person (10¹⁵) is about 200,000 times the population of humans on earth.

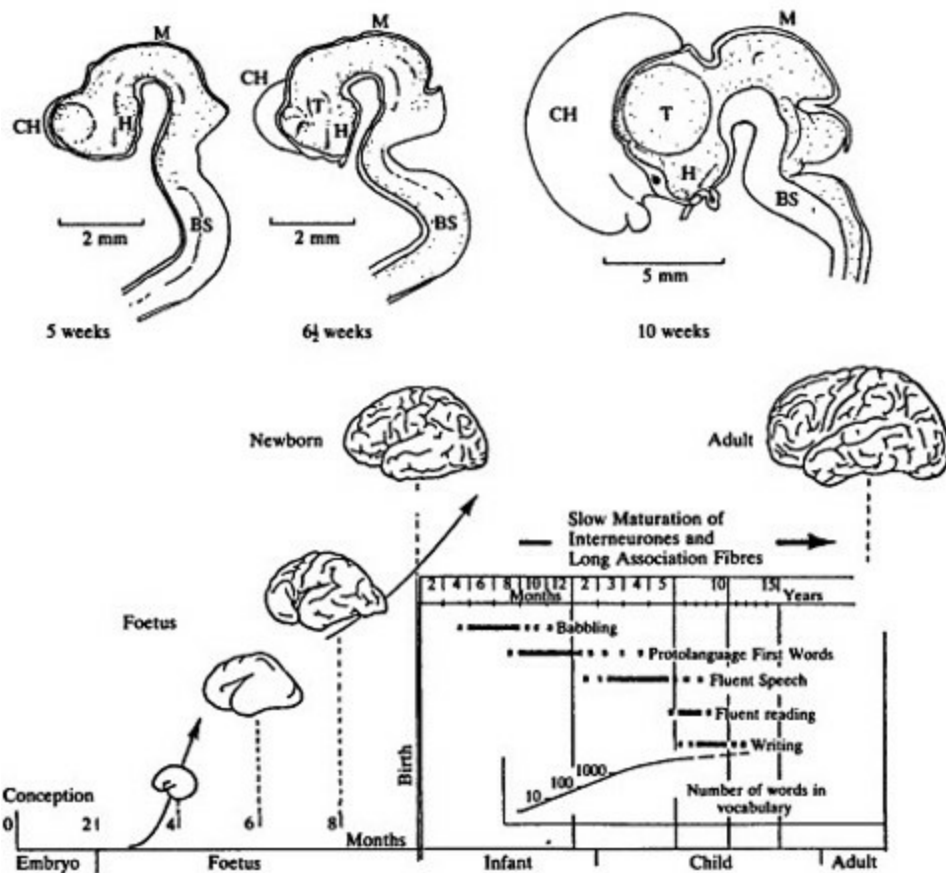

Prolific branching of dendrites and formation of synaptic contacts can be seen in microscope slides of the cerebral cortex of infants, and comparable developments occur in the cerebellum of infants and young children.

How are we to interpret these discoveries? How might specific connections be selected accurately to govern mental processes in this teeming array of minute living elements? On the selection of the right connections depends the development of skill in motor coordination, refinement of perception, retention of memories of all kinds, formation of a vocabulary, and development of increasingly critical and precise patterns of thought. The facts of brain growth do not imply that mental and

physical abilities governed by the brain simply expand and elaborate independently of stimuli. Nor, on the other hand, do they give the brain a passive submissiveness to experience. True, even in foetal stages the selection of nerve connections depends upon input from the maternal environment. Serious mental deficiencies in children can arise if the mother is poorly nourished or under mental stress during critical brain growth periods in gestation. But the process of gaining experience is at all stages an active one. After birth, stimuli are sought and actively taken up by a baby, not just submitted to. Those stimuli which are assimilated cause selections to be made from among rival adaptive alternatives within general rules for brain formation. These ground rules, including rules for recognizing other persons and for detecting their emotions from their expressions, are innate in the sense that they are formulated in earlier stages where stimuli had no effect. The learning involved takes place as part of a most elaborate developmental strategy that must be ascribed to a continuous regulated unfolding of nervecell interactions from the embryo to the adult.

The principles of how stimuli and genes act together to control brain differentiation are beginning to come to light. When embryo nervecells migrate and form into patterned aggregates, and when they grow long, branching axons that sort themselves in an intricate crisscrossing array to make up patterned circuits, they communicate by biochemical expressions of regulator genes that can switch the actions of other genes governing nervecell development. There are messageemitting and messagereceiving loci on the cell surfaces. These respond to hormones and growth substances that are produced by cells of all kinds. Once the network of nerve connections is formed, a new factor, conduction of nerve impulses, adds power and precision to this communication. The electrical discharges of neurones cause adjustments in their biochemistry because powerful intercellular chemical messages may be turned off or on by electrical excitation of the cell membrane.

In the 1940s, Roger Sperry performed surgical experiments with fish and amphibia to observe the regrowth of specific functional connections in the brain after nerves had been cut and rearranged (see NERVE CONNECTIONS: HOW THEY ARE FORMED; BRAIN

Growth of Cells in Striate Cortex

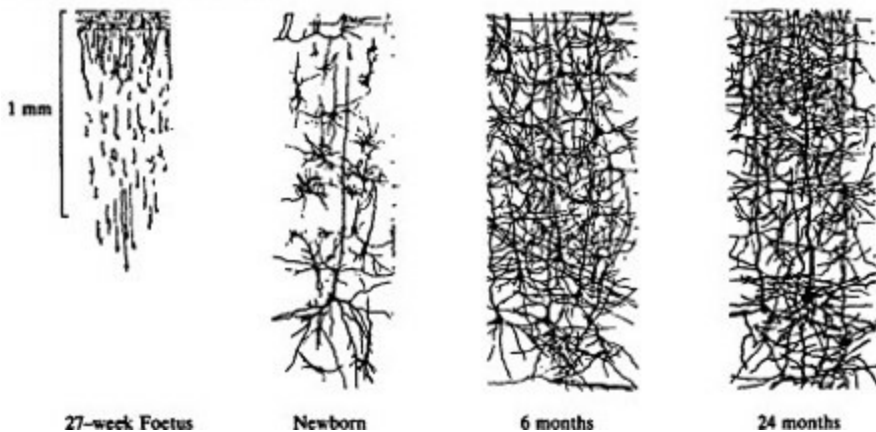

Fig. 2.

The cerebral hemispheres appear in the midembryo (one month gestation), expanding in midfoetal stages when cortical neurones multiply. A second surge of hemisphere growth occurs shortly after birth when cortical dendrites grow and glia cells multiply—synapses form at this stage. Cell maturation continues throughout psychological development.

CH = Cerebral Hemisphere; T = Thalamus; M = Midbrain; B = Brainstem; C = Cerebellum; H = Hypothalamus.

SCIENCE: SPERRY'S CONTRIBUTION). He proved that nerve networks could reform wellordered contacts, without benefit of learning by behavioural trial and error. He also ruled out a number of explanations of how this could happen, such as contact guidance and electrical field hypotheses, and concluded, as Cajal had done, that some unknown chemical 'landmarks' guided the nerve fibre tips to the right location. This 'chemoaffinity' theory has been upheld by subsequent studies, but it has been shown that no gene code can possibly specify, on its own, this cellto cell precision of nerve mappings in such wellordered arrays as the projections of the visual field. The intricate interconnected anatomy of the brain is formed as a result of the multiplying effects of many choices in cell differentiation that are governed by genes acting in the context of development. To effect this, there is much negotiation—a sorting or editing of connections, with removal of many, so that the remainder take up exactly right neighbourhood relations inside an overall array oriented approximately by chemical field markers that were set out early in the embryo period.

Stepbystep, in a program that keeps reference to the polarized symmetry of the body, the cells of the embryo nervous system multiply, migrate, grow axons and dendrites, and then form synaptic contacts. At each step there is either a potential excess with selective activation of those chosen to develop, or an actual exuberant overproduction of elements, followed by a selective elimination that leaves an effective arrangement, as in Darwinian evolution of species. Some cell lineages divide more than others and leave more offspring; many cells die after migrating; axons branch out widely, then most of the branches are pruned off and digested by phagocytes; only a part of the huge population of cell contacts are retained to form mature synaptic junctions that can effectively transmit nerve discharges. The multiplication, migration, and survival of neuroblasts, the growth and pruning away of axons and the reinforcement or suppression of synapses are decided by the molecular compositions of the surrounding media and nerve cell membranes. Trophic or inhibitory factors are produced by many types of cell, including nonneural supporting cells (glia) in the central nervous system. The glia make up a scaffold that guides migrating neuroblasts and the creeping of axon growth cones, and they assist in the maturation of axons and synapses. Within this tapestry of interacting components, nerve cells take many forms and become differentiated chemically. They come to contribute different patterns of electrical and chemical activity to the system.

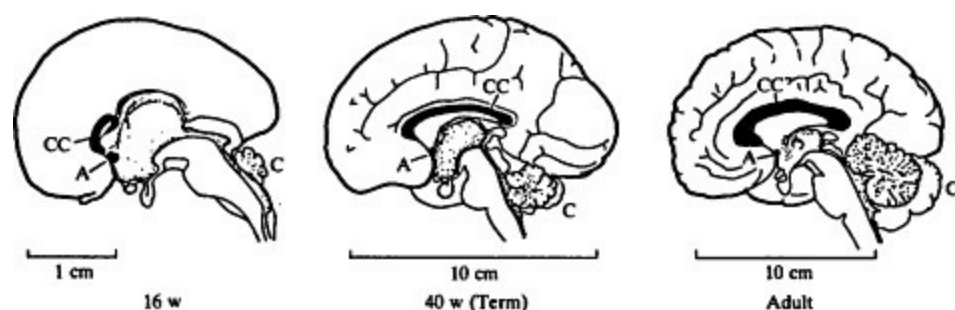

The forces of selection that shape the nervous system and weed out unwanted elements are created at first inside the body and in the spontaneously active nerve net, but in foetal and postnatal stages the brain is increasingly open to selective influences that enter the electrical traffic of the young brain from outside, through the sensory nerves. Chemical communication with the mother through the placenta significantly affects brain development *in utero*, and subtle refinement of brain structures may also take place in response to gustatory, mechanical, touch, and auditory stimulation. The foetus begins to have some control of this stimulation by moving to change posture, to displace limbs, and to swallow amniotic fluid.

At first the intercellular 'talk' that animates nerve cell interactions is spontaneously generated or intrinsic to the brain. Coupling or competition between active nerve cells at one place can be reproduced at remote locations to regulate the layout of contacts being formed elsewhere in the brain. But recent research has shown that sorting out of the most refined precision in sensory and motor projection systems depends on the timing and spatial arrangement of external stimuli. When an animal

orients a wellformed receptor array, like the retina of the eye, the patterning of stimuli due to structure in the environment is translated into patterns of nerve excitation.

Features like the edges of objects and the velocities of patches of light give order to nerve activity. This order enters into the editing and sorting process that grows the finest sensory integrative connections in the young brain. This explains why soon after birth a baby is so avid for visual stimulation with a fair degree of pattern in it, and why babies regulate their looking behaviour as they do. The great improvement in selectivity and discrimination of looking during the first month and a half of a baby's life requires the extra information about the state of eyetobrain connections which structured retinal stimulation provides.

At birth the human being enters a new world with vastly greater opportunities for experience. New forces on a body no longer floating, new levels and qualities of sound, new material taken in by mouth, air breathed by the lungs and bringing in new substances and microorganisms, new stimulation of the surface of the body, and the immense range of new visual information give the unfinished circuits of the cortex a fresh set of criteria for selective retention of functional nerve connections. More changes occur in the cellular structure of the cortex in the first six months after birth than at any other time in development. A large proportion of the millions of axon collaterals spanning the hemispheres and bridging the gap between them are eliminated, segregating intra and interhemispheric association systems (Fig. 3). Dendrites branch out from large cortical cells and receive astronomical numbers of synapses (Fig. 2). Connections by way of nerve tracts that link subcortical nuclei to cortex, cortex area to cortex area, and cortex to motor systems of the brainstem and cord are made more precise and more effective. These early postnatal building processes, and their continuation into childhood, create the essential anatomical and physiological basis for refined perception with precise and powerful motor con

Page 107

Fig. 3.

The corpus callosum has a maximum number of fibres at birth (approximately 1010) but increases in size by fibre thickening, and myelin deposition, after a majority arc lost in early infancy. A = Anterior Commissure; CC = Corpus Callosum; C = Cerebellum.

trol. They permit the elaboration of psychological representations or cognitive programs that give predictive mastery of events and objects in the world remote from the body.

Although these changes receive essential information from stimuli through sense organs, all of them continue to be guided by processes generated inside the brain. The control from within continues, as in embryo stages, to make selective hookups between converging neural elements that bear excitation from the receptors, leaving the greater part of potential linkages between convergent systems to be discarded. Thus, for example, in the selection of the precise cortical circuits necessary for binocular stereoptic perception of depth, which happens in a human baby about six months after birth, the choice of functional synapses that contribute to the detection of interocular disparities (differences between the retinal images) depends both on the coincidence of stimulus patterns from the two eyes and on a centrifugal activation of the receiving cell, by way of inputs to the cortex from the reticular formation of the stem of the brain. This corresponds to the observation that a baby has to be alert and seeking experience to benefit from the education that visual patterns give to the two eyes at this critical stage. Controlled movements of the eyes in precise unison are also vital to bring corresponding stimuli in register. It has been found that the visual cortex of girl babies gain binocular discrimination about two weeks ahead of boy babies, which indicates that, at some stage, sex hormones had an influence on the readying of these areas for visual information—possibly it is testosterone, produced in male infants for a few weeks after birth, that delays the process of cortical cell maturation.

The biggest developments in perception and in *the* formation of cognitive strategies that link perception to voluntary action, giving clear purpose to movements, undoubtedly occur in infancy or early childhood. That is the time when serious deprivation such as that due to blindness, deafness, limbleness, or to lack of affectionate care, can distort the growth of the brain most seriously. For example, defects in the optics or motor control of an eye (as in squint) cause the cortical connections of that eye to be pushed out of action by the more coherent and regulated input of the other eye.

Deprivation of all humane care and emotional support may cause mental deformity— even largescale anatomical abnormalities in the brain.

There is good evidence that the mechanism of brain growth operating before birth and in infancy is continuous with the mechanism for the longer and permanently impressionable function of learning from experience throughout life. Brain scientists are now hopeful that they may actually observe the anatomical changes that explain how we remember what we have experienced and how we keep the intricate images of movement that enable us to gain unconscious skill in the use of our bodies. But there is increasing evidence that the *self*organizing processes of brain tissue formation continue to have a hand in even the most specialized and culturally elaborated acquisitions of learning. There are regions of the cerebral cortex in the foetus that appear to be specially formed to engage in cultural life and acquire traditional skills (Figs. 2 and 4).

The cerebral hemispheres, one of the last brain areas to develop, appear in the early foetus and increase rapidly in size in midfoetal stages as nerve cells are multiplied in the still membranous cortex. A second 4fold increase in bulk takes place in the last two months of gestation and continues into the first few months of infancy (Fig.

2). This is due, not to multiplication of cortical neurones, but to their branching and to the formation

of the first connections that integrate the powerful cortical integrating tissues with the rest of the brain to make conscious perception, voluntary action, and intelligent learning possible.

The cells of the neocortex, generated round the cavities of the cerebral hemispheres (ventricles), move into the cortex between fifteen and twentyfive weeks after gestation. This phase is a crucial first step in the building of higher psychological functions. Immature neuroblasts migrate in waves to make a stratum called the cortical plate, later arrivals passing through earlier migrants so that the

Page 108

youngest cells are towards the outside of the hemispheres. This flow of neuroblasts into the cortical plate proceeds at different rates in different parts, the last parts to receive a full complement of potential neurones, at six months after gestation, being areas that will attain mature tissue structure years later, towards adolescence. Cells in cortex and subcortex that are dedicated to one psychological role start as neighbours in the periventricular germ layer, or even derive from the same stem neuroblast cell.

Late migrating components of the hemispheres tend to leftright asymmetry (Fig. 4). How hemispheric asymmetry begins and how it relates to genecontrolled asymmetries in the chemistry and immunological properties of cells widespread in the brain remains to be worked out. It is known that abnormal migration, in the left hemisphere, of one late contingent of cortical and thalamic neurones related to the perisylvian area, where temporal and parietal lobes meet, can lead to*dyslexia, a defect in language ability that makes it very difficult for a person of otherwise normal intelligence to learn to read and write. This is an example of a brain development fault beginning before birth that shows up only years later, in school performance. Another late maturing area is the prefrontal cortex. Research with monkeys has shown that memorizing the spatial arrangement of things for future reference, when action must be delayed, is a mind function that changes with age; it completes as a monkey nears sexual maturity. Monkeys less than one year old use one mental strategy, in the lower lateral parts of the frontal lobe, to keep the memory of where they saw some food hidden. After three years, the same task needs the upper lateral prefrontal cortex, in combination with deep nuclei toward the midline of the brain.

Transformation of psychological processes as new brain parts arrive at functional maturity confers a plasticity of function so that a child can partly recover from loss of brain tissue by injury or disease (see PLASTICITY IN THE NERVOUS SYSTEM). The developments also explain why injury of a given part of the cortex can have different effects in children and adults.

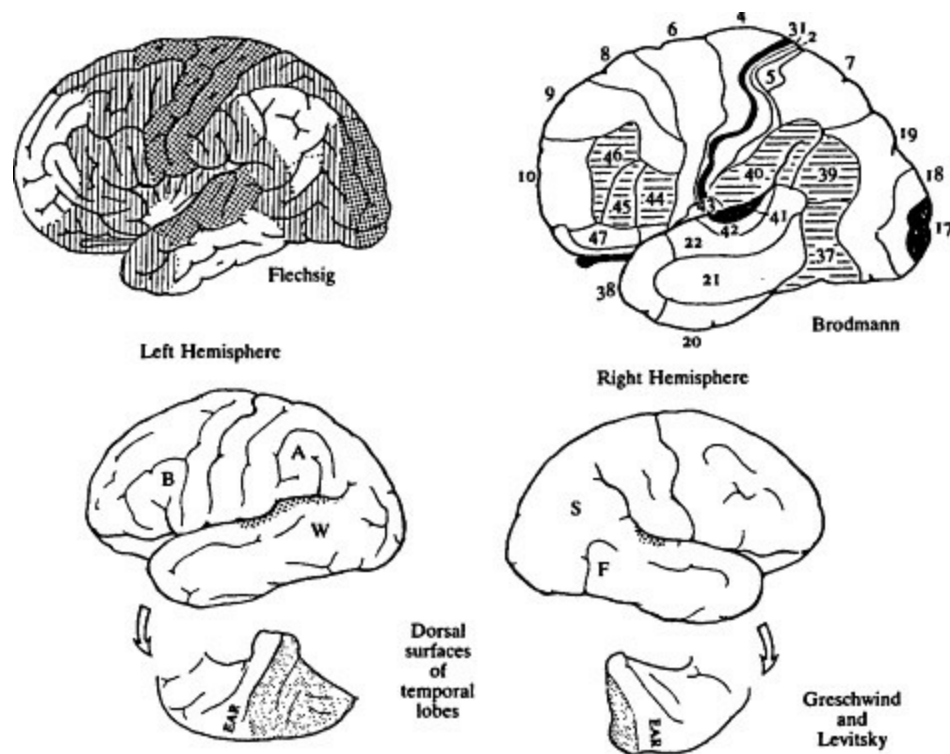

After birth, brain development depends on how patterns of stimulation from the outside world meet the varying inner states of brain activity. Stimuli to the infant are regulated both by the infant's movements and by the behaviour of caretakers who mediate between the environment and the infant, and the immature brain has powerful control of this caretaker behaviour, especially through emotional expression. Indeed, the most precociously mature functions of a young child's brain are those that communicate needs, feelings, and motives to other persons, and that lead them to present the world to the child in precisely regulated ways.

In future research, brain science will be concerned with breaking through the veil of ignorance that still conceals how developments in human brain tissue over the years of childhood relate to psychological maturation. In this phenomenon, unique in developmental biology, the state of morphogenetic regulators in an immature organism depends upon the affections and interests of more mature conscious beings, and upon the way the brains of these beings from the preceding generation have been programmed with cultural rituals and beliefs in an earlier childhood. Growing human brains require cultivation by intimate communication with older human brains. Thus are built the powerful collaborations of human society.

Anthropologists and psychologists consider language the hallmark of human kind. It permits symbolic communication without which traditions of belief and understanding could not be built up. It powerfully aids processes of thought and reasoning, even if it is not entirely responsible for these great glories of the human mind. There was, therefore, some surprise when brain scientists announced the discovery that territories of the left temporal and parietal lobes, which are essential for language understanding in the great majority of adult humans (Fig. 4), are already asymmetric in a human foetus of twentyfour weeks gestational age—four months before birth. Although quite indeterminate as to which language it will learn, the human brain is set to acquire some kind of language long before it hears a single word.

Complementary preadaptations or readiness in structure are seen in different cortical regions of the right hemisphere which seems, indeed, to be slightly ahead of the left hemisphere in development during foetal stages. These underlie this hemisphere's subsequent superiority in perception of form, in visuoconstructive skills and in other schematic processes that are of obvious importance in the development of technology and habits of interpersonal and cooperative life. The nerve-cell interactions responsible for postnatal changes in left and right halves of the brain relate directly to those neuroembryogenic processes which form cortical territories in the late foetus and in infancy, when cultural experience is only a remote factor in a future environment.

In the mature brain, detailed information about perceptions, memories, and fine motor coordinations can only pass over the interhemispheric space by a massive bridge of fibres called the corpus callosum (see SPLITBRAIN AND THE MIND). This structure develops in foetal stages, increasing in size from its first appearance at ten weeks of gestation until it has over a billion (10⁹) fibres at birth (Fig. 3). In the next three months, there is a decrease in size as a large proportion of this huge population of callosal axons is eliminated. This weeding out confines contacts between the hemispheres to certain cortical zones, separating groups of cells that send axons over the corpus callosum from other groups that send axons forward and backward, inside one hemisphere. In the mature brain, the cortex is composed of columnar territories of uniform size, and interconnections

Page 109

Fig. 4.

Top Left: Flechsig's map of cortical development (myelin deposition round nerve fibres). Stippled areas are mature at birth; shaded areas mature in early childhood; unshaded areas mature later.

Top Right: Brodmann's map of cortical areas. Shaded areas are unique to humans, tend to asymmetry, and are identified with learned cultural skills.

Below: Left and right hemispheres differ anatomically; auditory association areas (stippled) are larger on the left.

Psychological disorders after brain lesion depend on the area and hemisphere damaged; A = Angular gyms, important in reading; B = Broca's motor speech area; W = Wernicke's receptive speech area. The right hemisphere has territories more developed for spatial abilities (s) and for recognition of faces (F). The anatomic basis for these asymmetries is laid down in foetal stages.

between its parts, and with structures deeper in the brain, are arranged so they link columns into ordered systems. This orderly anatomy clears in infancy when redundant axons are eliminated and synaptic fields are sorted out, a process which forms the basis for sharp perceptions and precisely skilled movements. From four months after birth the interhemispheric bridge gains in bulk as its fibres receive a sheath of myelin. Interhemispheric communication matures in step with the development of mature synaptic arrays in different cortical areas over the first decade or so of childhood. Differences in the size and form of the corpus callosum in adults have been shown to relate to differences in hemispheric representation of cognitive abilities and to handedness.

It is now clear that the anatomy and function of human cerebral cortices are very variable. People

differ in the pattern of their mental abilities because their brains grow in different forms. Males tend to differ from females, lefthanders from righthanders and architects from psychologists. Some of this diversity of human minds, and their temperaments and aptitudes, will be preprogrammed in a great variety of outcomes of gene expression in nerve tissue development, but the same processes are also influenced by intrauterine and postnatal environments. Among the influential factors are hormones, especially sex hormones, nutrition, and state of health of the mother during pregnancy, chemical and immunological factors, viral infections, epilepsy, and trauma. A pregnant woman who takes psychoactive drugs or alcohol can be changing the development of her child's brain. Particular risks are associated with birth—the brain of a foetus or premature infant is sensitive to its chemical and physical environment which must be regulated inside narrow limits.

We are brought by recent findings to see the brain with new interest. This bewildering part of us is difficult to observe. It is still largely a *terra incognita*, as remote as Mars but greatly more

Page 110

relevant to our being. The more we learn of brain growth the more trust we gain in the belief that even our most cherished human qualities have a self-maintaining fitness. The process of brain growth may reasonably be said to be the source of our motives. We need to know more about how experience and practice give fulfilment to these most remarkable products of evolution.

BRAIN FUNCTION AND AWARENESS. It is something of a paradox that the most exacting studies of brain function are apt to come from research on animals, whose behaviour we can study with increasing sophistication, but who cannot communicate with us very fluently. In contrast, studies of human brain function derived from the clinic are apt to depend on just those methods of communication that we are precluded from using with animals. That is, most clinical tests of psychological capacity of human patients involve considerable verbal interchange between the patient and the examiner, often expressed in a form intended directly to reveal the patient's disorders. So, in a classical and routine examination of visual capacity, the patient is asked, 'Tell me what you see', 'How many spots do you see?', 'What letter is it?', and so forth. Or the patient with a memory disorder is asked, 'Tell me what you can remember from this morning', 'Do you recognize me?', 'What words can you recall from the list you just read?'

In studying animals' vision or memory, it is often assumed that we are simply transforming the questions we usually ask of human patients into an equivalent form, albeit one that is rather more cumbersome to transmit. Examined more closely, however, the resemblance is less than close. The animal reveals his capacity by displaying a discrimination between stimuli or events, which he has usually been trained to demonstrate by following some particular rule, and for which he is rewarded. The human subject also discriminates between stimuli or events, of course; but often the clinician does not study the discrimination as such, but rather the subject's commentary upon it, such as 'Yes, now I see the flash,' or 'I can see the letter A in the bottom line.' Even when the verbal response appears to be just an embellishment on, or a short cut to, the discriminative response, serious problems can arise if the subject is unable to render a commentary but nevertheless is capable of making the relevant discrimination—i.e. if he is restricted in the way that an animal is restricted when we study its visual capacity. We refer here not to the relatively trivial difficulty when a subject has, say, an impairment in the mechanics or the organization of speech. Even if a human subject is able to communicate freely and efficiently he may nevertheless be unaware of his own discriminative capacity and hence have nothing to communicate as a commentary.

It is only recently that this distinction, between a capacity and a subject's commentary upon it, has been recognized, and it has thrown light on some persistent puzzles in the comparative study of brain function in human and animal subjects. Two examples can be given. In both instances the differences between the results of research on humans and on other animals appeared to be so great that it was

argued that the brains of animals must be organized in a qualitatively different way from human brains, despite the very close anatomical similarity between them.

First, if the region of cerebral cortex to which nerve fibres from the eye ultimately project is removed, animals (unlike humans) can still discriminate visual events, although not as well as normally. This in itself is not surprising, because the eye sends information not only to the so-called 'visual cortex' but also directly to a variety of other structures in the midbrain and elsewhere. Indeed, the way in which vision is altered after blockage of one of the targets helps one to infer the type of capacity that the remaining targets must have. This residual visual capacity of animals has been studied over several decades, and techniques have been developed for yielding a good description of it. The paradox is that the human brain, while organized anatomically in a way that appears closely similar to the brains of other Primates, is said nevertheless to yield a state of blindness after removal of the 'visual cortex'. (Because the visual field projects upon the visual cortex in a wellknown retinotopic manner (see VISUAL SYSTEM: ORGANIZATION), most

Page 111

blindness is in fact commonly restricted to just a certain portion of the visual field, depending upon which part of the visual cortex is damaged, it being rare for the entire visual cortex in both cerebral hemispheres to be damaged). For example, when a light is flashed in the blind field of a human patient, and he is asked whether he sees it, he will say 'no'. A monkey, in contrast, if appropriately trained, will reach out to touch a brief visual stimulus, can locate it accurately in space, and can discriminate between lines of different orientation and between simple shapes. He will pick up even quite minute specks of food if they contrast well with the background.

This difference in outcome puzzled investigators as long ago as the end of the nineteenth century. They appealed to a doctrine of 'encephalization of function' to account for it. This doctrine asserted that, in evolution, visual and other functions somehow migrated to higher and new structures in the brain, so that in man visual function had reached the highest level, namely the visual cortex, whereas in lower animals a greater degree of visual capacity was subserved by lower midbrain or even brainstem structures. It was a somewhat curious doctrine, because the lower structures do not wither away in man, and therefore one wonders just what role they would have after they had been deprived of their earlier role. Be that as it may, it is only very recently that investigators have actually started to ask their human patients the questions in a form in which one is perforce obliged to ask them of animals. That is, the subject is asked to discriminate between stimuli, using a forced choice method—whether or not he says he can 'see' the stimulus. He is asked to guess, say, whether or not a stimulus occurred, whether it was located at position *A* or *B*, whether it was a cross or a circle, and so on. Using this approach it has been found that some human subjects with damage to the visual cortex can perform about as well as animals in the absence of such cortex. The subjects themselves may be quite unaware that they are able to perform so well, and indeed surprised to learn that they can, because they say they did not actually 'see' the stimuli. This residual capacity is called 'blindsight'. Of course, pathology in man is varied, and more often than not when visual cortex is damaged, the surrounding tissue is also damaged. Therefore, not all patients with blind fields associated with brain damage show blindsight.

There is an additional aspect to this discovery. The residual capacity in the monkey actually increases as the animal continues to use it; significantly, this improvement does not occur spontaneously, but with practice the region of only partial vision actually contracts. Recently, some human patients with field defects have been shown to have the same benefit: their regions of blindness (if caused by damage to the visual cortex but not, of course, if caused by damage to the eyes themselves) also contract with specialized practice designed to make them give forced-choice responses to visual stimuli in their 'blind' fields. It is not clear how much of this recovery is mediated by the surrounding intact visual cortex, and how much by one of the parallel pathways from the eye to the midbrain. Probably both are involved.

A second example implying differences in the organization of Primates' brains comes from the field of memory defects. Damage to certain midline structures in the human brain can yield a persistent state of profound memory failure. Patients apparently cannot remember fresh experiences for more than a few seconds.

Paradoxically, in animals it seemed for a long time that these same midline structures—apparently anatomically identical to those in man—could be dispensed with almost with impunity. No obvious losses of memory or learning capacity appeared to result. The story is similar in some respects to that of blindsight. It has emerged that the sorts of tasks that animals were traditionally taught to test their learning capacity, and which they succeeded in learning and retaining, can also be learned quite well by amnesic patients. Indeed, there is now a large catalogue of tasks that such patients are known to succeed in learning and retaining. They all share one property: in none of them is it necessary actually to ask the patient, 'Do you recognize this?' or 'What do you remember of the task we just saw?' Indeed a patient may acknowledge no memory for the task, even though he succeeded in it. For example, if shown a list of words, and later asked what the words were, he may well say he cannot remember even seeing a list of words. But if shown the first few letters of each of the words and asked to guess what words they stand for, he is likely to produce the very words for which he says he has no 'memory'. Or, to take another example, a patient will show a benefit of having solved a particular jigsaw puzzle by solving it faster the next day (but only the jigsaw he solved before). Amnesic patients can learn such tasks and show good retention over quite long periods—weeks or even months, in fact—although, again, as with blindsight, the capacity is distinct from an acknowledgement of it by the subject. It remains to be seen whether methods of retraining such patients, whose lives are severely crippled by memory impairment, can also be developed. There are at least serious efforts being made along these lines.

Both of these examples have come to light specifically in the context of a paradoxical and deep discrepancy between animal and human clinical research. But there are other examples that come directly out of clinical research. The best known are from work on commissurotomy patients, popularly referred to as '*splitbrain'

patients. In these, surgeons have severed the connections between the two cerebral hemispheres in order to try to control the spread of uncontrollable epileptic discharges throughout the entire brain. Such patients enable an investigator to direct perceptual information to one or other of the two cerebral hemispheres, and thereby to infer what its capaci

ties are in isolation from the other hemisphere. (For example, by projecting a visual image on to the left half of the retina, only the visual cortex of the left hemisphere is stimulated.) Research with such patients has strongly reinforced an already well-established view, namely that the verbal commentaries require the participation of the left hemisphere (especially in the righthanded subject). But it has also shown, interestingly, that information directed to the right hemisphere can still be used by a patient, even in response to a verbal instruction from the experimenter and even though the patient does not acknowledge his success. Thus, a subject will deny recognizing an object (masked from view) presented to his left hand (which is controlled by the right hemisphere). But at the same time the left hand will correctly select an object from an array if 'instructed' to do so by flashing the name on to the right side of the retina, so that the right hemisphere has access to the word. Of course a vast amount of our everyday activity is carried out without direct awareness: indeed, it would be wasteful actually to reflect on processes that can be dealt with in an automatic way, once they become routine—for example, constriction of the pupil or accommodation of the lens of the eye. A great variety of skilled motor acts, some learned and some not, do not warrant introspection. It is also wasteful to reflect on each occasion when we stop at a trafficlight that we 'remember' red means stop, even though this clearly reflects retention of a learned association. The brain may well reserve for itself only a small proportion of its capacity for those activities that form the corpus of material for the introspector of mental processes. The study of patients with 'blindsight', or of memory without awareness, or of splitbrain patients, not only highlights what regions of perception, memory, and other 'cognitive' capacities can be divorced from awareness, but also may allow an empirical analysis of the boundary conditions of those regions.

The examples taken from human clinical research go beyond anything that can be drawn from comparative research with animals. (Although, of course, corresponding regions of the brain can be studied, how can one ask an animal not only to discriminate or select a stimulus from an array but to reveal to us whether or not he can

'recognize' it or 'characterize' it?) Even so, some progress along these lines can be seen. Animal investigators in recent years, spurred on in part by the paradoxical discrepancies between their findings and those from the human clinic, have been able to evolve new methods of testing recognition memory in animals. It appears that recognition can be altered independently of an animal's capacity to discriminate stimuli and form simple associations between visual events and reward. But work has scarcely begun on the more fundamental problem of how to allow an animal not only to discriminate or learn and to retain but to acknowledge these acts. And, therefore, while the paradoxical gap between the results of animal and human brain research may have been reduced, we are left with the even more difficult problems: how would one know whether an animal possesses blindsight and when is an animal aware that he can discriminate? Is a frog or an insect ever aware of such a capacity? That question was raised in the nineteenth century by some of the pioneers of research on the visual cortex, but then afterwards largely ignored. For a long time it appeared that it could be ignored safely—that it might even be a pseudoproblem. But it is difficult to accept that animals, especially advanced Primates, differ so fundamentally from humans that they do not demonstrate the same division between automatic unmonitored acts and those acts that are so effectively monitored as

to enable further action to be based upon the knowledge of them. To ask such a question of an animal would appear to require not only the standard methods used to study its discriminative and mnemonic capacities, powerful as they are, but the introduction of a parallel response which could serve as a 'commentary' response, by which the animal could signal its acknowledgement that it has indeed 'seen' the signals, and ultimately might even offer a confidence level. Perhaps the important contribution that animal research has made towards uncovering unsuspected capacities in human patients will be repaid by the development of techniques that will allow us to ask much deeper questions of our animal relations.

BRAIN MANIPULATION, THE ETHICS OF. Brain manipulation—the changing of people's motivation or personality by physicochemical action on the mechanisms of the brain—is at least as old as the discovery of alcohol. The basic ethical and philosophical problems are as well illustrated in principle by the oldfashioned phenomenon of drunkenness as by the more subtle and bizarre changes that can be produced by modern drugs or brain surgery. In each case we have changes not just in the ability of the mind to make the body serve its purposes but also in the process and the purposes of 'minding' itself. The affected individual may find his priorities changed, his ability to think, remember, and plan disturbed, and his moods and relationships distorted or incoherent.

Such phenomena would be surprising if we thought of the mind as related to the brain in the way that, say, a driver is related to a car. Physical damage to the car might leave the driver unable to achieve what he wants; but it would not be expected directly to change what he wants, let alone his ability to think about it. With a different sort of thought model of the human being, however, the facts make sense in a way that attaches an even heavier responsibility to the manipulator. All the evidence to date suggests that the mind is much more intimately related to the brain than a driver to his car. The relationship is twoway, and has been likened to that between a message and the ink in which it is written, or between the equation being solved by a computer and the electronic workings of its transistors. Any change in the message must mean a change in the distribution of ink; any change in the equation must mean a change in the activity of the transistors. Conversely, some (though not all) of the physical changes we could make in the ink pattern would necessarily alter the message; and some (though not all) of the physical changes we could make in the computer would *ipso facto* alter the equation being solved. The one, we say, is 'embodied' in the other.

The working assumption of most brain scientists is that our conscious experience is 'embodied' in the activity of our brains in a rather similar sense: so that no change can take place in someone's conscious experience or personality without some corresponding physical change taking place in his brain. Conversely, it would be expected that some (though not all) of the physical changes we could make in his brain would *ipso facto* alter his conscious experience, or even the very structure of his personality. Thus the brain manipulator has the heavy responsibility of shaping not only what his patient can do, but also what sort of person he is.

Once this is recognized the ethical issues fall into place, in the same class as those raised

by*education and other ways of shaping and reshaping personality and motivation. Physical manipulation of the brain can be classified as a drastic alternative to more conventional methods of determining what sort of people we are. The essential ethical constraints—over and above those governing surgical or pharmacological intervention in general—are those that should inform and limit the practice of education. The same deepgoing tests of the manipulator's motivation are applicable, such as compassion, respect both for what the other is Page 114

and for what he can become, and the absence of selfseeking hubris. These, if accepted, would rule out all dictatorial abuse of drugs or neurosurgery to enslave fellow human beings.

It should be added that although it is already possible to demonstrate animals made hungry, thirsty, maternal, or sexy by electrical stimulation of the brain, such techniques are bound in practice to be crude and poorly selective. According to the neuroscientist Elliot Valenstein, 'the belief that we can stimulate or destroy a given region of the brain and reliably produce only one type of behaviour is sheer fantasy'. It seems fair to say that if a dictatorial government wanted to control its population, it would be likely to find some of the olderfashioned methods more costeffective than either mass brainimplantation or drugadministration.

Bracketing brain manipulation with education, rather than with something like heart surgery, should not blind us to one important difference between the two. In the upbringing and education of children the shaping process uses and (ideally) respects the subject's conscious mental processes; manipulation is exercised (quite ethically) at the *personal* level. Brain manipulation, however, whether by surgery, current injection, or drugs, is carried on at an impersonal level. Quite apart from the crudity of the means available, this introduces a factor of great ethical significance which has no parallel in education. It may be best illustrated by an analogy.

A human brain after many years of life can be compared with a chessboard (of gigantic complexity) on which the layout of the pieces reflects the history and identity of one particular game. Normal interpersonal communication, as in education, can be likened to the making of moves that respect the rules of chess, and so preserve the continuity and identity of the game. By contrast, physical brain manipulation can be compared with the removal or addition or displacement of chessmen without regard to the rules. The end result might or might not be a legitimately playable game; but, in a sense that could be important, the play would not in general be a continuation of the same game.

The corresponding question in any particular case of brain manipulation, then, is whether the individual who emerges from the exercise is still (for ethical purposes) *the same individual*. In the most radical (and purely fictional) case of complete 'brain transplantation', explored by H. G. Wells in 'The Story of the Late Mr Elvisham', the answer would presumably be 'no'. In general it would obviously be a matter of degree. All of our brains lose a small fraction of their nervecell population daily by natural decay, without disrupting the effective continuity of our personalities. (One might compare this with the amount of ink that can be lost from a written message without changing what it says.) The alternative, however, which may have to be faced in extreme cases of irreversible brain damage, would be that the life of the original individual had effectively been terminated. In that case, even though a viable human being were to emerge from the operation, it is arguable that such brain

manipulation should be bracketed for ethical purposes with homicide or murder.

BRAIN SCIENCE: SPERRY'S CONTRIBUTION. Roger Sperry, Trustee professor emeritus of psychobiology at the California Institute of Technology, is famous for experimental studies of how brain circuits are formed, and for research on mental activities after the connecting tracts between the cerebral hemispheres have been cut. He worked for his doctorate in close association with the biophysicist Paul Weiss, who had developed surgery to analyse how connections between nerves and muscles are patterned, and had demonstrated that the movement patterns of amphibia develop spontaneously in the embryo. By transplanting limb buds and rerouting motor nerves, Weiss found that salamanders could regain an excellent sequential control of their limb muscles, the nerves making connections that matched, not the locomotor usefulness of the movements, but the embryonic origins of the different muscles. Sperry felt there must be a more specific and refined control of the growth of nerve circuits than any existing theory could explain, and that the intricate networks of the brain must result from a highly differentiated genetic coding for nerve contacts. He transplanted the insertions of extensor and flexor muscles of rats, or cut and rerouted their nerve supply, and then observed their limb movements. He reported that the rats' motor system was almost completely lacking in plasticity: except for some editing out of false moves of the forelimbs, central motor command was inflexible. The rats' wrongly connected nerves or muscles continued to produce maladaptive movements.

In the early 1940s, with Karl Lashley, Sperry published a paper on the effects of thalamic lesions on olfactory learning in the rat, yet his main endeavour now was to explore the laws that fitted nerves into functional networks in development. He confirmed the finding by Robert Matthey in Switzerland and Leon Stone at Yale that after a newt's eye had been dissected from the head and replaced, retina and optic nerve would reconnect

Page 115

to the brain and normal vision would return. Sperry observed the behaviour of the animals more

closely; and he showed that when a transplanted eye had been rotated through 180°, movements to catch food after recovery of vision were precisely as predicted by the theory that cells at each retinal point had reconnected themselves to the same place in the brain as before surgery. All orienting reactions were the reverse of correct, like those of a person who has just put on inverting prisms, though for newts adaptive visuomotor coordination was not regained. This proved that the routing of nerves, beyond a random tangle in the rejoined optic nerve into the brain centres, was precisely guided by some pathfinding principle in which learning played no part.

Later experiments on amphibia showed that regeneration of links from eye to brain, and from brain to the muscles of the eyes and fins—both of which make intricate movements in these species— obeyed the law of innate specification of connections. With Norma Dupree, a fellow biologist, whom he married in 1949, he carried out an important study at the Lerner Marine Laboratory, Bimini, West Indies, which found evidence suggesting that motor nerves preferred to regenerate connections to their own muscles. This suggested that the salamanders Weiss had studied were atypical. Later Richard Mark, working with Sperry in California, showed this to be the case.

In 1950 Sperry reported that fish and newts with one eye removed and the other either inverted or transposed to the opposite side of the head behaved in a peculiar way. They remained quiet, if not caused to swim, but spun in accelerating circles as soon as they moved. This behaviour was affected only by removal of the midbrain, where the optic nerves terminate, and was unchanged by removal of the labyrinths (organs detecting accelerations and gravity) or severance of the oculomotor muscles. Sperry concluded that the midbrain is the site of a predictive adjustment of visual perception triggered by the impulse to turn. The signal on the retina that the external world was displacing relative to the animal's head, was now reversed along the front/back axis by surgery. It signalled that the world was receding, and the locomotor system then worked harder to catch up, like a kitten chasing the tail of another kitten running twice as fast. Sperry proposed that there is an internal brain signal, which he termed a 'corollary discharge from efference' that matches visual effects normally consequent on each locomotor displacement for its direction and speed. He pointed out that such a 'central kinetic factor' would help explain both perception of selfmovement and the constancy of perception of the spatial layout of the world while in motion. He had independently and simultaneously discovered the integrative principle coordinating perception with movement that von Holst and Mittelstaedt in Germany had found in the reflex optomotor responses of the praying mantis. They called it the 'reafference principle' and explained it, by the same mechanism as Sperry, under the name of 'efferencecopy'.

Sperry then returned to his old idea that many fundamental laws of perception are reflections of inherent and precisely structured mechanisms for patterning movements. In an essay entitled 'Neurology and the MindBrain Problem' (1952) he argued that motor output in free behaviour gave better evidence of the neural basis of integrative behaviour than did the enumeration of simple and unnatural reactions by largely inactive subjects to physical variation in imposed stimuli. He also questioned the anticonnectionist views of Lashley and the Gestaltists, and indicated that associationist learning theories are to be attacked by examining how patterns of response are coordinated, rather than by postulating field processes in the sensory cortex. He showed prophetic insight with regard to questions now being tackled by systems engineers and cognitive scientists

trying to model intelligence with computational machines, and also to those questions of interest to psychologists who seek to relate categories of perceptual processing to the problems the brain has to solve if it is to initiate movements that use terrain or objects efficiently.

Karl Lashley, Wolfgang Köhler, and others believed form recognition to be the result of field effects or interference configurations generated in a random cortical net, or of transitory electrical or magnetic fields arising between nerve cells in the grey matter. To test these ideas, Sperry and his students made minute crisscross cuts under microscopic control throughout the visual cortex of cats, riddled it with tantalum wires to shortcircuit any electrical fields, and implanted leaves of mica to interrupt local transverse currents. Then they subjected the cats to extreme tests of visual form discrimination. They found virtually no losses in vision, and concluded that form perception must depend on the passage of information in and out of small cortical territories, presumably by specific neuronal linkage with cells below the grey matter.

A graduate student, Ronald Myers, invented a delicate operation to cut the crossover of visual nerves ('optic chiasm') under a cat's brain, so that each eye would lead to only one cerebral hemisphere. In 1953 Myers and Sperry reported not only transfer of the visual pattern memory between the hemispheres in chiasm-sectioned cats, but also that this transfer did not occur when the huge fibre bridge between the hemispheres, the corpus callosum, was cut. The term 'splitbrain', with which Sperry's name is associated, refers to this operation and the research to which it has given rise. The operation proved that specific fibre connections could transmit learning, and further challenged Lashley's 'mass action' theory of brain systems.

Sperry and his associates made many experiments on the divided awareness and learning of splitbrain cats, confirming the role of the commissural fibres in memory formation, and he also explored systems by which vision or touch controls

Page 116

voluntary limb movements. The investigations were extended to monkeys: like cats, these showed independent learning in the two brain halves after complete section of the corpus callosum, and experiments found that vision and touch crossed in different parts of the commissure. Colwyn Trevarthen showed that splitbrain monkeys could learn two conflicting visual discriminations simultaneously; in other words, they could have double consciousness.

In the cat, each disconnected hemisphere directed movements of the whole body, but the motor system of splitbrain monkeys was partly divided. They were both less willing to respond with movements of the hand on the same side as the seeing hemisphere and, if forced into action, were clumsy with this combination, as if they became blind each time they moved. Clearly, when the two halves of the cortex were disconnected, only crossed pathways linking each half of the cortex to the opposite hand could guide the fine exploratory and manipulative movements of a monkey's fingers.

Splitbrain animals were used to reveal shifts of attention between the two separated halves of the cortex, and the effects on perception of sets to move in particular ways. Thereby fresh interest was

aroused in the global design of the mammalian brain for awareness, learning, and voluntary action. The minimum territory of cortex needed to retain learned control of the hands by touch or vision was determined by progressively removing all other cortex from one hemisphere of a trained splitbrain animal around the primary touch or visual area until losses occurred. The other half brain was left intact, so that behaviour could continue as usual outside the training situation where experiences were confined to the operated side.

Between 1950 and the mid70s Sperry continued to direct research on the formation of nerve circuits in lower vertebrates. He published some twenty articles explaining and defending his theory that most cerebral functions are determined genetically by some chemical or physiochemical coding of pathways and connections.

New methods for following nerve growth have revealed competitive epigenetic processes involved in sorting out functional connections while they were growing, but so far every attempt to overthrow the chemoaffinity theory by experiment has reached a point where some such selective principle has to be invoked. Sperry has certainly won his battle against the theories of the 1930s that conceived complex psychological functions to be entirely the result of experiences which impose selective influences on random and infinitely plastic nerve nets.

General articles on experiments with cats and monkeys expressed Sperry's belief that learning itself is the consequence of submicroscopic modification in cerebral circuits whose anatomical design is prewired according to genetic instructions. The latter set adaptive goals and give the organism categories of experience as well as intricately coordinated forms of action.

Around 1960, a Los Angeles neurosurgeon, Joseph Bogen, observed with Sperry that the behaviour of splitbrain monkeys outside test situations indicated that division of the commissures left motivation, consciousness, and voluntary action virtually unimpaired. Bogen pointed out that the operation offered promise of relief from debilitating epileptic fits which involved reverberation of discharges across the corpus callosum. In 1962 Bogen and Philip Vogel performed a total neocortical commissurotomy on a man who suffered frequent epileptic attacks, and Sperry and a graduate student, Michael Gazzaniga, were able to apply systematic psychological tests. After 1965 a growing team of researchers under Sperry's close direction, including Jerre Levy, Robert Nebes, Harold Gordon and Dahlia and Eran Zaidel, explored the state of divided and asymmetric mental activity in a small population of commissurotomy patients. The implications of the findings reached into all areas of human mental life, and excited immense public and scholarly interest. An account of the initial findings was given in Vinken, P. J. and Bruyn, G. W.

(eds.) (1969), *Handbook of Clinical Neurology*, vol. 4 (Amsterdam).

From this research came support for concepts of inherent modes of thought and asymmetric involvement of the brain in rational/verbal thinking, nonverbalizable imagery, and conceivably also mystical experience (see SPLITBRAIN AND THE MIND). It stimulated studies of patients with lateralized injuries of the brain and research on the perceptual, cognitive, and motor asymmetries of function in normal subjects. Sperry's hypothesis that the hemispheres are so constructed as to display

unlike psychological functions—genetic variation in*handedness, or the lateralization of language, being but two manifestations of human hereditary regulation—caused a reappraisal of the reasons for differences in intellectual and educational performance of different individuals.

Reflection on inherent mental processes in the human brain led Sperry to publish, in 1965, the first of a series of philosophical papers entitled 'Mind, Brain and Humanist Values'. He proposed a new monist theory of mind in which consciousness is conceived as an emergent, selfregulatory property of neural networks, which enables them to achieve certain builtin goals. These define requirements of the mind and psychological values which are given detailed form and direction by the rituals and symbols of tradition.

Sperry's philosophical ideas have proved somewhat controversial but derive great force from the range and depth of his experience in the field of psychobiology.

Among his publications have been his chapter, Mechanisms of neural maturation, in Stevens, S. S. (ed.), *Handbook of Experimental Psychology* (New York, 1951); Neurology and the mindbrain problem (1952, *American Scientist*, 40, 291312); The eye and the brain (1956, *Scientific American*, 194, 4852); The great cerebral commissure (1964, *Scientific Ameri*

Page 117

can, 210, 4252); Embryogenesis of behavioural nerve nets, in Dehaan, R. L. and Ursprung, H. (eds.), *Organogenesis* (New York, 1965); In search of psyche, in Worden, F. G., Swazey, J. P., and Adelman, G. (eds.), *The Neurosciences: paths of discovery* (Cambridge, Massachusetts, 1975); Forebrain commissurotomy and conscious awareness (1977, *Journal of Medicine and Philosophy*, 2, 10126); and *Science and Moral Priority* (New York and Oxford, 1982).

BRENTANO, FRANZ (18381917). One of the most original figures in the history of philosophy and psychology. In character he was impressive, courageous, even reckless. He was a Roman Catholic priest, but rejected the Pope's infallibility; and his marriage at the age of 42 meant that he had to resign his professorship at the university of Vienna.

Brentano was a man of broad intellectual interests. He is best known for his work in philosophy and psychology, but he also wrote on theology, ethics, and politics.

This, as we shall see, was not foreign to his great endeavour in the field of scientific psychology. Brentano was first interested in Aristotelian metaphysics and, though rejecting*Aristotle's system as a whole, he found in it an important startingpoint for his later reflections on the value and meaning of knowledge. But, having done away with Aristotelian philosophy, he was also deeply aware of the

weakness of the attempts of the psychologists of his time to develop scientific procedures within the framework of philosophical studies. These circumstances, as well as his personal convictions, led him to consider himself as being charged with the mission of reforming philosophy in a fundamental manner. In his view, this mission assumed an 'almost messianic sense' (Spiegelberg, 1960, p. 28).

This peculiar attitude was ultimately motivated by metaphysical concerns. As a result of his reflections on theology, Brentano developed a basically obsessive anxiety about time and eternity; having rejected his religious faith as far as dogmatic contents were concerned, he nevertheless remained deeply troubled by the problems of human destiny which such teachings necessarily raise. Since he could no longer rely on theology, he was bound to search for another lifereference. This he found in *experience*, i.e. in*consciousness. It is therefore not surprising tht he should have devoted his main philosophical effort to the epistemological analysis of the foundations of psychology.

The word 'experience' is misleading because it may be understood either as the content of consciousness in the sense of introspective psychology, or as the perceptual phenomena which make up our empirical knowledge of the external world. As a matter of fact, Brentano succeeded in transcending the classical opposition between immanentism and empiricism by developing an original theory of consciousness that allowed him to escape this wellknown dualistic conception of the psychological subject. This he achieved by stressing the fact that the fundamental property of consciousness is*intenttonality: every subjective experience can only make sense if it is understood as an *act* of consciousness referred to some object, the latter being either some perceptual content, or some mental construct independent of its object but, once again, necessarily referred to some kind of object. Within such a framework, psychological immanentism is condemned at the outset because, though internal *perception* readily exists in subjective experience, internal *observation* of the introspective kind is plainly impossible, since it requires that particular sort of dualism according to which the subject is at the same time an object for himself. If, further, this postulated 'object' is defined as a 'scientific' one, as in early experimental psychology, the study of experience amounts finally to paradoxical realism, because it is a realism devoid of any empirically definable 'reality'.

Given these difficulties, we must now ask ourselves in which sense Brentano claims to be an empiricist, as testified by his wellknown contention that experience is his

'only teacher' and by the significant title of his main work, *Psychologie vom empirischen Standpunkt* (*Psychology from the Empirical Standpoint*) (1874).

Empiricism, in this context, carries the meaning of a return to the only unavoidable experience, viz. the subjective one as constitutive of a relation to the world. We know from*Descartes's philosophy that his *Cogito ergo sum* led him to a similar attitude regarding the foundations of metaphysics and of science. The basic difference in Brentano's system lies in the fact that, unlike Descartes, he does not discard the relation to experienced objects for the sake of the socalled illusions of the senses but strives on the contrary to establish a firm worldreference for every conscious phenomenon. This is the reason why he speaks of *acts* of consciousness, designating thereby not the facts of actual behaviour but the constitutive power of the self as such.

In order to circumscribe the realm of psychic phenomena, empirical psychology must first proceed to a descriptive survey of subjective experience by way of intuition.

This first phase is not meant to be introspective; it is in fact an attempt at delineating psychology's own field of investigation, i.e. at a prescientific level. This basic task of classifying the 'acts' is ultimately phenomenological and represents the epistemological moment of Brentano's endeavour. In the partial republication of his original work in 1911 under the title *On the Classification of Psychic Phenomena*, Brentano refers to it as 'psychognosis' or 'phenominognosis'. Once this has been completed, the second task of empirical psychology is to establish psychological science as such by evidencing the causal relations between phenomena, eventually up to

Page 118

the physiological level. Brentano refers to this part of his work as 'genetic' psychology. We see therefore that what he is aiming at is finally a kind of experimental psychology epistemologically well founded, i.e. relying firmly on actual subjective experience.

It is worth noting that the publication of *Psychology from the Empirical Standpoint* coincided almost exactly with that of Wilhelm*Wundt's *Grundzüge der physiologischen Psychologie (Foundations of Physiological Psychology)*, both works appearing in March 1874. However, of these two founding treatises, for many decades only that of Wundt exerted a wide influence on the developments of psychology as a science. This was most probably due to the fact that in Wundt's system the relation of psychic events to physiological ones was more readily understandable, because Wundt took the existence of phenomena of consciousness for granted, under the form of introspectively accessible 'objects', whereas in Brentano's view the very concept of object could only be defined through the intentional founding acts. Historically speaking, it seems that the positivistic impetus given by Wundt to the new science of consciousness was much stronger than the epistemological warnings of Brentano concerning the *possibility* of a scientific psychology.

More than a century has now elapsed since the birth of experimental psychology, and we are in a better position to appreciate the results. Whatever tendencies made their appearance in psychology during this long period of experimenting and theorizing, we know that the debate is not closed. Brentano's teachings have made their way through the school of Graz and were responsible for the emergence of both*Gestalt psychology and*Husserlian phenomenology. The psychological positivism inherited from Wundt has evolved in its own way; it has not only yielded visible results, but has also given rise to a great deal of methodological and even epistemological reflection. This in itself testifies to the fact that the question of the *essence* of psychic phenomena, to use a phenomenological expression, is an unavoidable one. No doubt it would be careless to consider that a satisfactory answer to it will be found by merely increasing the quantity of factual results, since psychological *data* are the products of intentional acts of scientists. Today's psychologists are therefore indebted to Brentano—be it in an indirect fashion—for his early endeavour to lay the epistemological foundations which psychology needs, in order to exist as an adequate science of man's subjective experience.

BREUER, JOSEPH (18421925). *Freud described his close friend and collaborator, Joseph Breuer, as 'a man of rich and universal gifts, whose interests extended far beyond his professional activity'. For Breuer's professional activities and achievements extended from being a distinguished physician in Vienna, to discovering the significance of the vagus nerve for controlling breathing, and to establishing the essential functions of the semicircular canals for the sense of balance. He is, however, known best for his work on*hysteria— following the celebrated case of Frl. Anna O.

During her father's last illness Anna O. developed paralysis of her limbs, and anaesthesias, as well as disturbances of vision and speech. Breuer noted that she had two alternating personality states: one more or less normal, the other that of a naughty child. He found that the symptoms were reduced or disappeared after she described her frequent and terrifying hallucinations. This 'talking cure' or 'chimneysweeping', as they called it, led Breuer to the use of hypnosis to speed things up, and to the concept of catharsis. Anna O.'s true name was Bertha Pappenheim (18591936). She was highly intelligent and unusually physically attractive. She became the first social worker in Germany and founded a journal. She never was entirely cured.

The Anna O. case made a deep impression on Freud, who heard of it shortly after Breuer terminated treatment in June 1882. Discussions of it with Breuer were a formative basis of Freudian theory and psychoanalytic practice; especially the importance of fantasies (in extreme cases, hallucinations), hysteria (which was first fully recognized by*Charcot), and the concept and method of catharsis which were Breuer's major contributions. Breuer also introduced the use of hypnosis as a clinical tool. Freud adopted it for a time but later gave it up in favour of*free association.

BREWSTER, SIR DAVID (17811868). Scottish physicist, born at Jedburgh and educated at Edinburgh University, of which he became vicechancellor in 1860.

He was elected a fellow of the Royal Society in 1815 and was active in the foundation of the British Association for the Advancement of Science. His main interest was optics, and in 1816 he invented the kaleidoscope. He also improved Wheatstone's stereoscope (or at least made it more convenient,

by introducing lenticular prisms rather than Wheatstone's mirrors) so allowing pairs of large pictures to be presented, one to each eye, in spite of the small interocular distance and the inability of the eyes to diverge for fusion. He also made important discoveries on the polarization of light (notably Brewster's law, that when the polarization is at a maximum the tangent of the angle of polarization—Brewster's angle—is equal to the refractive index of the reflecting medium).

Page 119

Wade, N. J. (1984). *Brewster and Wheatstone on Vision*. New York.

BRIGHTNESS. The sensation of light which is roughly associated with the intensity of light at the eye, or its luminance. The sensation of brightness is affected by the adaptation level of the eye and by various contrast phenomena—so brightness cannot be measured in physical units. (See VLSUAL ADAPTATION.) **BROAD, CHARLIE DUNBAR** (18871971). English philosopher, professor of moral philosophy at Cambridge (193353). He carried out detailed conceptual analyses of science (*Scientific Thought*, 1923), of mind (*Mind and its Place in Nature*, 1929), and of ethics (*Five Types of Ethical Theory*, 1930). His *Examination of McTaggart's Philosophy* (19338) contains interesting discussions on time.

See also EMEROENCE AND REDUCTION IN EXPLANATIONS and PARANORMAL.

BROCA, PAUL PIERRE (182480), French surgeon and anthropologist, professor of surgery and anthropology in Paris, was the only son of a doctor at Sainte

FoylaGrande, a small town in the Gascogne, on the fiver Dordogne, east of Bordeaux. He is remembered chiefly for establishing in 1861 that destruction of an area of grey matter not much larger than 4 square centimetres—'Broca's area'—makes a person unable to speak—Broca's (expressive or motor)*aphasia, by him first called 'aphemia'. In practically all righthanded people this area, he also found, lies in the left; hence it is called the 'dominant' hemisphere of the brain. His test case was a patient nicknamed 'Tan', because 'tantan' were the only syllables he could produce for an answer. By contrast, Tan's understanding of the spoken word was considered to be intact. For years Tan had also been paralysed on the fight side—presumably through a succession of strokes—and had become Broca's surgical patient because of an infected bed sore. He soon died. At autopsy his brain showed the essential lesion situated at the hind end of the third, or inferior, of the three frontal lobe convolutions (or gyri). Here, for the first time, it was demonstrated with fair precision that a small set of muscles as well as a mental function—the expression of ideas through words—could be localized in a fairly circumscribed portion of brain tissue. The observation has been confirmed innumerable times since.

(In 1870 Gustav Fritsch and J. L. Hitzig localized motor function, Carl*Wernicke three years later a receptive speech area.) Before Broca established this localization, only a few diehards had been upholding Franz Joseph*Gall's vague contention of half a century earlier that the frontal lobes generally 'preside over the faculty' of speech.

Broca's other major contribution to understanding the relationship between the structure of the brain and mental function concerns what in the 1950s was revived under the designation of the '*limbic system'. This comprises the convolutions of the inner wall of the cerebral hemispheres and part of the inferior aspect of the frontal lobes. Broca based his concept of the 'great limbic lobe' on the fact that it is relatively underdeveloped in aquatic mammals and Primates, including the human, as compared with lower mammals, which rely to a much greater extent on the sense of smell, and have otherwise less developed hemispheres. On this basis Broca contrasted a 'brute' part with an 'intelligent' part of the brain. Today the limbic (threshold) system is recognized for being concerned with emotion, instinct, and visceral control.

When in 1859—also the year of Darwin's publication of *The Origin of Species*—Broca was prevented in the Société de Biologie from reading a series of his papers considered too revolutionary as they negated the permanence of species—he founded the Société d'Anthropologie (the first under this name), and later a laboratory, museum, and institute. One of the papers was based on a study of fertile 'leporids', so-called in France because they were a cross between a hare and a female rabbit.

Broca also first described Cro-Magnon and Aurignacian, or palaeolithic, man, developed a large number of instruments for measuring skulls (craniometry), employed the novelty of statistical standardization, and lent the budding science of anthropology his eminently critical spirit. He inaugurated the study of prehistoric trephining of the skull, and exploded the 'Celtic myth' (that the Celts constitute a racial group with inherited characteristics) and other racial prejudices: 'Spread education, and you improve the race,' were his words. In his early years he belonged to a small group who used the microscope to detect cancer cells, and he discovered their spread via the venous system. He published some 500 papers but his only major book was a standard monograph on aneurysms.

He was also active in political life, holding radical views. He was elected to the French Senate in 1879, but died one year later having delivered only one memorandum, which pleaded to grant public high school education to females. He was sceptical about the prevalent view of equating female inferiority with the female's relatively smaller brain: 'An enlightened person cannot think of measuring intelligence by measuring the brain', he wrote.

F. S.

BROWN. Although perhaps the commonest colour, brown is not in the spectrum: it is not a spectral hue. It cannot normally be produced by a mixture of any three lights—as can the spectral hues (see COLOUR VISION: BRAIN MECHANISMS; COLOUR VISION: EYE MECHANISMS)—and is thus somewhat mysterious. It seems to depend on contrast, and on perceived surface texture, which may also affect other colours.

Page 120

BRUNSWIK, EGON (1903–55). Austrian-American psychologist, born in Budapest and educated in Vienna. He intended originally to be an engineer but deviated to psychology and worked in the

Psychologisches Institute in Vienna under Karl Bühler, where he obtained his doctorate and became a *privatdocent* in 1934. He spent the following year as a visiting lecturer at the University of California at Berkeley, to which he returned in the following year with the intention of becoming a permanent immigrant to the United States. He became an assistant professor in the department of psychology and in 1947 was promoted to full professor.

Brunswik's early interests lay almost exclusively in the field of visual*perception, and he published a scholarly monograph on object constancy based on experiments carded out in Vienna before he emigrated to the USA (*Wahrnehmung und Gegenstandswelt*, 1934). In America he extended and developed his interests in perception, in part as a result of his close friendship with E. C.*Tolman, with whom he published a joint paper on 'The organism and the causal structure of the environment' (*Psychological Review*, 22 (1935), 4377). He also developed a strong interest in the design of psychological experiments, producing an original, though difficult, monograph on *Perception and the Representative Design of Psychological Experiments* (1956). He was also much interested in the philosophy of science and the history of psychology.

BURT, SIR CYRIL LODOWIC (18831971). British psychologist, born in London, the son of a medical student who was later to become a general practitioner in Warwickshire. Burt is remembered primarily for his pioneering development of psychology in the fields of education and guidance. While still a schoolboy he met and came under the influence of Francis*Galton, who was a patient of his father's, and his whole life's work can be regarded as an attempt to uphold the Galtonian tradition of individual psychology. This tradition emphasized the importance of individual differences in ability and character, the role of heredity in determining these differences, and the need to develop statistical methods in order to handle quantitative measures and assessments.

Burt received a classical education at Christ's Hospital and Oxford University. It was at Oxford that he came under the influence of William*McDougall, who was at the time reader in mental philosophy. He assisted McDougall in collecting psychological measurements for a survey of the British people sponsored by the British Association for the Advancement of Science. The data collected during this survey provided the material for his first important article, 'Experimental tests of general intelligence', and set the pattern for his life's work. After graduating in 1907, he spent some time in Oswald Külpe's laboratory at the University of Würzburg, and then took a lectureship in Liverpool under C. S.*Sherrington. He remained in Liverpool for five years, continuing to work on*intelligence, and constructing new types of verbal reasoning test. In 1913 he was appointed psychologist to the London County Council. This was a new appointment, and the first of its kind in Britain. Burt's job was to assist the Council's education committee in two main tasks; the identification of pupils requiring special treatment by reason either of mental subnormality or of behavioural maladjustment,

and the selection of gifted pupils for secondary education. In furtherance of these aims he conducted a systematic survey of the distribution of educational abilities among London schoolchildren, and compiled and standardized a set of mental and scholastic tests that remained in use for more than forty years. In addition to his psychometric work Burt ran what was in effect the first child guidance clinic in Britain. The material he collected in this clinical work formed the basis of his classical treatises, *The Young Delinquent* (1925) and *The Backward Child* (1937).

Burt's routine duties with the London County Council occupied only part of his time. On the foundation of the National Institute of Industrial Psychology in 1921 he assisted C. S.*Myers in establishing a vocational guidance service; and in 1924 he became parttime professor of educational psychology at the London Day Training College. Aided by teachers, social workers, and students he collected during this period a large body of data, clinical and psychometric, including data on twins, which he was to make use of in his subsequent publications. In fact the bulk of Burt's data was almost certainly collected between 1913 and 1932, before he was appointed to the chair of psychology at University College, London, in succession to Charles*Spearman.

This appointment marked the climax of, and at the same time a turning point in, Burt's career. Until 1932 his energies had been directed primarily towards applied problems; after 1932 he turned mainly to theoretical and methodological questions, chief among which was factor analysis. Building on the foundation laid by Spearman, Burt introduced new mathematical techniques (by this time he had become a competent statistician), and provided new evidence for group ability factors to supplement Spearman's general factor, 'g'. His views were set out definitively in *The Factors of the Mind* (1940), and later in the pages of the *British Journal of Statistical Psychology*, which he edited, for a time with Godfrey Thomson, from 1947 to 1963. Burt never wavered in holding that there was a 'general factor' of cognitive ability, that this

Page 121

factor was largely innate, and that it roughly corresponded with what in popular language is called 'intelligence'. These views of Burt had considerable influence in the shaping of the educational system established by the Education Act of 1944. Burt had frequently been consulted by the official committees on education during the 1920s and 1930s, and during the Second World War he was an adviser to the armed services on matters connected with personnel selection and training. In recognition of this work he was knighted in 1946.

Burt retired from his chair at University College in 1950, and for the remaining twentyone years of his life lived quietly in his London flat. His activities were restricted by attacks of Ménière's disease, which had commenced during the war. This prevented him from carrying out any field studies or research, but he continued writing, most of his publications being either of a theoretical nature or based on data collected in the early part of his career. Among the latter were his articles on the multifactorial theory of inheritance, which contained the results of his twin studies.

He had from very early days been interested in the question of inheritance, and was from the beginning a convinced Mendelian. Even prior to the First World War he had suggested that Mendelian

genetics could be applied to the inheritance of mental qualities. By the 1930s he had become familiar with Ronald Fisher's work on quantitative genetics, and in a famous article written together with an alleged collaborator, Miss Howard, and published in 1956, he concluded on the basis of an analysis of the test scores of twin pairs reared together and apart that 'intelligence was to an overwhelming extent innate'. It is generally agreed that Burt was a pioneer in the application of multifactorial genetics to psychometric data, and his work in the area had a considerable impact. Further articles in 1966, written with another equally mysterious collaborator, Miss Conway, and backed up by a much larger twin population, appeared to lend additional weight to his earlier conclusions. There is little doubt that these articles were a response to the attacks to which his views on inheritance were increasingly subjected from the 1950s onwards. It was only after Burt's death in 1971 that serious discrepancies and flaws were detected in his data on twins, and it is virtually certain that he never in fact collected the additional twin material which he professed to have acquired during his retirement, or that he was assisted by any collaborators. Illness and disappointments may partly explain Burt's frauds, but cannot condone them. His reputation following this exposure suffered a catastrophic decline, so much so that there is a tendency to overlook the important achievements of his early years.

Burt was Britain's first applied psychologist. He laid the foundations of applied educational psychology, vocational guidance, and child guidance in Britain; developed many of the psychological tests that were employed widely during the first half of this century, and refined the techniques of statistical analysis. To a considerable extent he put applied psychology on the map, and made it seem relevant and practical. He was highly regarded by those most closely associated with him between 1910 and 1950. Nevertheless, there were always weaknesses in Burt. He was never at heart a scientist. Much of the data he collected were hastily gathered and of doubtful quality. He was an able and ambitious man, who early came to regard the Galtonian tradition almost as gospel truth and himself as Galton's heir. He was immensely erudite, industrious, and accomplished; to those who were prepared to look up to him, he was kind and generous. But he could not take criticisms or rebuffs; he could not brook opposition; and in the last resort he tragically chose to cheat rather than see his opponents triumph.

BURTON, ROBERT (1577-1640), author of *The Anatomy of Melancholy*. Burton was born at Lindley in Leicestershire and went to Brasenose College, Oxford, in 1593, becoming a student of

Christ Church in 1599 and vicar of St Thomas's, Oxford, in 1616. In about 1630 he also became vicar of Seagrave in Leicestershire, but for most of his life he lived a 'silent sedentary, solitary, private life' at Christ Church.

The Anatomy of Melancholy was first published in 1621. Melancholy was, he considered, an 'inbred malady in every one of us' and he wrote on it 'by being busy to avoid melancholy'. The book is divided into three parts: the first deals with the causes and symptoms of melancholy; the second with its cure; and the third with the melancholy of love and the melancholy of religion. He expanded the subject, however, to cover the whole of the life of man, and on every page there are many quotations and paraphrases from a very wide field of literature, giving the book the reputation of a storehouse of miscellaneous learning rather than a medical treatise.

BUTLER, SAMUEL (1835-1902). British author, painter, musician, and eccentric philosopher, born at Langar, Nottinghamshire, where his father was rector. He was a direct descendant of Samuel Butler (1612-80), the author of the satirical poem *Hudibras* (1663), which lampooned puritanism, and the grandson of Samuel Butler (1774-1839), classical scholar and Bishop of Lichfield and Coventry. Educated at Cambridge, he emigrated to New Zealand in 1859, where he ran a successful

Page 122

sheep farm, returning to England in 1865 to concentrate on writing and painting.

Erewhon (1872) is satirical romance set in the land of Erewhon (roughly nowhere backwards). In chapters 235 there is an extended discussion of the effects of machines on people, and of consciousness and intelligence considered in terms of actual or potential machines, as well as animals and plants. Thus: There is no security against the ultimate development of mechanical consciousness, in the fact of machines possessing little consciousness now... who can say that the vapour engine is not a kind of consciousness? Where does consciousness begin and where end? The shell of a hen's egg is made of a delicate white ware and is a machine as an eggcup is; the shell is a device for holding the egg as much as the eggcup for holding the shell.

And considering flyeating plants:

When a fly settles upon the blossom, the petals close upon it ... but they will close on nothing but is good to eat; of a drop of rain or a piece of stick they will take no notice.

Curious that so unconscious a thing should have such a keen eye to its own interests! If this is unconsciousness, where is the use of consciousness?... Shall we say that the plant does not know what it is doing merely because it has no eyes, or ears, or brains? If we say that it acts mechanically only, shall we not be forced to admit that sundry other and apparently very deliberate actions are also mechanical? If it seems to us that the plant kills and eats a fly mechanically, may it not seem to the plant that a man must kill and eat a sheep mechanically?

There is a prophetic account of artificial intelligence, as Samuel Butler considers the rapid development, and imagines future machines: There was a time when it must have seemed highly

improbable that machines should learn to make their wants known by sound, even through the ears of man; may we not conceive, then, that a day will come when those ears will be no longer needed, and the hearing will be done by the delicacy of the machine's own construction—when its language shall have developed from the cry of animals to a speech as intricate as our own? ... We cannot calculate on any corresponding advance in man's intellectual or physical powers which shall be a setoff against the far greater development which seems in store for the machines. Some people may say that man's moral influence will suffice to rule them; but I cannot think it will ever be safe to repose much trust in the moral sense of any machine.

Machines are outlawed in *Erewhon*—as potentially far too dangerous for man to live with.

In *Erewhon* and in some of his other writing, for example *Life and Habit* (1877), *Luck or Cunning* (1886), and in his *Notebooks* (1912, edited by H. Festing Jones), he expressed his views on Darwinism. Though he accepted natural selection he protested against the banishment of mind from the universe and argued for the inheritance of acquired habits. The novel *The Way of All Flesh* (published posthumously in 1903) is largely autobiographical and explores family strife and morality in ways that affected Shaw and later writers.

Page 123

C

CAFETERIA EXPERIMENTS. The selfassessed dietary preferences or needs of animals (and perhaps humans), indicated by freechoice feeding from a large variety of their normal, or sometimes unfamiliar, foods or substances. There is some evidence that animals may choose substances containing vital minerals which have an effect only some days, or weeks, after eating. It is not clear how these preferences arise by learning when the effect is delayed for so long.

CAJAL, SANTIAGO RAMON Y (18521934), Spanish neuroanatomist. See RAMON Y CAJAL.

CALCULATE. To use numerical techniques to find the answer to mathematical problems by formal rules, such as those of arithmetic. The word is derived from the Latin *calculus*, meaning small stone, referring to the ancient, and indeed prehistoric, use of pebbles for counting, later formalized in the abacus. The first gearwheel calculating machine was built by Blaise Pascal in the year of Isaac Newton's birth, 1642. It is odd that this and many later demonstrations of the calculations of 'mental arithmetic' being undertaken by machine did not, at once and generally, suggest that human thinking may be carried out by physical brain processes and may be largely or completely unconscious.

CALCULATING GENIUSES. The term 'calculating genius' describes anyone strikingly more able than normal to do numerical calculations mentally. Since the term is relative to what is regarded as normal, it is applied to people of three different types. (i) Children whose ability is precocious, i.e. exceptional for their age but not necessarily by comparison with many adults. (ii) Mentally retarded people in whom mental calculation is an 'island of ability'. Their ability is not usually outstanding by normal standards but contrasts with their general lack of ability in other respects. (iii) People whose

ability is exceptional relative to the adult population at large, and among whom calculating geniuses, in the strict sense, are to be found.

In studying calculating geniuses, four general points merit emphasis. First, the ability rests on the individual's knowledge of numerical facts and shortcut methods. To illustrate, you can multiply by 25 by dividing by 4 and multiplying by 100: for example, 16 times 25 is 4 hundreds. The answer, 400, is attained so rapidly that it seems miraculous to anyone unfamiliar with the short cut. Now, there is literally no end to the numerical facts, interrelations, and short cuts that may be discovered; and when these are deployed in mental calculation, the resulting performances can be impressive, especially to the uninitiated. Mental calculators of high calibre skilfully deploy extensive, recondite knowledge of facts and methods which are largely unknown to, and unsuspected by, most people, and which have usually been discovered by the calculator himself.

Secondly, people who have acquired a small amount of numerical knowledge can go on by themselves to discover and elaborate new facts and methods, and progressively build calculating ability that is out of the ordinary. Selftaught and with no need for external equipment, they can, unaided and unobtrusively, build an ability which may be well developed before it comes to public notice or before they themselves become aware that they can do something unusual. It may easily be supposed that the ability blossoms abruptly and fully formed. However, there is no evidence that ability develops other than by prolonged, cumulative experience.

Furthermore, ability atrophies with disuse.

Thirdly, calculating procedures taught at school are designed for use in conjunction with a written record of the various steps taken, and are not serviceable in mental calculation. To illustrate, multiply 123 by 456 using your accustomed paperandpencil method. Now repeat exactly as before but, this time, try to do the entire calculation in your head without writing anything. You lose track, don't you? So would mental calculators. They would use other methods—of which there are many—

that lend themselves better to mental working. They would, also, generate the answer (56,088) in natural lefttoright sequence, not righttoleft as happens with your paperandpencil procedure. In brief, the numerical language needed for mental calculation is, in many respects, different from that taught in school. This explains why the unschooled are not necessarily disadvantaged in developing talent in mental calculation and why such people often claim, in retrospect, that schooling would have been a positive hindrance.

Fourthly, it is difficult to discover in minute detail how any individual calculates. A certain amount can be inferred from objective characteristics of performance; but reliance must also be placed on subjective reports which, apart from their inescapable limitations, encounter certain difficulties. When the calculator is highly educated and articulate, he may take his numerical know

ledge so much for granted that he neglects to make it explicit, even if able and willing to do so, once

the need for communication becomes apparent. When young or uneducated, he may lack vocabulary to describe his selftaught knowledge. George Parker Bidder (1806-78), for example, was a calculating genius who became a distinguished engineer and gave an autobiographical account of his talent. At six, when he began seriously to calculate, he could not read or write, had no notion of written numbers, and had never heard the word 'multiply'. He remarked, 'The first time I was asked to "multiply" some small affair, say 23 by 27, I did not know what was meant; and it was not until I was told that it meant 23 times 27 that I could comprehend the term.'

The difficulties are worse confounded when the calculator is a public entertainer who contrives theatrical effects and deliberately conceals the tricks of his trade. He may, for example, give the square roots of numbers called out by the audience. His swift, accurate answers are impressive because we all know how cumbersome it is to calculate square roots. What we do not realize is that he has no need to calculate at all. He assumes that the audience will, to save labour and be able to check his answer, take some number, square it, and give him the result. So, assuming a perfect square, he applies special numerical knowledge and, by merely inspecting the number and especially its last two digits, detects what the square root must be. With cube rooting, the inspectional technique is even easier, granted knowledge of certain numerical facts and the assumption that the given number is a perfect cube. Such an entertainer would be embarrassed if given a number which is not a perfect cube and asked to express its cube root to several decimal places.

Fairly full and reliable information exists about the biographies and abilities of several people who properly deserve to be called calculating geniuses. Of these, the ablest and best documented is A. C. Aitken (1895-1967), an outstanding mathematical scholar with exceptional allround intellectual accomplishments. At the age of 13 he became fascinated by mental calculation, and then spent years exploring numerical facts and calculative methods. In middle age, mental calculation lost its intrinsic appeal, and for certain calculations, such as multiplication by very large numbers, he used electric calculating machines which had, by then, come on the market. However, he still found it convenient, in his mathematical research, to do some calculations mentally, and so he never lost his ability. His nimble deployment of deep numerical knowledge is illustrated by the two following commentaries, both transcribed from a taperecorded session.

After expressing $1/851$ as a decimal, he reported as follows

The instant observation was that 851 is 23 times 37. I use this fact as follows. $1/37$ is 0.027027027, and so on repeated. This I divide mentally by 23. 23 into 0.027 is 0.001 with remainder 4. In a flash I can get that 23 into 4,027 is 175 with remainder 2. And into 2,027 is 88 with remainder 3. And into 3,027 is 131 with remainder 14. And even into 14,027 is 609 with remainder 20. And so on like that. Also, before I even start this ... I know that there is a recurring period of sixtysix places.

He was asked to multiply 123 by 456, and gave the answer after a pause of two seconds. He then commented as follows I see at once that 123 times 450 is 55,350, and that 123 times 6 is 738; I hardly have to think. Then 55,350 plus 738 gives 56,088. Even at the moment of registering 56,088, I have checked it by dividing by 8, so 7,011, and this by 9 gives 779. I recognize 779 as 41 by 19. And 41 by 3 is 123, while 19 by 24 is 456. A cheek you see; and it passes by in about one second.

The study of calculating geniuses gives insight into how people develop and deploy their varied talents, and how development depends on the interplay of potential ability, interest, and opportunity. It also shows how intellectual skills must be organized differently in order to meet special requirements, such as calculating mentally rather than by using external recording devices. It reminds us that there are many ways of calculating—for example, logarithms, electronic calculating machines, and several forms of abacus, among which the Japanese *soroban* is especially efficient in expert hands. Each of these calculative systems has its own balance of strengths and weaknesses, and each requires its user to master a distinctive repertoire of skills.

Much of the literature about calculating geniuses is patchy and regrettably unreliable. This is not always because people are inclined to exaggerate, but because it is so easy to gather false impressions when care is not taken to consider each calculator individually and to make precise observations about his ability. We go seriously astray if we assume that every calculator works in exactly the same way, or by conventional procedures that are somehow speeded up. Each uses a knowledge of numerical facts and methods which is, in its details, largely selftaught and uniquely his own.

CALIBRATE. To adjust or compare an instrument with a standard, which may be manmade or naturally occurring. The readings of instruments may be calibrated with correction tables, or curves, so that their errors can be compensated.

One can think of much sensory adaptation as setting the calibration of sensory systems—which can be upset by maintained stimuli or by distortions

Page 125

tions, such as prolonged viewing through deviating prisms or distorting lenses. (See, for instance, CONTINGENT PERCEPTUAL AFTEREFFECT.) **CALIBRATION ERROR.** See ILLUSIONS.

CANNON, WALTER BRADFORD (18711945). American physiologist, born at Prairie du Chien, Wisconsin, and educated at Harvard, where he was George Higginson professor of physiology at the Harvard Medical School from 1906 until 1945. As a student of medicine he started by studying the phenomenon of swallowing; this led him to observe the motions of the stomach and intestines, and his

observations were summarized in *The Mechanical Factors of Digestion* (1911). He gradually moved towards studies of emotion as related to bodily changes, and this resulted in the important book *Bodily Changes in Pain, Hunger, Fear and Rage* (1919; 2nd edn., 1929), and in the work which remains a classic, *The Wisdom of the Body* (1932). For further details, including his critique of the James

Lange theory of emotion, see EMOTION.

Cannon developed the concept of*homeostasis, which in modern terminology is the*feedback control of servosystems. This concept was not mathematically expressed until the work of Norbert*Wiener in the 1940s, when it became the basis of*cybernetics. Cannon was the first to see the importance of such regulatory mechanisms, which now control complex machines as well as organisms. His work is also a basis of current ideas on*psychosomatic disease.

CAPGRAS' SYNDROME. This rare and unusual psychological disorder was first described by J. M. J. Capgras (1873-1950) and Reboul-Lachaux in 1923 under the title of 'L'illusion des sosies'. The patient comes to believe that familiar persons around him, usually close relatives, have been replaced by impostors who have assumed the exact appearances of those whom they have supplanted. Although this delusional belief has most often been described in patients suffering from schizophrenia or affective psychoses, it can also occur in the presence of organic disease of the brain. The poet Cowper, who suffered from recurrent bouts of manic-depressive psychosis, apparently was suffering from the condition when he came to doubt whether his friend, the Revd John Newton, was real or some phantom masquerading in his shape (Lord David Cecil, 1965).

Although 'L'illusion des sosies' is usually translated as 'the illusion of doubles', it is evident that the afflicted person is suffering from a fixed delusional belief and not simply a misinterpretation of appearances. The term 'sosies' derives from the story of Amphitryon and his servant Sosias as recounted in the play by Plautus and later in revivals of the same story by Molière, Dryden and, most recently, Giraudoux. Robert Graves (1960) recounts how Zeus planned to seduce Alcmene, Amphitryon's beautiful wife, by impersonating him during his absence at the wars. To add verisimilitude to the deception he persuaded Mercury to assume the shape of Sosias (Sosie) and pretend that he had been sent ahead to announce Amphitryon's return. To prolong his enjoyment of Alcmene, Zeus arranged that the sun and moon should halt in their courses, so protracting one night to the duration of three. When the real Amphitryon finally returned he was not a little disappointed at Alcmene's lack of enthusiasm for his embraces. Nine months later she gave birth to Heracles.

Related to Capgras' syndrome is the Illusion de Frégoil, in which the victim claims that persons well known to him are impersonating others, usually individuals said to be persecuting him. Frégoil was a well-known actor, famous for his ability to represent others by changing his facial appearance. The Frégoil phenomenon seems to be even rarer than 'L'illusion des sosies'.

The psychopathology of Capgras' syndrome has been variously interpreted. Some have regarded it as an extreme form of depersonalization. Marked ambivalence towards the person thought to be impersonated allows the patient to project negative feelings on to the impostor while preserving

normal feelings of affection towards the one who has been supplanted. Such formulations may serve to explain this phenomenon in persons suffering from one or other of the functional psychoses, but they are inadequate when the delusional belief appears as the result of some physical disease or injury of the brain. In many patients the delusion remains fixed and unchanging but in others the phenomenon may gradually fade, although it is probably true to say that, whatever is done to help the patient, some lingering doubts about the true identity of the alleged impostor will persist.

CARMICHAEL, LEONARD (18981973). American psychobiologist, educator, and administrator. He was born in Philadelphia, and educated at Tufts University and Harvard.

Beginning in his student days Carmichael was attracted to the fields of animal behaviour, neuroembryology, neuroanatomy, and neurophysiology. These were topics which guided his considerable research efforts early in his career and which remained central to his scientific interests throughout his life. He was the first academic psychologist to study the prenatal origins of behaviour. In a series of now classic experiments begun during his first academic post at Princeton in 19245, Carmichael (1926) attempted to determine whether the experimental suppression of all motor

→

Page 126

behaviour in developing frog embryos, by the use of a paralytic anaesthetic, would impair the normal development and manifestation of swimming in the hatched tadpole. He found that the treatment had little if any effect on later behaviour; the treated tadpoles swam as efficiently as normal frogs. This was one of the first scientific demonstrations that practice, use, or experience during early development are not necessarily critical for normal neurobehavioural development. In subsequent years Carmichael and his students conducted important and extensive pioneering studies on foetal behaviour and physiology in mammals.

In addition to his laboratory research, Carmichael made many scholarly contributions to the field of psychobiology. Paramount among these was his editing of two editions of a fundamental reference work in the field of developmental psychobiology, *The Manual of Child Psychology* (1946,1954).

Over a period spanning more than fifty years, Carmichael was a strong proponent of a developmental and psychobiological approach to the study of behavioural problems, and as a result he had a vital

influence in formulating, and fostering the development of, our modern conceptualization of these problems.

Carmichael was widely honoured during his career, and, in a brief autobiography published in 1967, he noted that 'if I were asked what thread seems to me to have run most consistently through my career, I could answer the question in one word, *Research*' (1967, p. 52). Despite having stopped his own direct involvement in laboratory research by about 1940, it is therefore fitting that it is his early research contributions that will remain as his most important and lasting legacy.

Carmichael, L. (1967). An autobiography. In Boring, E. G. and Lindzey, L. (eds.), *A History of Psychology in Autobiography*, Vol. 5, New York.

CARR, HARVEY (1873-1954). American psychologist, born in Indiana and educated mainly at the University of Chicago, gaining his doctorate in 1905. He replaced J. B. Watson as an assistant professor when Watson left for Johns Hopkins in 1904, and remained in Chicago right up to his retirement in 1938, being chairman of his department for much of this period.

Carr's main interests lay in space perception, on which he published a useful book, and comparative psychology, the study of which had always been prominent in the Chicago laboratory. While Carr held to a behaviourist line in the case of animal psychology, he remained convinced that human psychology could not be satisfactorily explained without reference to consciousness. At the same time, he was distinctly sceptical of conventional classification in psychology and always warned his pupils of the hazards of reification. He was even doubtful whether psychology justified its claim to be a fully fledged scientific discipline.

O. L. Z.

CARROLL, LEWIS (pseudonym of Charles Lutwidge Dodgson, 1832-1898). British author and logician. He was mathematical lecturer at Christ Church, Oxford (1855-1881). *Alice's Adventures in Wonderland* (1865) and *Through the Looking Glass* (1872) introduced logical puzzles to children and to their parents. He also wrote serious logical and mathematical works: *Euclid and his Modern Rivals* (1879), *Curiosa Mathematica* (1888-1893), *Symbolic Logic* (1896), and a paper on Zeno's paradoxes, 'What the tortoise said to Achilles', in *Mind* (1895).

CARTESIANISM. See DESCARTES, RENÉ.

CARTOON. The fact that even very simple drawings convey facial expressions and other rich perceptions is excellent evidence of the creative power of perception.

Cartoonists, by discovering which features of drawings are important, have managed to latch on to the key features for normal perception. There must be a great store of knowledge of perception (if implicit) that artists use. See also ART AND VISUAL ABSTRACTION.

CATECHOLAMINES. The principal catecholamines found in the mammalian nervous system are noradrenaline (norepinephrine), *dopamine, and *adrenaline (epinephrine). The adrenal medulla, an endocrine gland which receives innervation from the sympathetic nervous system, contains the largest quantities of catecholamines body. This tissue was used in pioneer studies to determine the biosynthetic pathway for the catecholamines. This is as follows: TYROSINE

ADRENALINE.

The ability of cells to synthesize catecholamines depends on the presence of enzymes which catalyse the conversion of tyrosine, taken up from the bloodstream, to dihydroxyphenylalanine, dopamine, noradrenaline, and adrenaline. Noradrenaline and adrenaline in the adrenal medulla function as hormones and are released into the bloodstream in response to activation of the input it receives from the sympathetic nervous system. This occurs during physiological responses to stressful stimuli such as sudden anger, fear, severe cold, or physical exercise.

In the peripheral nervous system, the postganglionic neurones of the sympathetic division of the *autonomic nervous system synthesize and release noradrenaline as a *neurotransmitter, thereby influencing the activity of smooth muscle cells in a wide variety of tissues. For example, they control the diameter of the pupil, the smooth muscle in blood vessels of the salivary glands (thus influencing glandular secretion), the rate of the Page 127

heartbeat, the diameter of the coronary arteries, the diameter of bronchi in the lungs, the activity of smooth muscle in the bowel (thus influencing movement of intestinal contents), the smooth muscle activity in a variety of pelvic organs, and the diameter of small blood vessels and hence bloodflow in large areas of skin and muscle throughout the body. These diverse tissues can thus be influenced by the sympathetic nervous system to respond in a coordinated fashion to stressful stimuli. The wellknown cold sweaty hands, fast heartbeat, dilated pupils, and pale complexion produced by fear are explicable in terms of the known hormonal and neurotransmitter actions of the catecholamines.

The brain contains another and separate family of neurones using catecholamines as neurotransmitters. These contain either adrenaline, noradrenaline, or dopamine.

Adrenaline neurones are few in number and are located in the brainstem. They send their axons down into the spinal cord and into the hypothalamus, as well as to a region of the brainstem known as the nucleus of the tractus solitarius. (For a description of the structure of the brain, see NERVOUS SYSTEM.) There is evidence that adrenaline plays a role in this latter nucleus in the control of bloodpressure. Abnormally high bloodpressure is a common clinical problem, and it is therefore of interest that a genetically distinct strain of laboratory rat has been found in which there are abnormally high quantities of the enzyme that synthesizes adrenaline. These rats suffer from high bloodpressure.

Noradrenaline neurones are scattered in small groups throughout the brainstem. The largest of these, the locus coeruleus, contains only a few thousand neurones, but they provide branching axons which together innervate a vast area of the brain and spinal cord. Furthermore, neurones may provide axons to innervate, for example, both cerebellum and cerebral cortex. Therefore these neurones may influence widely separate and functionally distinct brain areas simultaneously (see NEURONAL CONNECTIVITY AND BRAIN FUNCTION). Morphologically these neurones have many similarities to other parts of the brainstem reticular formation, and make many functional contacts with other divisions of the reticular formation. All the evidence points to the fact that the synaptic actions (see SYNAPSES) of noradrenaline are relatively diffuse (or hormonelike) and act over a relatively slow timecourse of seconds (compared to a timecourse of milliseconds for*acetylcholine), while the action of the transmitter is mediated by slow chemical changes rather than fast changes in ionic channels in the nerve cell membrane. In most cases it seems that the action of the transmitter on single neurones is inhibitory, although it appears to operate without altering the responses of neurones to other specific input stimuli.

As would be expected from the very widespread distribution of noradrenaline fibres in the brain and spinal cord, they appear to influence a correspondingly large number of functions. There seems little doubt that they are involved in the regulation of general brain states such as arousal and sleep, and the coordination of the many brain functions appropriate to these states. It is of interest that drugs which appear to have clinical activity in alleviating depressive illness are able to act by altering the availability of noradrenaline at the receptor level. Noradrenaline fibres may also have a role to play during the establishment and selection of normal synaptic connections during development and in the recovery of function after damage to the nervous system.

The third main group of catecholamine neurones of the brain are those utilizing dopamine as transmitter. These neurones have been the subject of much research, because there are two common clinical conditions alleviated by drugs which interact with dopamine neurones—*Parkinsonism and*schizophrenia.

CATHEXIS. See FREUD ON MENTAL STRUCTURE.

CATTELL, JAMES McKEEN (1860-1944). American psychologist born in Easton, Pennsylvania, the son of the Presbyterian president of a small East Coast university. He studied under Rudolf Lotze (1817-1881) at Göttingen, following which he worked for three years with Wilhelm*Wundt at Leipzig and took his doctorate.

He then spent a year at St John's College, Cambridge, and at this time made the acquaintance of Francis*Gaitton, by whom he was immensely impressed. Had he stayed permanently in Cambridge—which at the time he was strongly tempted to do—it is likely that he would have played an important role in the growth and development of experimental psychology in the University.

Cattell's work at Leipzig was largely concerned with measurements of reaction times, which he continued for some time at the University of Pennsylvania after his return to the United States, publishing an important paper with C. S. Fullerton on the perception of small differences. His next move was to Columbia University, where together with E. L. Thorndike he built up the leading laboratory in America principally concerned with mental tests and the measurement of individual differences. It would thus appear that it was Galton rather than Wundt who had the major influence on his career.

CAUSAL THEORY OF MENTAL CONCEPTS. See MENTAL CONCEPTS: THE CAUSAL ANALYSIS.

CAUSES. The earliest treatments of causality link the concept firmly to that of explanation. Aristotle defines *aitia* (the Latin translation of which is Page 128

causa, from whence our 'cause') as something which answers the question 'why?' (*dia ti?*). Such a question asks for an explanation of some kind, an answer beginning

'because ...'. If one asks what distinguishes an explanation from other forms of information, such as a mere description, the answer implicit in Aristotle's discussion is that an explanation starts with what is taken to be a correct description of something and indicates what constrained or necessitated that thing to be as it is. An explanation, in other words, shows how the possibilities were restricted so that things *had* to be that way, so that had one known the explanation he would have been justified in expecting things to be that way. This is a task which the citation of a cause is meant to perform. A cause is cited to explain, to show that something is or was in some way necessary.

It is a mark of how the concept of cause has taken on a meaning more specific than simply 'an explanation' or 'what explains', that the so-called 'four Aristotelian causes' are likely to strike a modern mind as having little to do with causes. Regarded as a fourfold classification of explanatory patterns, however, the doctrine is not at all implausible. (The following examples are not Aristotle's, but Aristotelian in spirit.) If one asks why a certain act which resulted in the death of a person counts as murder, one will be referred to an account of what murder is: an *Aristotelian formal* explanation. If one asks 'through what' (a more literal translation of *dia ti?*) means a murder was carried out—was it poison, gunshot, a blow to the head?—one will be referred to an Aristotelian *material* explanation. If one asks why the murderer committed the act, one may be asking for a motive, such as inheriting the victim's money, which is an Aristotelian *final* explanation. Or one may be asking what prompted the murderer to act just then (a short temper and an insult, or greed and the victim's threat to alter his will), i.e. for an Aristotelian *efficient* cause/explanation.

Of the four, it is most natural nowadays to speak of 'cause' in connection with the last of these and

then only in connection with a subclass of what Aristotle termed 'a source of change or remaining the same'. For Aristotle gives as examples of such 'causes', human agents, their dispositional states, and also what may be called

'triggering events', i.e. events which set in motion some further event. It is examples of the last sort that set the pattern of contemporary discussions of causality. The historical reason for this lies in a shift in thinking about patterns of explanation which took place in the seventeenth century.

Aristotelian explanations of natural phenomena ultimately come to rest on the natures (forms,*essences) of things, which are expressed in terms of complexes of active and passive powers. Thus a concept of natural agency is central to Aristotelian explanations of natural phenomena; things cause changes to take place (or fail to take place) by virtue of the powers which constitute them as the sorts of things they are. As a result of developments in the seventeenth century, explanations came to be thought of as resting on laws rather than on natural agencies. A law is a relationship between quantitative aspects of natural phenomena which can be expressed in the form of a mathematical function. What was explained was no longer the action of one thing on another, but the lawgoverned interactions which took place between things, such as the motions which resulted when one body collided with another.

But the notion of agency, which is almost certainly modelled on the way we account for the affairs of human beings, is deeply rooted in our thought; and as long as the implications of the shift in explanatory practices were unclear, there was a tendency to look for the powers which had belonged to agents in the events governed by laws, as though an event at the beginning of some lawgoverned interaction had by itself the power to effect what took place.

The eighteenthcentury philosopher David Hume was able, without any deep familiarity with the science of his day, to reflect in his analysis of causality both the change in forms of explanation to patterns of interaction and the precarious position which the notion of agency had come to occupy. He concluded that a cause was an

'object' (a word which many read in this context as 'event') preceding and spatially adjacent to another (the effect) where we have observed objects resembling the first in 'like relations of precedence and contiguity to those objects that resemble the latter'. As for the limitation of possibility which is the function which cause performs in explanation, Hume dismissed the notion of power as without foundation in experience and concluded that our idea that what we identify as related as cause and effect are in some way necessarily linked is the product of feeling the habit of mind which has been formed by observing so many similar pairs of objects, the one preceding the other.

Hume's analysis does far less justice than does Aristotle's to the variety of forms of explanation which we still use with apparent success every day, and it has not gone unremarked that his approach to *necessity* undermines the hopes of science to establish for us what are the laws of nature. His analysis has, however, had the salutary effect of raising the question of the empirical foundation of our (supposed) knowledge of necessity, and the possibility of our giving explanations. One way of trying not to capitulate to Hume is to preempt the question and to argue along the lines suggested

by*Kant that experience, i.e. anything that would constitute an empirical foundation for any knowledge, must use, if not the notion of cause, then that of natural possibility/necessity. There would, if this strategy were successful, be no question of our right to use these notions, only a question of how well we manage to use them.

CENTRES IN THE BRAIN. Some neurologists believe that there are specific regions in which, in some sense, particular sensations are located. The 'pleasure centres', discovered by James*Olds, are regions that, when stimulated electrically, produce intense pleasure in man. When the stimulation is selfadministered with a level switch by an animal, the animal may stimulate himself for hours on end, and will ignore food, sex, or other typically pleasurable stimuli or situations. It is interesting to find that this socalled brainreward system depends upon the activity of biogenic amines, particularly dopamine (see CATECHOLAMINES). Observations have been made in the USA on patients with electrodes implanted in the septal region of the brain. When asked to comment on how they felt when the electrodes were stimulated, they reported having a 'good feeling', which appears to have had some of the qualities of sexual pleasure. Enjoyable feelings were also said to follow electrical stimulation of other parts of the limbic brain, but unpleasant feelings were caused by stimulation of the hippocampus and amygdala (see LIMBIC SYSTEM).

The observations of Olds on animals with implanted electrodes that caused almost continuous selfstimulation have been considered as explanatory of the behaviour of some drugdependent subjects who inject themselves repeatedly with opiates for pleasure (and in response to a conditioning process created by the drive of the nervous system to reinforce activities which provide satisfaction). This highly reinforcing selfstimulation activity in animals is blocked by drugs such as phenothiazines, although the ability to press the bar which stimulates the implanted electrodes is not lost.

CEREBELLUM. The region of the brain (posterior below the striate cortex) mainly responsible for coordinating movement. See NERVOUS SYSTEM.

CEREBRAL CORTEX. The outer layer or 'bark' (from the Greek) of the brain, associated with sensory perception and the higher mental functions. It appeared late in evolution, and is especially developed in man. See NERVOUS SYSTEM.

CEREBRAL DOMINANCE. See HANDEDNESS; NEUROPSYCHOLOGY.

CEREBROTONIA. See BODY BUILD AND PERSONALITY.

CHANCE. See POSSIBILITY.

CHANNELS, NEURAL. One normally thinks of a channel as a physically existing and easily seen structure, such as a river course. Nerve fibres are, similarly, easily seen courses along which neural signals flow. The situation, however, is not at all simple in neurophysiology because a whole sensory modality, such as vision or hearing, may be called a channel, even though many thousands of nerve fibres comprise these 'channels'. Conversely, and even more tricky, a single physical channel may transmit several channels of information. Thus telephone systems employ a single highfrequency link along which many messages can be simultaneously transmitted, each on its own 'carrier frequency' which is modulated by the channel signals to keep the messages separate. Here the separation is given not in any obvious physical or visible way, but by splitting the very wide frequency range of the carrier into several frequency bands, which provide independent information channels. There seem to be somewhat analogous ways in which different signals are carried separately on shared nerve fibres. Also, by selective attention it is possible to switch from one signal source to another, so that that which is effective depends on selection rather than simply on laid down neural channels.

It is now believed that the visual system is organized into many more or less independent channels, not only for colour (which uses three channels) but also, and perhaps more surprisingly, for different orientations of lines or edges, directions of movement, brightness, and texture size. Isolating and studying channel characteristics is an important part of current experimental work on how the senses function. Just how the channels converge to a single unified perception (which used to be called the*common sense) is not yet understood.

What use are channels? If information transmission was the only requirement for designing sensory channels, then just one, covering all the physical information, might suffice. However, the information also has to be analysed and, if there are many different channels, they can sort the information into relevant categories to start the perceptual processing. Many of the objects in the environment are only recognizable in terms of a combination of different physical attributes (think how you would recognize bacon cooking). Likewise many of our actions are determined by the information from various different physical sources. These different physical attributes and sources have therefore to be distinguished and it is convenient to allow the selectivity of channels to make the distinctions. Conversely, sometimes a particular object can be partially specified by one source of physical information (think how you can search a crowd for a friend wearing a scarlet hat), and in this case a channel more or less specific to that information is very useful.

If I have a private channel from A to B, the receiver at B knows a great deal about the incoming messages in advance, such as their type and range, because these are simply inherent to channel.

The selectivity of a channel is a type of advance knowledge which allows the receiver to correct any systematic errors in the channel. Imagine a channel transmitting edge curvatures, which are physically as often curved one way as any other. If the receiver simply compares each incoming message with the distribution of messages that it has received in the past it will automatically*calibrate the channel for any distortions that it introduces.

All channels have physical limits on the amount of information that they can transmit, but some physical attributes, for example luminance contrast, can take a wide range of values. In such instances, it is useful to be able to split the whole range into a number of separate bands and assign one channel per band. This arrangement allows the transmission of a wide range of values with high accuracy.

Luminance contrast is an interesting case. Imagine a diffuse shadow lying across a finely chequered surface. The luminance contrast between any adjacent black and white squares will always be the same because the shadow will equally affect the two. However, the luminance contrast between a black and a white square that are separated will be affected by the shadow, which may lie over one but not the other. Longrange contrast is different in this case from shortrange contrast, even though they physically overlap in space. A channel for contrast must work over some predefined spatial range, and a longrange channel would be indifferent to shortrange contrast and vice versa. Therefore it is necessary to have several contrast channels each selective for a different spatial range.

Many physical aspects of our environment have this complicated overlap property. The wavelength of light is another instance: any physical surface reflects a wide range of different wavelengths. Sound and speech is another interesting case. In a room where several people are speaking at the same time, the air is vibrating in response to all of them together. The perceptual process has a problem, the*'cocktail party problem', because it has to break the air vibrations down in portions that will allow it to select one speaker's message. The hearing system has channels that are selective to frequency of sound and direction and these are thought to provide the basis for this selection.

It is sensible to have many channels for several reasons. They organize the overall sensory information into a structure which is suitable for subsequent cognitive processing. They also allow for automatic calibration and adaptation to prevailing conditions in the physical environment.

Empirically, it has so far proved easier to identify channels than to discover how their outputs are combined or used. Channels can be discovered by seeking interactions between the processing of very similar physical stimuli. Gazing at a periodic pattern of high contrast black and white stripes will make the visual system less sensitive to very similar patterns, but does not affect sensitivity to patterns where the stripes have a considerably different size or direction (see CONTINGENT

PERCEPTUAL AFTEREFFECT). Similarly, similar patterns will interfere when present simultaneously if they are processed by the same channel. In these observations the important point is the selectivity of the effect for a particular range of physical stimuli, and this range is thought to correspond to the selectivity of the channel itself.

CHARCOT, JEAN MARTIN (182593). French neurologist, born in Paris, where he qualified in medicine. In 1853 he began to work at the Salpêtrière, becoming physicianin chief in 1866 and professor of clinical neurology in 1882. He was a brilliant diagnostician and was the first to recognize a number of nervous diseases including multiple sclerosis and the 'lightning pains' of tabes dorsalis. Towards the end of his life, he became much interested in*hysteria and its treatment by hypnosis, in which he likewise became deeply interested. Among the many who studied with Charcot was Sigmund*Freud, upon whom he made a lasting impression.

CHESELDEN, WILLIAM (1688-1752). British surgeon, born near Melton Mowbray in Leicestershire. He became surgeon at St Thomas's Hospital, and later at the Royal Hospital, Chelsea, where he organized the separation of the old Barber-Surgeons Company, to found the Corporation of Surgeons in 1745 by Act of Parliament. The foremost surgeon of his day, and an excellent anatomist, he was influential also on account of his birth, as his family was entitled to a coat of arms—an unusual advantage, as surgeons of his time were seldom socially acceptable. He was a close friend, among other intellectuals, of the poet Alexander Pope and the painter Jonathan Richardson, whose fine portrait of him hangs in the Council Chamber of the Royal College of Surgeons. Cheselden attended Sir Isaac Newton in his final illness, advising against an operation for stone.

Cheselden was the first to create by operation on the eye an artificial pupil; and he developed improved procedures and instruments for removal of cataract. A case of restoration of sight in 1728 remains famous: the removal of congenital cataracts by 'couching' in a boy 13 or 14 years old who had no previous vision except some indication of the colours of bright lights. (See BLINDNESS, RECOVERY FROM, for a full discussion of this case.) Cope, Z. (1953). *William Cheselden*. Edinburgh and London.

CHILD ABUSE. Human beings can go to great lengths to care for and to protect children; yet since history began children have been abused. It was not, however, until the nineteenth century that social reformers in Europe and North America influenced legislation by showing that children employed under conditions accepted as normal were in fact being seriously abused.

Awareness that the two contradictory states, caring for children yet abusing them, could exist side by side was not apparent to members of the medical profession and many others caring for children until very recently. Despite a description in 1888 of the signs of child abuse, it was not until Henry Kempe and his associates published in 1962 the now classic paper, emotively entitled 'The Battered Child Syndrome', that professional eyes opened. Shock and initial disbelief were followed by a growing acceptance of Kempe's findings, leading to an extensive literature and registers of children at risk. This sharpening of awareness is illustrated by the paediatrician who, in a recent presidential address, while pointing out clearcut and unequivocal signs of physical abuse in infants and young children, stated that over a period of seven years of general paediatric practice he had never seen a case of child abuse because he had not been looking for it.

The item 'child abuse' refers to a number of areas and is usefully considered under three headings. These cover (i) general neglect, systematic poisoning, and physical violence—which in recent years has been euphemistically relabelled nonaccidental injury; (ii) sexual abuse, which since the late

1970s has become increasingly recognized and found to be widespread; and (iii) psychological abuse, a concept that is gaining ground. It is safe to work on the assumption that children subjected to any form of general physical or sexual abuse will also suffer psychological abuse. Moreover, many children who are not physically abused are deliberately made to suffer painful psychological states such as fear, rejection, and loneliness which constitute abuse. The statements that follow refer to findings on nonsexual physical abuse.

All figures on the extent of child abuse are at best imprecise estimates. Furthermore, findings from different studies are not easily compared because workers tend to focus upon different aspects of the subject and to express their findings in different ways. It can however be estimated that in the USA approximately one in every hundred children under 18 is physically abused, sexually molested, or severely neglected; the figure is probably about the same for England and Wales. It is a conservative estimate that up to 10 per cent of abused children die, and that at least 25 per cent suffer serious neurological damage with impairment of intelligence. The epidemiology of child abuse has been reviewed by Jack Oliver (in Smith, 1978). Since about 1960 the figures have tended to increase, but it is an unanswerable question whether this reflects greater recognition of the condition or an actual increase in its extent.

Child abuse is not a haphazard occurrence, despite evidence that anyone sufficiently stressed by adversity is liable to abuse a child judged uncooperative. As a group, abusers show certain characteristics, although many people with the same characteristics do not abuse children. For instance, abusers are most frequently parents, stepparents, or others in charge of the child. Parents who abuse tend to be young, unskilled, and often from lower social classes. Criminality, recidivism, and low intelligence are common; whereas mental illness, severe alcoholism, and drug addiction are less frequently found. There is evidence that many abusers show disorders of personality, or neuroses coupled with a sense of low self-esteem, but there is no homogeneous personality profile. They tend to have difficult relationships with their spouses or partners, family, and friends, and consequently have little support or help despite, frequently, suffering hardships such as poor housing and unemployment.

Abusing parents have themselves usually been abused as children. They frequently function at the emotional level of a young child, and the abuse occurs during outbursts of uncontrolled anger. They have, almost always, unrealistic expectations of the abused child, who is expected to be obedient and empathic to the parents'

needs, and to have a degree of control over natural functions and behaviour appropriate to a much older child or to an adult. This feature is frequently so marked as to constitute a role reversal: it is as if the child is expected to be the parent of the parent.

There is no one set of characteristics that distinguishes children who are abused, although there is evidence that some groups are especially vulnerable: for instance, the youngest child, any under two years, the premature, and children with congenital deformities. Commonly one child in a family is abused more than the others.

There is now evidence that it is a common human characteristic for parents not to feel love

immediately for their newly born offspring and that a loving, protective attitude becomes established as a result of social interaction between infant and parents, in which each plays a part—a process often referred to as 'bonding' (see ATTACHMENT). In many instances of abuse associated with difficult family relationships, the ability of parents to develop their capacities to protect and to care consistently for an infant appears to be limited. In such families particular dynamic patterns can be identified. For example, so long as the infant is an 'easy baby', rewarding to handle and healthy, all may be well; and while this state continues the infant may be protected and loved. Intense anger, associated with irresistible impulses to force the child to comply with the parents' wishes, is, however, aroused whenever the infant's behaviour leads one, or both, parents to feel inadequate (the

Page 132

irritable or sickly baby, the baby who is difficult to feed or to pacify), or to feel rejected by the baby (the unresponsive baby who seldom smiles). In other instances, anger is directed towards the baby because the relationship cannot be isolated from the relationships the parents have with each other or with other members of the family.

Some common examples of family dynamics associated with abuse are: (i) The parents feel they are in some way to blame, because the child is malformed, or because the child's physical attributes or sex do not meet with family or cultural expectations. (ii) One parent, usually the father, or a sibling, feels unloved and jealous because of the attention given to the baby by the other parent. (iii) Anger aroused by someone towards whom a parent cannot show anger is redirected towards the baby, who cannot retaliate. (iv) Abuse is a Medea-like attempt on the part of one spouse to take revenge on the other. The assumption is that it will hurt that spouse if the baby is hurt. (v) A lovehungry parent may demand an unrealistic degree of altruistic devotion, companionship, and love from a child who is attacked because he or she cannot meet these expectations. An overview of the subject of child abuse has been edited by Ellerstein (1981).

We are still far from constructing a comprehensive theoretical model to explain social behaviour in man, and it may never be possible to explain all instances of child abuse by a single model. For example, abuse by parents who suffer recognizable mental illness—when the abuse is often bizarre—may have a distinctive origin.

Nevertheless, many of the characteristics described above are seen frequently enough to suggest that it may be possible to find a theory that will allow useful predictions to be made in many instances of child abuse. The model would have to explain why intensely angry impulses towards a child are regularly aroused whenever the behaviour of the child results in a parent feeling inadequate, lonely, or rejected. Ethologists such as Konrad Lorenz have suggested that harmful behaviour to babies and young animals is inhibited by an innate releasing mechanism which responds to the total configuration characterizing 'babyishness'. For some unknown reason those who abuse their children are apparently not endowed with this innate response to their offspring's behaviour and morphological features. The most comprehensive theory available today postulates that anger as described above is an emotional response to rejection and to a sense of inadequacy. This is attachment theory, formulated by John Bowlby and elaborated by Mary Ainsworth.

Attachment theory has been described as 'programmatic', in that it acts as a guide to understanding data and to further research. It can be seen as a new paradigm for understanding social development. The theory has integrated several major trends in biological and social science. It is based on the assumptions (i) that behaviour is organized around plans to reach set goals, (ii) that in order to reach goals one has to have internal representations, or working models, of the world in which one acts, and of one's self in action in that world, and (iii) that behaviour is governed by control systems—kinds of mechanisms such that certain behaviour is evoked by specific circumstances and terminated by others. Using these basic assumptions, attachment theory postulates that the infant is born with the potential to develop an internal behavioural system mediating attachment behaviour. The goal of attachment behaviour is to attain physical closeness to and interaction with familiar, more experienced people (attachment figures). Attachment behaviour can be activated at any age, and is aroused whenever strangeness, fear, or physical states such as hunger, fatigue, or malaise are experienced. There is also a complementary inbuilt system, usually fully functional in adults, which mediates parental caregiving. Caregiving behaviour, when effective, terminates attachment behaviour in another person, and restores a child (or indeed another adult) to a state in which he or she is able to explore and to enjoy the surrounding world and relate to others in a caregiving way. Without such experience of caregiving the child, or adult, feels angry and rejected; angry protests then alternate with states of despair.

Child abuse is difficult to treat; but in many instances it is possible, after the first discovery of abuse, to promote the development of effective parental caregiving behaviour, by providing understanding helpers who act, as it were, as surrogate grandparents, taking an active part in supporting and educating parents so that they can achieve a sense of attainment about their lives and parental responsibilities.

Punishment of abusing parents is singularly ineffective. A reason for this can be predicted from attachment theory. Punishment, in so far as it evokes fear and feelings of rejection, arouses the parents' own attachment behaviour and leaves them disassuaged. Moreover, the parents are not helped to develop effective parental behaviour.

It is an important preventive measure to take steps to promote the development of affectionate parentchild relationships, by ensuring that the child and parents have the opportunity to interact right from birth onward, and so build up the new relationships. There is now growing evidence (Bretherton and Walters, 1985) that development of harmonious relationships between parents and child is facilitated first by close physical contact between them in a supportive, comforting environment immediately after birth followed by responsive, supportive, and companionable interaction thereafter.

Nevertheless, in some instances it is found that, even with help, a parent's capacity to care for a child reliably and consistently cannot be sufficiently developed. Then a second home, with consistent and loving surrogate parents, has to be

found for the child, in order to ensure not only that he survives but that his development in all its

aspects proceeds as well as possible. Without such measures an abused child is unlikely to become an effective parent when he grows up, and is liable to continue the tragic tradition of abuse into which he was born.

CHILDHOOD. The way societies treat their children, how they regard them, and how they order their lives reveal a great deal about the values of those societies. In Britain, a curious ambivalence about children has been displayed since the end of the First World War. There has been a flood of books on childrearing, much discussion and theorizing about their upbringing and early education, and a plethora of educational toys. The general assumption has been that this is the golden age of childhood, an enormous lollipop that will last for ever. At the same time, though, there is much envy of children and aggression towards them: they are battered, beaten, and sexually exploited (see CHILD ABUSE) and in modern warfare they are killed and injured with impartiality.

In the twentieth century it looks as if childhood is celebrated more selfconsciously than at other times. As Aries (1973) has pointed out, the concept of childhood as a phase of life existing in its own right is a relatively recent one. Children have always been appreciated as a means of continuing the family line, a way of achieving a kind of immortality, a source of labour, and an investment for the future. But since, in the past, means of contraception were inadequate, more children were born than could possibly be fed in times of food shortage or poverty. They were commonly killed off either by exposure in the open or by being subjected to lethal childrearing practices. Disease, famine, and war carried off many more and kept the world's population in check. Christian fastidiousness about the preservation of life checked the practice of infanticide in Europe, but unwanted children were left at churchdoors or outside almshouses. The foundling homes were a response to this practice. If the child was strong enough to survive, he was incorporated into the adult world and put to work as soon as possible. The chief distinction between adult and child was that the child being smaller and weaker was worth less and so paid less than the adult in his prime. The appalling incidence of infant mortality set limits to the relationship between parent and child. What was the use of becoming fond of a child who was almost certain to die? The duty of the middleclass parent was to prepare the child for the afterlife, and the possibility of salvation, rather than for the world he was likely to inhabit for so short a time. A look at the readers and grammar of a Puritan family makes this point forcibly: 'Child, you will not live long so prepare to meet your God!' seems to be the predominant message. In an agricultural society where food was produced by labourintensive methods, there was a place for the labour of those workingclass children who survived. If they were set to work at the earliest

possible age, this was not merely exploitation: their labour was an important contribution to the needs of the family. The Industrial Revolution too, is often stigmatized as a period of particular horror for children, and our attention is drawn to the small boy sitting for hours opening and shutting a trapdoor in a coalmine, or the halfnaked girl dragging a cart full of coal behind her, or to the child mutilated by unprotected machinery. All this happened, and was dreadful, but it must also be remembered the child was contributing to the survival of his family. Workingclass families had no alternative and at least the child could take pride in his achievements. The almost desperate resistance to compulsory education when it was first introduced in the nineteenth century is evidence that many families needed their children's wages and could not afford to lose them to the schoolteachers. Even today many workingclass children are eager to leave school as early as possible, in order to earn a living and support themselves. And this is at a time when changes in industrial practice make the employment of the young uneconomic.

The modern child is more likely to survive into adulthood than his predecessors (although the survival rate of workingclass children is still lower than that of middle

and upperclass children); and with survival as a probability new attitudes have arisen. Moreover, now parents can control the number of children they have and can space out pregnancies. Together with children who are 'wanted' comes a belief in the goodness of childhood. Jean Jacques Rousseau's conviction that the child is born pure but is ruined by the impositions of civilization which fetter and corrupt, and William Blake's view of the child's innocence and beauty, have powerfully affected society's view of childhood, which has come to be treasured for itself. This new vision was celebrated widely in nineteenthcentury painting and poetry: the innocent child was set alongside the 'noble savage' and on to both were projected society's yearning for a better state. (The strain of maintaining the purity of this image of childhood was perhaps partly responsible for the decline into the sentimentality about children characteristic of middle and late Victorian times.) Then Sigmund*Freud's theories of the powerful (but not specific) sexual drives in the small child undermined this unrealistic view of young innocence. And so two views of childhood have continued to exist side by side in our own time: the child as a beautiful and creative individual in his own right, and as one whose

Page 134

libidinous and chaotic energies must be harnessed and educated.

The 'permissive' view of childrearing has become firmly established both in the USA and in Britain. Beneath the belief that it is wrong to give a firm structure to the life of the child, lurks the hope that life will be better for the child than it has been for the parent, even if there is no clear view of what is 'better' in terms of human security and happiness. Sometimes permissiveness has led to a disastrous abandonment of common sense and has caused much unhappiness to both parents and children.

Respect for the child has, however, made family life less formal and has made schools happier places to be in; an appreciation of the creative abilities of children and closer attention to their ways of learning have been positive benefits of this new respect.

On the other hand, opposed to this belief in 'freedom' for the child, has run an undercurrent of envy,

fear of the child's sexuality, and even a hatred, which is expressed in punishment and exploitation. Relegation of the child to the nursery or boarding school, baby batterings and scoldings, the feelings of guilt engendered by the prohibition of masturbation or the insistence of regular bowel movements have all taken their toll. A. S.*Neill wrote of this 'hatred of children' and insisted that it was the root cause of most of the problems of childrearing—bedwetting, thieving, and the inability to learn. These represented the rebellion of the child against its restrictive upbringing. Life in our large cities brings further restrictions—many children have little mobility, are confined to the upper floors of tower blocks, and have inadequate facilities for play. Often their capacity to understand and to learn are underestimated: they are assumed to be ignorant of the facts of death, sex, or race. It is hard to accept that children, like all human beings, are in their own terms engaged in the task of making sense of the world.

Finding that it is seemingly impossible to bring up children satisfactorily, many in the West have turned to other civilizations for hope and guidance. One thing is certain: the ills of Western civilization have not been cured by changes in childrearing methods. Truby King's fourhourly feeding schedule did not cause the First World War nor Dr Spock the urban guerrilla!

Dispassionate evaluation of an activity as complex as parenthood is not easy. Children are at once relatively weak and vulnerable and also potentially disruptive of adult peace of mind. There is now a long period during which children have time to become adults; adolescence has been interposed between childhood and adulthood. It used to be that a Jewish boy was told at his bar mitzvah ceremony at the age of 13 that he had become a man; this is still so, but now he must be content, as all youths must be, with the prospect of years at school and possibly, if lucky, professional training before admission to adult society. Girls are in the same predicament: they may secure recognition by early motherhood, otherwise they may have to accept even lower status than boys at school and at work.

The problems associated with adolescence have long been recognized. A society that celebrates childhood, however equivocally, finds it exceedingly difficult to tolerate adolescents. Babyfaced charm gives way to gauche assertiveness, and the object of biologically triggered, parental protectiveness becomes a challenge to authority. Adolescents in Western society have a generally poor image. Aided and abetted by entrepreneurs for commercial gain, they tend to set up what seems to be a separate culture designed to exclude adults. In part this attempt to establish a separate identity is in reaction to a society unable to find a constructive place for them.

In dress, in music, and in their general lifestyle, adolescents assert themselves by banding together—though preserving the class distinctions which characterize their parents: the middleclass 'hippy' dropout is very different from the workingclass punk rocker. Their activities are envied and feared. Some adults fear that the young may usurp their rights and privileges; others regret their own lost, though less liberated, youth; many envy the lack of obligations and the freedom of movement and expression that the young seem to enjoy. Adolescents are often the target of the moral panics that sweep society from time to time.

It has to be accepted that there never has been a golden age of childhood when children were cared

for without question and when filial duties were carried out without protest. In recent times attitudes to childhood have changed in complex ways. Parents may enjoy their children more positively than those in other centuries have been able to do, but they still have to cope with the envy and inner conflict that is an inevitable part of their relations with the young. A proper balance between the care and the control of children remains

difficult to achieve.

CHILDREN'S DRAWINGS OF HUMAN FIGURES. Children's drawings are often very beautiful. As the article about them in *The Oxford Companion to Art* says, 'The art of children is not a vehicle for the greatest expression of the human mind, but within its limits it offers a rare perfection of feeling and expression.' Even the collection of decrepit monstrosities shown in Fig. 1 is beautiful. But of course, if these drawings are supposed to be realistic (as we must accept that they are) something is very queer. The realism concerned must be realism in rather a special sense. It results from a sensibility to which, it seems, all children intuitively aspire.

The drawings have an undeniable underlying logic: they have been called the products of 'intellectual realism' as opposed to 'visual realism'. The question is, precisely what kind of logic they reveal. According to what kind of rules are these children operating? Recent books which discuss the results of detailed experimentation have been written by Freeman (1980), Gardner (1980), Golomb (1974), and Goodnow (1977).

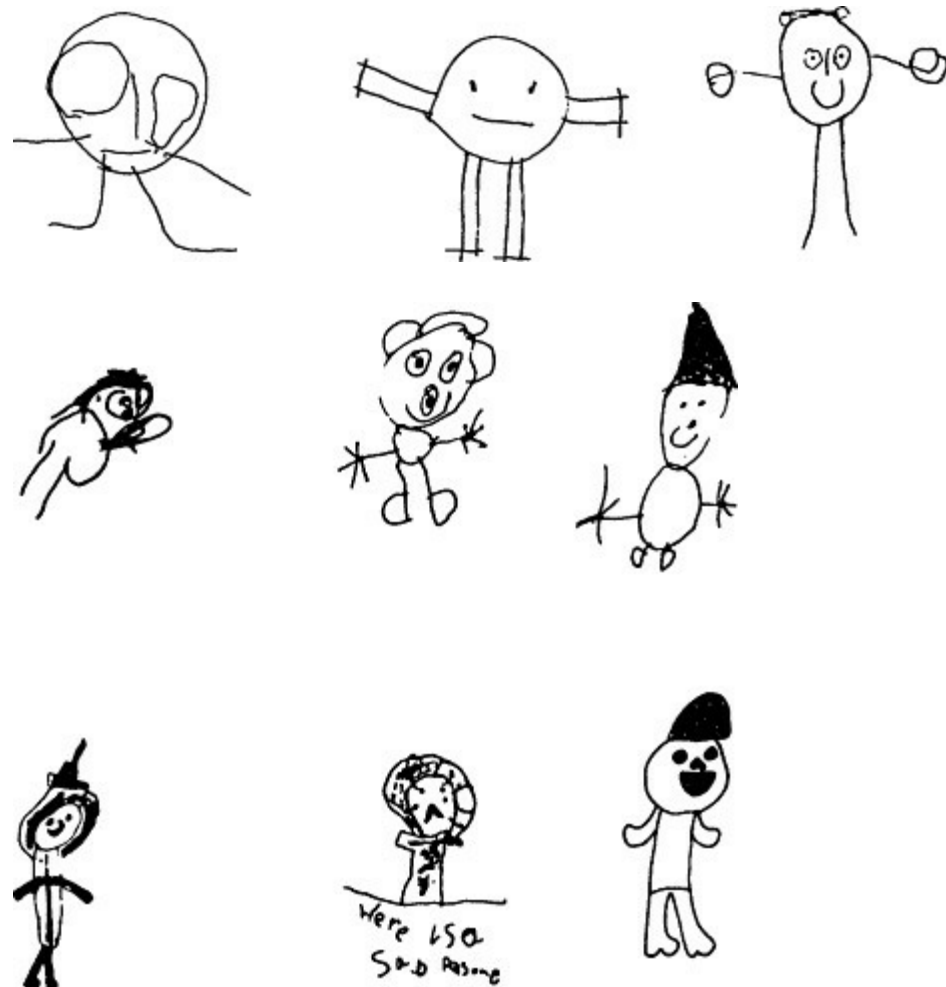

Without a sophisticated theoretical model of the workings of the child's mind, we shall never know exactly what he or she intends to represent. We cannot rely upon the drawings to give us direct access to the inner world of the child, as though they were faithful reflections of 'body images'. First, it is debatable how far an activity which demands sophisticated motor control can ever be free of planning problems specific to the medium. Secondly, as Neisser (1970) explains, in order to use the concept of a mental image it is necessary to have evidence for its place in a mental system that is independent of the phenomena to be explained. Otherwise one falls into circular judgements whereby the form of the mental image is deduced from the drawing and then used to explain it. Thirdly, as Abercrombie and Tyson (1966) point out, it is necessary to have criteria specifying the standard of comparison. If a child who draws a disjointed human figure always draws incoherently, whatever the topic, one would say that the child could not draw adequately rather than that she had a fragmented body image. No research project to date has come near to solving these three linked sets of problems, though Shontz (1969) made a commendable attempt. Therefore, although the child's system of thoughts and feelings about himself and others undoubtedly influences many aspects of his drawings, there is no acceptable

evidence that his conceptual system is necessarily the major determinant of the form of any particular drawing.

Faced with these difficulties, some authors have simply attempted to classify drawings. R. Kellogg (1970) produced an elaborate taxonomy of forms based partly on the mandala. Certainly some of the forms are extremely striking in that they seem to conform more to radial symmetry than to the elongated conventional figure whose progression towards visual fidelity is shown in Fig. 3. The ubiquitous 'tadpole' is shown in Fig. 2. But Kellogg's formal scheme does not appear in the development of individual children (Golomb, 1981). So if it is unsafe to assume an infantile urge

Fig. 1.

towards radial symmetry, perhaps radial forms such as the tadpoles represent the solution to a special kind of problem. The child may intend to produce an elongated figure but always slips up in the execution. According to such a view, the drawings would show us more about the child's mastery of spatial relations in laying out lines on a page than about urges governing mental imagery or aesthetic aims. One argument runs as follows.

First, in order to draw body parts and represent the relations between them, the child must have mental representations of them *available*. However, this does not guarantee that the representations will be *accessible* when they are needed. Performance in a task involving the active use of memory can never be assumed to be completely efficient. If one wishes to investigate the contents of memory, it is common practice to 'prompt' the subject, using cues for recall, rather than rely upon unaided performance. So with drawings, if one dictates the parts of the drawing simply by naming them, the child will often produce a vastly improved drawing, showing that she had been aware of the parts but could not call them up for herself. Again, provision of an incomplete drawing often cues the child into producing new parts: even inveterate scribblers may suddenly demonstrate their knowledge, as in Fig. 4. Clearly we ought not to judge the child's ability on the basis of spontaneous drawings without considering the conditions under which she would draw differently.

Page 137

Fig. 4.

This preschool child, who had never produced anything better than a scribble, responds excellently by adding limbs to an incomplete figure predrawn on the page.

Secondly, even if the child has access to all the necessary information, she cannot produce it all at once on the page. Drawing is sequential: one can only draw one thing at a time; and there are specific problems inherent in organizing serially ordered behaviour. One problem often manifests itself in a tendency towards endanchoring: the ends of a series can often be recalled or responded to with greater reliability than intermediate items. The phenomenon is most marked with temporal series, but can apply to spatial series too. The enditems in the human figure are the head and legs. So we expect them to be produced more reliably than the body or arms. This is indeed the case. Indeed, when we consider the facial features alone, there is some evidence suggesting that the eyes and mouth are more reliably drawn than the serially intermediate nose.

We can now see how the tadpole figure might be generated. The child might even have available a full body image, but would preferentially access the terminal head and legs. It seems to be the case that most tadpoledrawers produce the body parts in the order: head, legs, arms. In such a case the arms are more often put on the head than on the legs. But what kind of rule guides armpositioning here—is the child really aiming for the head? If we were to intervene and draw a body for him, would she then attach the arms to the body?

To put the argument formally, there are two possible responses. One is to attach arms to the head, the other to attach them to the body. The series in Fig. 5 presents two sets of stimuli (*a* and *b*), scaled according to headbody ratio, which might influence the relative strengths of the two responsetendencies. Experiment shows that it does so. The majority of tadpoledrawers do not

consistently go for either the head or the body, but to whichever circle is the larger. The headbody
Fig. 5.

Drawing completion tasks involving stimuli scaled according to
headbody ratio. Where will the children attach the arms?

Page 138

a leopard, which are clearly based on her method of drawing the human figure.

ratio reliably controls the locus of arm attachments: the 'bodyproportion' effect. So none of the simple accounts based on body image, which children have in their minds as a result of extended sensory experience, can be *quite* right, for they do not predict drawing behaviour associated with the tadpole stage.

The technique opens up the possibility of forcing children to make graphic decisions, in a way that is not possible if one confines oneself to collecting their spontaneous products. This applies most strongly to twoyearold children who cannot yet draw: they willingly undertake such a drawingcompletion game, and it can be shown that they too reliably attach the arms to whichever shape is the larger. Interestingly enough, even when they progress beyond the tadpole stage in their drawings many children show this phenomenon for a time; so the transition from a tadpole to a more conventional figure may not represent a sharp break.

What does the drawingcompletion evidence show? It may show that the children simply regard the larger circle as the *real* body, and they know that bodies have arms. However, the basic phenomenon appears even when the children have been asked to draw a nose or a navel immediately prior to attaching the arms. They do so correctly, treating the circles appropriately as head and body, but cannot avoid attaching the arms to the larger circle. Thus the bodyproportion effect attests to a graphic production problem: a problem in organizing lines on the page and handling the interactions between what is already on the page and what is to come. Mastery of this for one topic may be generalized to tackle others (see Fig. 6).

The same approach may be used in analysing the representation of complex scenes involving the combination of separate forms (see Fig. 7). Psychologists are now engaged on research into children's depiction of occlusion (hiding of further by nearer objects), elevation, relative orientation, and perspective. Already one new puzzle has

Fig. 7.

Sarah's drawing of a car with passenger and driver:

a first attempt at unification of separate forms,

'Transparency drawings' by two children aged 5 years 6 months, in which a hidden object is shown in its entirety. Perhaps 'superimposition' would be a better term than 'transparency'. The first drawing shows a pirate in a lifeboat, the second shows a house with a bed and a person in it.

emerged. Given the striking nature of 'transparency representations' (see Fig. 8), which are often held to be the hallmark of 'intellectual realism', why are they so very difficult to obtain under experimental conditions.'? The status of this indication of drawing ability is one of the topics increasingly questioned as experimenters move away from the 'development of drawings' to the psychological development of the child drawer (Freeman and Cox, 1985).

CHILDREN'S UNDERSTANDING OF THE MENTAL WORLD. One of the most important powers of the human mind is to conceive of and think about itself and other minds. Because the mental states of others (and indeed of ourselves) are completely hidden from the senses, they can only ever be inferred. Thinking about these unobservable states is a subtle business indeed, but in one way or another an essential part of our social life. One could be forgiven therefore for assuming that the deployment of such a 'theory of mind' must be a very late accomplishment of childhood and that it must require the benefit of education and tutoring. Recent research, however, is beginning to show that this 'theory' emerges during the preschool years and depends upon specific innate mechanisms.

The most important kinds of mental state that we infer and attribute have a characteristic form. First, they have a *content*—they are about something; second, they take an *attitude* to the content— whether the content is believed, hoped, or desired; and third, they say who is taking this attitude to the content. So, for example,

'John believes it is raining' has John taking the attitude 'believes' to the content 'it is raining'. We use such attributions to explain and to predict behaviour. So, 'John jumped into the doorway *because* he believed it was raining and he will now put up his umbrella *because* he wants to remain dry.'

We can look experimentally to see whether a child can use such attributions in this way. A powerful test of this is when the child can predict someone's behaviour on the basis of an attributed false belief. This attribution will differ from and indeed contradict the child's own beliefs and so provides a stringent test of the child's ability to conceive of beliefs as beliefs.

For example, Sally hides a chocolate in a certain box, then goes out for a walk. Meanwhile, someone else, Ann, arrives, finds the chocolate and transfers it to a basket near by. Ann too then departs. A short time later Sally returns, wanting her chocolate. We can test a child who has been watching these comings and goings, to see if he (or she) understands the various events, and satisfy ourselves that he does. We can then go on to ask

the child, 'well, where will Sally look for her chocolate?' If the child understands that Sally will still believe her chocolate to be in the box (while he himself knows it is in the basket), then he will point at the box. If, on the other hand, he cannot work out what Sally will believe, he will predict Sally's behaviour in terms of the actual situation and point to the basket.

Wimmer and Perner (1983) and BaronCohen, Leslie, and Frith (1985) found that most 4yearold children can pass this test. On the other hand, most 3yearolds will fail. Those who fail consistently point to where the chocolate really is, as if Sally too would know this. One way of understanding the 3yearolds' failure is in terms of a fundamental logical ability which they, but not the 4yearold, lack.

For example, it may be that before about 4 years, children are not capable of simultaneously conceiving of and appreciating two alternative and contradictory models of reality.

Thus the very young child can work only with his own model of the situation as he perceives it and not at the same time with Sally's model, which is different from and contradicts his own. By 4 years of age this ability has appeared and the child can now successfully predict Sally's behaviour (where she will look) according to Sally's model of the situation.

Another task requiring appreciation of simultaneously contradictory models of reality occurs when an object appears to be one thing but is really another. For example, a child is shown a sponge which has been cleverly disguised to look like a rock. The child is allowed to discover that really it is a sponge, and is then tested to see if he can appreciate the contrast between what it looks like and what it really is. J. H. Flavell has tested children on this sort of task. Again it appears that most 4yearolds succeed while most 3yearolds fail.

Thus it seems that the appreciation that people can have different ideas about a situation develops between 3 and 4 years of age. But is this ability to conceive of alternative realities really absent at 3 years?

Consider what is involved when a 2yearold child engages in pretend play. Let us suppose that the child sees a banana on a table in front of him. He decides to pretend that the banana is a telephone and accordingly picks it up, holds it at the side of his face, and simulates talking. It is most unlikely that the child has made an error and has wrongly identified the banana as a telephone, for he can see that the banana is a banana. So at one and the same time he is representing the situation as one which contains a banana and one in which the banana is a telephone. Isn't this child appreciating alternative and contradictory models of the same situation?

Consider also what happens when a child watches his mother pretending to take imaginary clothes off a teddy bear and throw them in a pile. She dips the teddy into an imaginary tub, splashes it with imaginary water, and 'soaps' it with a toy brick. What is the child to make of this? What his mother actually does is merely wiggle her fingers in the vicinity of the teddy, put teddy on the floor, accompany more finger wiggling with slurping noises, and rub the teddy with the toy brick. Clearly the child has to infer from this—from what he actually sees and hears—what it is that his mother is pretending.

The price of not being able to infer that someone is pretending something can be very high for a young child. A 2yearold observing his mother at a telephone is able to acquire useful information about telephones and social practices, even though he does not yet really understand what is going on. But think of the same child seeing his mother pretend that a banana is a telephone. If he interprets this literally he may end up with some very funny ideas about bananas or his mother, or both.

Moreover, at the same time as learning about objects and social practices from observing others, children at this age are also learning what words mean. So if a 2yearold interprets 'Here, take the telephone' literally when what his mother is handing him is in truth a banana, language learning is put

in jeopardy as well. The fact that such socially shared pretence does not have ill effects shows that young children can and do understand the alternative 'reality' of pretence while relating it to the literal reality of what they see before them.

If the 2yearold is so expert at handling alternative and contradictory models in pretence, then why is the false belief situation (as exemplified in the chocolate box/basket test) so difficult? Why do so many children fail even at 3 years old?

The ability to *conceive* of alternative realities cannot be the breakthrough that brings success in false belief or appearancereality tasks. But the critical change might be in the child's ability to *handle* such contradictory models—for example, in the ability to work out *precisely* what the alternative should be.

In pretence, the alternative model is essentially merely stipulated or invented. And even where the child has to work out what it is that someone is pretending, it is usually the case (*always* if the child is to succeed?) that the pretence can be read off from, or at least strongly suggested by, what the other person is literally doing.

The false belief task, however, differs in both these respects, for here there is a right and a wrong answer—it has to be worked out and cannot be read off. In the chocolate test, for example, Sally's belief has to be worked out by the child on the basis of what Sally saw and did not see of the situation. Once that is done the child must deduce what Sally will do on the basis of that belief.

Even so, we may wonder if difficulty in working out the alternative model accounts entirely for the twoyear lag in solving the false belief task. In the rock sponge appearancereality task, can the child not just 'read off' the appearance of the sponge that looks like a rock? Why is that so much more Page 141 difficult than 'reading off' what someone is pretending?

Before we try to answer this, let us return to the 2yearold and pretending. When the child works out that his mother is pretending that the banana is a telephone, he is attributing a mental state to her—the mental state of pretending (attitude) that a banana is a telephone (content). A 2 ½ yearold girl watches her brother who pretends to fill a cup with water and then turns this cup upsidedown over the head of a doll. She reaches for a cloth and pretends to dry the doll, showing that she has worked out the consequences of an attributed pretence. This involves both attributing an alternative model and handling it cognitively.

Furthermore, analysis can show that being able both to pretend and to make attributions of pretence to others requires mastery of exactly the same *logical structures* as understanding mental states in others (Leslie, 1986). For a discussion of the peculiar logical properties of things which express mental states—for example, sentences about mental states or thoughts about thoughts—see CONSCIOUSNESS.

So even the very young child can handle the basic logic of mental states. Despite this, most children fail in false belief tasks until about 4 years of age. Our question is, why? So far we have suggested

that the failure has something to do with not being able to work out what belief someone with a given exposure to a given situation will have.

Perner, Leekam, and Wimmer (forthcoming) took sixteen 3yearolds who had failed the false belief task and showed them a Smartie box (for a confection well known to British children), asking them what they thought it contained. The children answered, 'Smarties'. They were then shown that in fact the box contained no Smarties, just a pencil. Nine of the children could tell the experimenter, 'I thought it contained Smarties, but I was wrong.' These children were then asked, 'When we bring your friend in and show him the closed box, what will he think is in it?' Amazingly enough, they all answered, 'A pencil'!

This shows that these 3yearolds, despite their ability to model and report a false belief, were unable to understand where the belief came from. Despite the fact that they themselves had just undergone the process of acquiring that false belief, they were quite unable to understand and reconstruct the process, and were thus unable to predict what would happen to their friend.

Adults attribute mental states to machines and plants without actually believing that mental states really exist inside the machines or plants. For example, a person says that his central heating system *knows* when it's cold and *wants* to keep the house warm. He does this to describe its behaviour; but whatever it is that responds to the temperature and makes the heating come on, he never believes that it is a thought or anything like a thought. Can it be in a similar way to this that the young child attributes mental states to people and that, under special circumstances, the child will even attribute mental states in order to understand behaviour, but without regarding them as *things which really exist*?

What would follow from the child's regarding mental states as real? It would allow the buildup of general knowledge to begin, with general knowledge about mental states. If mental states are real, they must exist somewhere (but where?) and most importantly, they must be part of the *causal* fabric of the world (but how?). It may not even occur to the very young child that mental states are actually caused by other things—by concrete events—and that they are in turn the *cause* of other real things such as behaviour. Without this insight, there is no reason for a child to look closely at situations and people's exposure to them, with mental states in mind. But once a child does, he or she will consider what events lead to what mental states. It seems that these developments begin to take place between 3 and 4 years, culminating in the cognizance that led to the 4yearolds' remarkable success in the Wimmer and Perner false belief task reported in 1983.

Wellman (1985, 1986) showed that 3yearolds have the beginnings of a cohesive and explanatory theory of mind that include ideas about the way mental states exist.

For example, they understand quite clearly that while a banana can be eaten, the thought of a banana cannot. When explaining these differences even young children have recourse to mentalistic language and locate states of mind as being in the head. For example, in explanation of whether or not a dream is real, a child might say

'it's in his head, it's only pretend'. Indeed, it is striking how often in these contexts a child qualifies the mental state with 'just', 'just pretending', or 'only', 'only a dream'.

Such qualification seems to contrast the mental state with concrete publicly observable objects and events. This focus upon the different reality status of mental events is a perfectly proper emphasis for the child to have and in itself demonstrates the subtlety of early human understanding.

This focus may, however, exact a price in obscuring the fact that mental states are real enough, only in a different way from the concrete world. Again, the crucial step in coming to think of mental states as real will be the linking of them *causally* with the concrete world: if mental states can be both the effect and the cause of something concrete then they must themselves at least be *real*, if not concrete.

The task then for the 4yearold is to link his developing understanding of causal mechanisms in the physical world with his theory of mind. We know that by 4 years children have a good grasp of the essentials of physical mechanics (Bullock, Gelman, and Baillergeon, 1982). One aspect of this has to do with understanding when people are and are not in a position to see and hear things—Level 1 understanding in Flavell's (1978) sense. This then could provide the bridge enabling the 4yearold to

Page 142

link up his causal understanding of the concrete world with his more abstract understanding of the mental world.

Understanding false belief requires the child to realize that Sally's exposure to the chocolate in the box will *cause* her to believe the chocolate to be in the box, while her nonexposure to its change of location will leave this belief unchanged. Thus when Sally comes back again it is this unchanged belief about the box that will determine her search behaviour. Likewise, in the rock sponge example, understanding appearance reality requires the child to figure out what mental state (belief) would result, given exposure to only some of the visual properties of the object. In a sense, the child could indeed just 'read off' the appearance. But what mental state would such an appearance cause in someone who does not know what the object really is (has not been exposed to the other perceptible properties as well)? This may be what provides the insuperable problem for the very young child.

We are suggesting, then, that children start with a causal theory of behaviour which admits only of concrete objects and events as causes of behaviour. Their ability to attribute mental states develops independently and in parallel with this, and is used only in special circumstances—for example, pretence, or reporting the fact of knowledge changes. But at around 4 years of age the two capacities are brought together and the child enlarges its notion of possible causes of behaviour to include mental states. From now on, mental states can cause behaviour, while (perceptual) exposure to situations can cause mental states (which then represent those causing situations). Now it becomes sensible, and indeed natural, for the child to pay attention to the causal relationships between situations, mental states, and behaviour.

Mental states become part of the causal fabric of the world and will now therefore be predictable, reliable, and *learnable about*.

Finally, it seems that there are children who do not develop a theory of mind in the normal way. These are children who suffer from the syndrome of childhood*autism.

Such children have severe impairments in their social skills. BaronCohen, Leslie, and Frith (1985) tested a group of autistic children of high ability with borderline to average intelligence on the false belief task. Their performance was compared with a group of*Down's syndrome children who were more severely retarded and with a group of much younger normal children. The Down's and young normal children performed remarkably similarly, with the vast majority of them passing the false belief task. However, the vast majority of the autistic children failed, pointing consistently to where they themselves knew the object to be.

Subsequently, as a followup, these children were tested with a picture sequencing task (BaronCohen, Leslie, and Frith, 1986). The pictures depicted various kinds of events. Whereas the autistic children performed very well indeed on picture stories depicting both causal mechanical events and social behavioural events, their performance with regard to events which crucially involved understanding the protagonist's mental state was extremely poor. This pattern of performance was quite different from both the normal and the Down's syndrome children.

The autistic child, then, appears to have a theory of mind impaired in a way that is not accounted for by general mental retardation. It is too soon to say with confidence precisely what is wrong, but it seems that such children are not simply like very young normal children—for the autistic child appears to show highly abnormal development in pretend play; indeed pretend play may even be entirely absent. Where that is the case it seems likely that the child has suffered a serious neurodevelopmental problem that unfortunately strikes at the innate basis of his theory of mind.

Page 143

way of representing it visually, i.e. writing it, developed gradually by the ancient Chinese.

The Chinese script (adopted by the Japanese and Koreans, whose own languages are unrelated to Chinese but who nevertheless use it, especially for the many loanwords they have incorporated from Chinese, much as English has from Latin and Greek, and who eke it out with their own phonetic symbols) differs from all others in wide use today by being logographic: that is, instead of aiming at recording segments of sound that strung together can notate speech, its symbols or characters each represent a *logos* or unit of meaning in the language's construction. In Chinese this is always a grammatically invariable monosyllable, which may be a word used independently, like 'house' or 'boat', or 'man' or 'kind'; or may be combined with other such monosyllables to form polysyllables, like 'houseboat', 'boatman', or

'mankind'. All words of more than one syllable in Chinese were at least originally of this type; wordforming syllables such as 'er' in 'farmer' and so on, which never existed as independent words, did not feature in Chinese wordmaking. Furthermore, grammatical inflexions which also had no independence as words, like our plural

's' and past tense 'ed', had no place either. Chinese lacks the kind of grammar that makes them necessary: expression of plurality, tense, and the like in Chinese is voluntary, and when necessary is

performed by means of independent syllables such as 'twothree', 'some', 'just now', 'long since', and so forth. Otherwise it is left to context. Chinese is therefore described by linguists as an extreme example of the 'analytic' as opposed to the 'synthetic' type (exemplified by Latin and Greek) of human language; and the logographic system of writing invented for it is possible and suits it, as it would not a language of less analytic nature. Because of its analytic nature Chinese has always resisted the importation of foreign words, which would be mere sounds resistant to analysis in Chinese terms; preferring to translate or otherwise find purely Chinese expressions for new ideas from abroad. Etymology, usually a learned subject to those with more synthetic languages and who import foreign words, is to a much greater extent self-evident to the Chinese and is recorded faithfully in their logographic script. The logograms themselves (or ideograms, but this name is ambiguous in so far as it is also used for certain kinds of them only) were devised in several ways. First, there are those most obvious, *the indicative*: for example, one stroke for 'one', two strokes for 'two', a dot above a line for 'above', a dot below a line for 'below', and signs such as 力, strength and 田, fields, for

'(able-bodied) man, male, masculine'. Each of these logograms was invented to write a monosyllable, with its range of meanings and sometimes minor variations in pronunciation according to usage (for example, as between 'to love' and 'lovely, good'). They were tied to the language for which they were devised as a system of writing it, and did not otherwise depict things or ideas (even though they contained no indication whatever of pronunciation, any more than arabic or roman numerals show how they are pronounced). Finally there is the category, to which the great majority of Chinese characters belong, that do contain some indication of pronunciation. They are divided in two, as the so-called *borrowed characters* (i.e. any symbol belonging originally to any of the above categories but supposedly

'borrowed' only for its sound without respect to its meaning), and the so-called *phonetic compounds*, of which part was a *borrowed character* (called the 'phonetic'

by Western scholars) according to traditional descriptions, and part (the 'determinative', 'signific', or 'radical', the latter because of its use as a key in arranging characters in dictionaries) serving to distinguish between words with similar pronunciation. Such words are inevitably legion in a monosyllabic language—like English

'bear', the animal, and 'to bear', to carry, be strong enough, endure. In a phonetic compound, the animal might be distinguished by having 'mammal', and the verb by having 'hand' (which is often used to indicate verbs in Chinese) added to a 'phonetic' which they would share.

In any Chinese text, although many of the characters may be formed by the other methods of character-formation (especially those for some common words), the great majority will usually be found to belong to the phonetic compound class, which is even said to account for 95 per cent of the characters listed in Chinese equivalents of the *Oxford English Dictionary*; and each, when etymologies are given, will be described merely as so-and-so 'determinative' with so-and-so

'phonetic'. Such character 'etymologies' do not seem as interesting as the analysis of the other, 'poetic' kinds of character-formation, and yet it is

these very characters which, when examined afresh with the assistance of newly discovered ancient forms, throw light on the evolution of language. A simply phonetic explanation, though it seems to be universally accepted for most of these so-called phonetic compounds, encounters great difficulties. In the first place, they are by no means truly phonetic but allow extraordinary differences in pronunciation between the supposed phonetic element as a character itself and composite characters containing it: why then were they chosen? Reconstruction of ancient pronunciation, in which the great Swedish phonologist Bernhard Karlgren was a pioneer in the first half of the twentieth century, seems to have brought a degree of reason into these anomalies, showing that they were once somewhat *less* unlike than now; but why, if they were intended to represent pronunciation, should they have been unlike at all? As Karlgren said in his seminal *Analytic Dictionary of Chinese and Sino*

Japanese (1923), they cannot, by all experience of phonetic laws, once have been the same and then diverged. Why then should there be such anomalies in this supposed phonetic spelling as mixing P with M, or N with T, in characters sharing the same 'phonetic element'? Karlgren could only resort to a theory of 'homorganic spelling', whereby sounds made with the lips or sounds made with the tongue against the teeth could each be treated alike, as M and P, N and T, and so on; but why should the ancient Chinese, to whom the differences between these 'homorganic' sounds were as important as to anyone else, have done anything so perverse? Could they have read texts written by such a system? In short, does it make any sense to think of the compound class primarily as a phonetic system of spelling? And if it was not, what was it? There is a vast number of Chinese characters that can be used as supposed 'phonetic elements' in constructing others (much greater than is needed for a simply phonetic function, especially one so imprecise); yet there is remarkable consistency in the choice of one of them, even a very poor phonetic match, for the writing of a given word as a so-called 'phonetic compound'.

There is only one explanation for all this: that the 'phonetic element' also had a *meaning* and that that was even more important than how it was articulated. Let us look again at and pronounced *rù* in Modern Standard Chinese but *yap* in Cantonese and reconstructed as *niep* * by Karlgren for the language of about 600 B.C. The same drawing with a bar or bars behind it, is '(to have) present in mind', 'to think about', 'to remember' (*nian* in Modern Standard Chinese, *him* in Cantonese).

Karlgren did not, in fact, treat these various characters as having the same 'phonetic' although, by his own rules, there was no good reason why he should not have done so.)

Another word for 'to have present in mind', 'to think' is written with determinative 'heart, mind' and a different so-called 'phonetic', , said to be a 'longtailed bird', and this one; but ancient pictograms show

them respectively as

and reveal a crowing cock and a squatting hen. Composite characters with the latter as 'phonetic' are used in writing words vaguely related to the hen and to one another phonetically, with a great variety of meanings: 'to be plump', 'isolated', 'stay in one place' (all like a broody hen) and to 'brood', 'think obsessively', as in English. Branching forth, as it were, from some of these ideas, which the hen illustrates, are others (given various determinatives) that can seem exceedingly remote from it: 'high' (of a mountain because isolated by its height) and metaphorical, noble meanings from that; 'moored' (of a boat); 'constant' (of a principle); even a particle with meanings like 'at' a place or time, or isolating a word or phrase for the purpose of drawing attention to it, and so on. The hen, her broodiness and sitting, are put on one side or forgotten, as conscious metaphors must be for language to develop freely from them; but there has to be a conscious metaphor *to start with* for a word to be created, because communication can only take place given a presumption of references shared in common between those endeavouring to communicate.

Ultimately, these must be to com

以

以

以

Page 145

mon observation and experience of the world; and it is therefore not surprising to find close parallels in the etymologies of words in phonetically, grammatically, and historically unrelated languages. And even in cases where there are no such parallels, ultimate etymologies will very seldom not be comprehensible to any human being.

What about the name of the hen herself? In English it was just the feminine gender (something lacking in Chinese) of an old word for a cock, cognate with 'chant' (cf.

'chanticleer'); in Chinese it probably meant 'squatter', also relating it to a verb: in both cases something that could be acted, gestured, before a word was made.

The animal, a 'bear' has been mentioned. Etymologies in dictionaries of English ascribe this word to a root meaning 'brown': as a colour name, an abstraction certainly not amenable to acting. But a

Chinese character suggests that it may have been one and the same with the root of the similarly pronounced verb 'to bear'. An early version of the character (on a bronze of the eleventh century BC)

is taken now by most scholars as a pictogram, a drawing of a bear, so contradicting the view of an early work (AD 100) on a contemporary version of it, which saw the

of this character representing an old Chinese word for a 'bear', is seen on its own in the earliest, oracle bone script of the second millennium BC as an excellent onestroke drawing of the profile of a hand in a carrying, *bearing* posture,

and meant 'bearing in the hand', hence 'taking with one', 'using as an instrument' and the like (now written with the addition of 'man' determinative as and one of the commonest words in the language). Although this is now pronounced *yi*, reconstructed phonology shows that as *dieg* * it could well have been the 'phonetic' (or represented the 'root') in

, which was part of the drawing

of a stag, to represent a large animal. So 'a physically *strong* (the root of the word) large animal' was the information conveyed in the Chinese character for a 'bear', which has been too readily supposed a crude and incompetent ('primitive') drawing. Moreover, IndoEuropean philologists may need to think again about the derivation of our name for the animal. Supposing it just to have meant 'brown', they assume 'beaver' (which was the same root reduplicated) to have meant 'very brown'—as if this were the best name our ancestors managed to think of. Might it not have been a *busy bearer* of materials for its dams? And might not 'brown' itself, certainly from the same root, have implied the colour of strength and health? That is an idea which can be acted, but metaphors do not provide meanings (intentions) in themselves, needing *context*.

This is well illustrated by a Chinese character with meanings now like 'to retire to rest', but in ancient texts also 'to go busily to and fro'. The character

, which was

'tree' plus 'bird's nest', illustrated the metaphor lying behind both. Birds 'nest' (go to roost) at sunset and 'nest' (build, go to and from their nests) in spring. Contexts would make it perfectly clear which sense was meant before the notion grew of 'words' possessing meanings in themselves: a notion that has given endless trouble to philosophers since, but which became necessary for human organization, government and institutions, and for the establishment of laws.

Two Chinese characters for 'words', now for 'child')—whence 'complaint', with legal connotations in these and other characters incorporating it. Though both these characters now have only to do with speech and language, the first, augmented by 'mouth', represented originally *speech about a complaint*, including pronouncement of judgment; while the second, augmented by 'hands unravelFrog', represented *analysing the complaint*, pleading. (The hands unravelling showed them with a thread between them, on either side of a bar; so could indicate, according to context, *tying* the thread around the bar or *untying* it. In English the verb 'to ravel' can have similar opposing meanings,

as will be seen in the *Oxford English Dictionary*. Again an image of an activity was shown, while the specific meaning depended on context.) Pleading is still its sense in ancient texts, whereas now it is like the *lexis* of 'lexicon' and used in the Chinese name for a dictionary.

In the purely metaphorical stage of language, there was no cause to think about its components individually as 'words' with fixed intentions: Chinese characters show legal processes, when they came to be important, as that cause. The revolution then brought about is the reason for misunderstanding now about the original nature of Page 146

Chinese script; as it is, too, for much of the confusion about the dual nature of human language, both natures vital now to thought and communication. The newer, artificial (logical) language strives for precision; but the original, natural (poetic) language remains necessary for creative thought.

A. R. V. C.

CHINESE IDEAS OF MIND. In traditional Chinese philosophy and science the psychological was almost never regarded separately from the physiological. The stance was holistic, in contrast to common IndoEuropean thinking stemming from ancient Greece, where*Plato and his school conveniently distinguished matter from ideas, and the soma from the*psyche. Yet the Western tradition has in the twentieth century given rise to an array of psychobiological monistic attitudes, which have as their *raison d'être**idealism, reinforced by JudaeoChristian tradition. (For further discussion, see MIND AND BODY; MINDBODY PROBLEM; **EVOLUTION**: NEDDARWINIAN THEORY.)

Philosophical antidualism in China can be traced to the Warring States period (481221 BC), to Confucius (Kong Fuzi or Kong Qiu, 551479 BC), and even earlier.

Chinese rationalism of various schools generally opposed supernatural conceptualizations; and an organic outlook on interactions between man, nature, and government became firmly entrenched in the minds of literate people. Religious supernatural thinking nevertheless continued within popular Taoism.

Earlier Chinese sources demonstrate commonly held animistic modes of thinking—devils and spirits were thought to be able to possess the human body and soul and thus produce physical, behavioural, and social disorders. These supernatural factors were soon paralleled by the concept of natural factors such as cold, heat, wind, drought, and humidity, affecting the human body in much the same way. Confucians, on the other hand, created a highly rational, though metaphysical, system of thought characterized by numerology and what may be termed 'correlative' thinking. Objects and phenomena in the universe were seen as belonging together in groups and governed by superior principles. Numerological systems were used to analyse the phases of change that these groups, consisting of concrete as well as abstract things, went through, and the changes were believed to occur in resonance, or 'in correlation' with one another. Examples of these numerologies are the wellknown yin and yang used in any analysis of paired relationships, the Five Phases (*wu xing*, earlier misleadingly rendered as the Five Elements) used in correlating anything divisible in fives, and the Ten Heavenly Stems and Twelve Earthly Branches used jointly mainly for calendrical purposes. In

these contexts, they used terms, more usually applied to the supernatural, in borrowed and natural senses. Supernatural forces were disregarded—there is no way of gaining knowledge about gods; thus they are of no interest. Any dichotomy between the body and an intrapersonal soul was similarly disregarded.

Chinese literate tradition, dominated by Confucian rationalism, thus took a decidedly 'organic' point of view on psychological matters. It did not discriminate between physical, behavioural, emotional, or social cues when incorporating them into more general concepts used in medicine, psychology, or politics. This organic outlook appears to be deeply ingrained in the minds of Chinese, and other East Asians, and helps explain why their attitudes towards psychological explanations of human behaviour differ from those of Westerners. The Chinese never developed any psychology of the*unconscious.

Nevertheless, the history of Chinese philosophy is replete with arguments concerning 'principle' versus 'practicality', and 'idealism' versus 'empiricism'. One finds varying degrees of emphasis on *xin* ('heart' or 'mind'), as opposed to *wu* ('things'). For example, the most idealistic school of philosophy in the Song dynasty was that of Lu Xiangshan (113891), who wrote: 'Space and time are [in] my mind, and it is my mind which [generates] space and time' (Needham and Wang, 1962, p. 508).

A somewhat later but more influential idealist thinker was the neoConfucian Wang Yangming (14721528). Wang's *xinxue* (study, or school of the mind) emphasized that man should endeavour to become a sage—regarding heavenandearth and all men and things as a unity of close relationship, and relying on [moral]

principles (de Bary and Bloom, 1979). Wang wrote: 'The master of the body is the Mind; what the Mind develops are Thoughts; the substance of Thought is Knowledge; and those places where the thoughts rest are Things' (Needham and Wang, 1962, p. 509). Confucian *xinxue* was distinct from its *shixue* (real or practical learning). The Japanese BuddhistturnedneoConfucian Hayashi Razan (15831657), influenced by the Wang school, held that 'principle [*li*] is prior and material force [*qi* , often transcribed as *ch'i* , the Chinese counterpart to the Greek concept of *pneuma* = vitality] posterior', but he came to experience difficulty in sustaining this position:

Principle and material force are one and yet two, two and yet one. This is the view of the Song [neo]Confucians. However, Wang Yangming claims that principle is the regularity of material force and that material force is the operation of principle. If we follow the latter view, then there is the danger that everything will be chaotic. (de Bary and Bloom, 1979).

Buddhism, spreading from India to China in the second century AD onward, held a decidedly idealist position in declaring the visible universe an illusion: the world was nothing but mind, and the individual's mind was part of the universal mind. The Chinese Buddhists substituted *xing* ([subjective] nature) for *qi* (material force, or *pneuma*). They came to form one strand in neoConfucian organic philosophy, but they failed to alter the Page 147

fundamentally holistic outlook of indigenous Chinese thought patterns. (For further discussion of the Buddhist position, see INDIAN IDEAS OF MIND.) The absence of a mindbody dichotomy is clearly

seen in the traditional Chinese medicine of the literate classes. In the rational tradition, supposed pneumatic imbalances between internal organs were analysed in terms of a 'manifestation type' (*zheng*) of a disorder, according to specialized rules for diagnosis, including tongue inspection and pulse palpation. Widely differing disorders ('mental' as well as 'physical') would be shown to have a similar type of manifestation and thus receive similar treatment, such as herbal drugs or acupuncture.

For these reasons, psychiatry has no independent status in traditional Chinese medicine. Instead, concepts with a clearly psychiatric content are found widely dispersed in various fields of medicine. Not surprisingly, therefore, the Chinese word for psychiatry (*jingshenbingxue*: 'mentaldiseasestudy') is a modern translation.

Psychology as a discipline (rendered in Chinese *xinlixue*: 'mindprinciplestudy') was introduced in Chinese universities around 1915. The subject has had a strongly practical application both before and after 1949. During the 1950s Soviet influence was dominant, with Pavlovianism the leading creed (see PAVLOV); a great deal of research attention was devoted to medical, labour, and educational psychology as well as to the development of moral character (Chin and Chin, 1969).

Psychology, along with sociology, ceased to exist as an academic subject for a decade during the Cultural Revolution but was academically rehabilitated in the subsequent liberalization movement.

CHOICE, BIOLOGICAL. The concept of choosing is, of course, a notion that is primarily applied to human beings; and it may seem absurd to speak of a bacterium as exercising choice, for that is one of many attributes that humans like to reserve for themselves. But is this exclusive view either wise or justified? Of course there are many things humans do that other animals don't, but the biologist suspects that by looking carefully it may be possible to discover in nature something of the origins of even the most distinctive human features. Such influences, though remote, may be revealing if they show characteristics that special human features share with more humble life processes.

Choice implies the capacity to select from a set of possible actions those that are likely to achieve some end, given the circumstances. This involves a series of concepts very strange to a scientist. First, there must be a chooser. Next, given the conditions, he 'can' do more than one thing, i.e. he is not fully 'determined'. Most difficult of all, he acts in pursuit of some aim, objective, or end. It is said on all sides that such words should be used only of humans, and some scientists themselves have been among the leaders in decrying 'teleology'.

It may be difficult to discern 'ultimate' meanings in nature, but can even the wisest theologian do more than make guesses about ultimates anyway? What the biologist sees is that organisms show evidence that they act with a direction or aim, namely to ensure that life continues. As Monod (1972) expresses it, 'objectivity obliges us to recognize the teleonomic character of living organisms'. The life that is preserved is first of all that of the individual and then of his species. The fundamental fact about the acts of all living creatures is that they involve this tendency. This is an influence that should never be forgotten, even in the most abstract thinking of philosophers. The biologist can examine how living actions come to be so directed that they produce this effect. Is there evidence that in any clear sense organisms actually seek to maintain a given standard?

The continuity of life is ensured by a continuous series of selections among sets of possible alternatives. We do not know precisely how life began, but early on it involved a selection of only a few among all the ninetytwo naturally occurring elements. The sets of nucleotides then established, with their mutants, have provided the raw material from which further selections have been made. Moreover, every organism during every second of its life is making repeated selections among the various metabolic pathways that can be followed.

This immense sequence of selections certainly has at least a formal similarity to what humans call choice, but where is the chooser? In enthusiasm over the discovery of the genetic code, biologists often imply that DNA and its replication is, as it were, the essence of life. This is to omit the living creatures themselves and the processes by which they are maintained. The whole 'function' of the DNA is to provide instructions that allow the individual life to continue. Genes alone can do nothing. They can produce a new organism only if they find themselves in a *system*, equipped with all the appropriate enzymes and other materials for synthesis. The very existence of such a system depends upon all the long, past history of the species and of life itself. When bacteria are placed in lactose, the decision to synthesize galactosidase depends not only on the presence of the relevant gene but on the whole system that detects the new sugar, communicates with the genetic material, and allows synthesis and the use of the enzyme. The whole organism is thus the chooser, and it is aiming at a previously defined target or standard, which is set in this case by the demand for energy. If this demand is not met, mechanisms are

Page 148

brought into action that detect any possible fuel and so alter the organism's own action that it can utilize whatever is available. Thus it is ensured that departure from the target through lack of sugar activates mechanisms that can correct the deficiency. So in a precise sense there is an individual chooser, acting to achieve a specific preset aim, even in this simplest of examples. It is an essential of any living thing that it must make such repeated decisions, using the best information available from outside and from within itself. And every human 'knows' that this is also what he must do throughout his life.

It may be objected that there is an essential difference between such 'selections' and human 'conscious' choice. This indeed raises great difficulties, but we are concerned here to emphasize the

possible significance of similarities, which remain relevant even if there are also differences. Of course, the word 'choice' can be arbitrarily restricted to humans, but to do this for any type of activity is to give up the possibility of learning from man's animal ancestry. As Trevarthen says of language, 'Biological causes run deep. One does not find complex, highly evolved life processes showing no evidence of their origin from simpler adaptive functions.'

It may also be objected that given lactose the bacterium has no real 'choice', it *must* make galactosidase, and the action is as 'deterministic' and 'chemical' as any other. This objection points very clearly to the problems raised by discussions of choice and free will and the importance of an analysis that includes *both* human and other biological information. When we insist that our own choices are 'free', do we really mean that they are wholly indeterminate? Surely that would imply that they were the result of chance, the very opposite of our meaning. What we want to indicate by 'free choice' is decision made according to our own needs, aims, and standards and with our information, not made under duress to meet the needs of others. What the bacterium is doing is choosing the appropriate one from its own set of possibilities, rather than being forced to make some other protein, as it would if invaded by a virus. It is true that its set of alternatives is limited; it cannot decide to try to jump out of the culture and back into one containing glucose. But we do not have an indefinite range of choice either.

As organisms have become more complicated the number of possible lines of action open to them has increased; in human beings it is very great indeed. Making choice between so many nearly similar paths of action (for example, by speech) is our specifically human property. We cannot be fully human unless we operate it freely (and, incidentally, social systems that allow this freedom may well prove to be at an advantage over those where choice is limited by convention or compulsion).

With the increasing complexity, organisms have developed very elaborate control mechanisms, each with its reference targets. The fact that they seek to achieve specific targets becomes very obvious. We now even have some knowledge of the Operations in ourselves by which departure from reference standards is detected and corrected. Nerve cells in the hypothalamus of the brain provide such references for control of temperature, eating, drinking, sex, and much else.

The realization that choice is a property of all living things gives us great help in understanding the world and our place in it. It shows that the activities of life do indeed have a direction and an aim. Life originated perhaps 3,500 million years ago, and since then there has been a definite progress, in the sense of the increasing information and order in organisms. The increase has been achieved as a result of repeated selections or choices made by organisms between alternative possible courses of action.

CHUNKING. The Scottish philosopher Sir William Hamilton (1788-1856), born in Glasgow (where his father and grandfather held the chairs of Anatomy and Botany) wrote: 'If you throw a handful of marbles on the floor, you will find it difficult to view at once more than six, or seven at most, without confusion.' This was confirmed by the English economist, William Stanley Jevons (1835-1882), by throwing beans into a box and estimating their number. He found that he never made a mistake with three or four, was sometimes wrong when there were five, was right about half the time with ten beans, and was usually wrong with fifteen. These experiments are cited by the American psychologist George Miller (1956), the author of the famous paper 'The Magic number seven, plus or minus two' (1956).

Miller found that more items can be remembered when they are coded, or 'chunked'. Thus, we can remember more numbers or letters when they are in recognized sequences or words. So chunking enormously increases effective memory and perception. One might think of perception of objects as 'chunking' the sensory and stored data into large units—which are objects as perceived.

Miller, G. (1956). Information theory, *Scientific American*, August.

Miller, G. (1956). The Magic number seven, plus or minus two. *Psychological Review*, 63, 2, 81-97.

CLADISTICS. A system for classifying organisms. The word 'clade' was coined by Julian Huxley in 1957, to refer to characteristics that can be used as units for setting limits to classes and establishing hierarchies which may or may not be associated with evolutionary sequences. The cladistic system of classification—which, for some reason, arouses heated controversy—has three axioms. (i) Features shared by organisms (homologies) reveal hierarchical ordering in nature. (ii) Hierarchical orderings are economically expressed in branching diagrams, or 'cladograms'. (iii) The nodes in

cladograms represent common features (homologies) shared by organisms—so cladograms can be used to represent and suggest biological classifications. The method can be used outside biology—for example, in geology, or linguistics, or wherever homologous characteristics can be recognized and there is no adequate structure of theoretical understanding for classification. The method demands explicit decisions on what are to be accepted as valid homologues, and this can be a useful exercise. Absence of characteristics (such as absence of teeth in birds) may be accepted for cladistic classification.

The current controversy over cladistics and Darwinian evolution seems to be based on the notion that cladistics is somehow opposed to or provides evidence against evolution; but this is mistaken. It can offer classifications which do not assume evolutionary sequences; but this is all to the good, as classifications which assume particular evolutionary sequences can generate vicious circular arguments in biology. See EVOLUTION: NEODARWINIAN THEORY.

Patterson, C. (1980). Cladistics. *Biologist*, 27, 234-40.

CLAIRVOYANCE. See EXTRASENSORY PERCEPTION.

CLAPARÈDE, ÉDOUARD (1873-1940). Swiss psychologist and educationalist, who studied at

Geneva, Leipzig, and Paris, and with his cousin Flournoy founded the journal *Archives de Psychologie* (1901). He became director of the experimental psychology laboratory at Geneva University and later founded the J. I.

Rousseau Institute for Educational Science. He had strong clinical interests and made a number of studies of the psychological sequelae of injury to, and disease of, the human brain, including a seminal study of the partial preservation of recent memory in amnesic states despite what appears to be total forgetting. He also published, in 1900, an important review on defects in the visual recognition of objects (visual agnosia) in *L'Année Psychologique*, vol. 6, pp. 741-43. His books include *L'Éducation fonctionnelle* (1921).

CLASSICAL CONDITIONING. See **CONDITIONING**.

CLASSIFICATION, BIOLOGICAL. See **EVOLUTION: NEODARWINIAN THEORY**.

' **CLEVER HANS**'. A famous horse once thought to possess powers of telepathy. The horse (of a Russian trottinghorse breed), which lived in Berlin at the beginning of the twentieth century, could apparently perform arithmetic in the presence of its owner by tapping a hoof on the ground to count out the answer. Fraud seemed unlikely since the owner and trainer, Herr von Osten, would allow people (free of charge) to watch the animal perform and even to question it themselves.

The phenomenon was investigated in 1904 by O. Pfungst, a student of the psychologist C. Stumpf, and Pfungst subsequently reported his findings in a book, *Clever Hans*. His conclusion was that the horse was receiving clues from gestures made, probably unwittingly, by the owner and other questioners—an example of nonverbal communication which is easily taken for telepathy.

See also **EXTRASENSORY PERCEPTION**.

Pfungst, O. (1911), *Clever Hans* (trans. C. L. Rahn). New York.

CLOCK, BIOLOGICAL. See **BIOLOGICAL CLOCK**.

' **COCKTAIL PARTY** ' EFFECT. The rejection of unwanted messages by the ears. This rejection depends largely on binaural hearing, and allows signal sources to be localized. However, the quality of the voice, such as the sex of the speaker, can also be used to accept or reject messages. See **ATTENTION** and **CHANNELS, NEURAL**.

Carterette, E. C. and Friedman, M. P. (1978). Perceptual processing. *Handbook of Perception*, 9. New York and London.

CODE, CODING, AND DECODING. When physical events or patterns, such as letters and numbers, represent a message, the message is said to be 'encoded' in the marks or events. Thus neural signals (action potentials, see **NERVOUS SYSTEM**) are coded activity from the sense organs and

must be decoded to be useful.

The amount of information that can be transmitted depends not only on the band width (the frequency response) of the*channel but also on the appropriateness of the coding. Morse code is efficient because the most frequent letters are the shortest—they have the fewest dots and dashes—and so occupy least time.

For*cognition—perception or behaviour based on knowledge—neural signals are 'read' on the basis of knowledge or assumptions, which may be false. See INFORMATION THEORY.

COGNITION. The use or handling of knowledge. Those who stress the role of cognition in*perception underline the importance of knowledgebased processes in making sense of the 'neurally coded' signals from the eye and other sensory organs. It seems that man is different from other animals very largely because of the far greater richness of his cognitive processes. Associated with*memory of individual events and sophisticated generalizations, they allow subtle analogies and explanations—and ability to draw pictures and speak and write. The word 'cognition' is probably related to 'gnomon'— the shadowcasting rod of a sundial—which measures the heavens from shadows.

COLOUR SCALING. See RETINEX THEORY AND COLOUR CONSTANCY.

COLOUR VISION: BRAIN MECHANISMS. In COLOUR VISION; EYE MECHANISMS William Rushton outlines the trichromatic theory that colour vision is mediated by three different kinds of retinal receptor, each responding best to light from a different part of the visible spectrum. The theory is based firmly on the empirically established trichromacy of colourmatching: given any four coloured lights, it is always possible to place three of them on one side of a foveal matching field and one on the other, or two on one side and two on the other, and by adjusting the radiances of three of them cause the two sides of the field to match. When the observer makes his adjustment he is thought to be equating, on the two sides of the field, the rates of quantum catch in the three classes of cone. If the two sets of quantum catches are identical, then we may suppose that subsequent neural events are also equivalent and the two sides of the field will look alike to the observer.

However, the trichromatic theory limits itself to predicting whether or not two colours will *look alike*; it does not tell us how they will actually look to the observer.

Opponent colour theory. Historically, a number of rivals to the trichromatic theory have taken as their startingpoint the phenomenology of colour. The most celebrated of these rivals is the 'opponent colour' or 'tetrachromatic' theory of Ewald*Hering. The trichromatic theory, in the form that it was advanced by Thomas*Young, James Clerk Maxwell, and Hermann von*Helmholtz, does not obviously account for the fact that a mixture of yellowy red and yellowy green can produce a yellow

that is without trace of redness or greenness. Hering proposed that colour analysis depends on the action of two types of detector, each having two modes of response: one detector that signals either red or green, and a second that signals either yellow or blue. Finally he supposed that brightness depends on a system that signals white or black. Thus one can see a colour that looks greenish, and bluish, and dark; but not one that is both reddish and greenish, or both light and dark, and so on.

Nowadays it is generally held that a complete theory of colour vision must draw elements from both the trichromatic and the opponent colour theories. Indeed, Helmholtz himself proved that the two theories are not incompatible, since a simple transformation could change the three receptor outputs into two difference signals and one additive signal. Wasserman (1978, pp. 913) gives Helmholtz's argument. Unfortunately, this statement by Helmholtz appeared only in the second edition of his *Handbuch der Physiologischen Optik* (1896) and was missing from the third edition (1909), the latter being the one translated into English (by the Optical Society of America, in 1924).

Electrophysiological studies of opponent processes. A transformation of the kind considered by Helmholtz probably occurs in the retina itself. In 1958, MacNichol and Svaetichin found that, at the level of the horizontal cells in the goldfish retina, light of one wavelength may depolarize (i.e. excite) a cell, whereas light from a different part of the spectrum may hyperpolarize (i.e. inhibit the cell). In the absence of stimulation the cell's electrical potential has an intermediate value, and this potential can be increased or decreased by stimulating the retina with different colours. Soon afterwards De Valois reported opponent responses in the lateral geniculate nuclei of macaque monkeys; and others have reported such responses at the level of retinal ganglion cells in the monkey, although it has so far proved difficult to obtain recordings from the more distal cells of the Primate retina. Thus De Valois was led to propose that colour information is transformed from a

'component' system (three cone types giving responses that increase with increasing intensity of stimulation) to an 'opponent' system in which some wavelengths cause an increase in a given retinal signal and other wavelengths cause a decrease. Such an opponent system effectively transmits colour difference signals: for example, a cell that increases its firing rate as a result of stimulation with red (R) light and decreases its firing rate with green (G) stimulation can be said to be signalling $+RG$.

If colour difference signals are transmitted, can we tell which combinations of receptor responses are 'differenced'? There is some doubt about this, since the electrophysiological reports are not entirely consistent; but by and large, if we call the three cone types R , G , and B , neural pathways have been found that signal $\pm (R$

$G)$ and $\pm [(R + G) B]$. It should be noted that in the second of these expressions, the sum $(R + G)$ may be taken as signalling 'yellow'. This may be the explanation for why yellow is the fourth psychological primary—along with red, green, and blue. It seems that the responses from the R and G cones are added, thus generating a spare colour (yellow) that looks neither green nor red, and is complementary to blue. For details of the physiological evidence for opponent processing, see De Valois and De Valois (1975).

Psychophysical studies of opponent processes. There is good psychophysical evidence that

opponent colour channels exist. Thus the efficacy of two adapting fields of different wavelength (or the detectability of two lights of different wavelength) may be less when the two are concurrently presented than when either alone is present (see Mollon, 1982). In these experiments the

$$L = 0.3R + 0.59G + 0.11B \quad (1)$$

$$R - L = 0.7R - 0.59G - 0.11B \quad (2)$$

$$\text{and } B - L = -0.3R - 0.59G + 0.89B \quad (3)$$

Page 151

observer is asked only to detect a liminal (difference) stimulus; he is not asked to make subjective judgements about the quality of the colour appearance.

It is currently a controversial question how closely these psychophysically demonstrated opponencies are related to the phenomenological oppositions of red and green and of yellow and blue. The latter oppositions, however, can be systematically measured. This was classically done in the 1950s by Jameson and Hurvich (see Hurvich, 1978), using the method of *hue cancellation*: to measure, say, the amount of yellowness in a series of wavelengths from the longwavelength part of the spectrum, the experimenter adds blue light of a fixed wavelength to each in turn of the long wavelengths. The long wavelengths would range from a slightly yellowish green to a deep red. For each of these test wavelengths, the observer is asked to adjust the added blue light until the mixture looks neither yellowish nor bluish. The amount of blue light required is the dependent variable and is taken as a measure of the yellowness, the 'yellow chromatic valence', of the test wavelength.

Luminance. The main tenet of opponent colour theory is that there are two independent '*channels' signalling colour information. One of these signals red or green, the other signals yellow or blue. But from trichromatic theory it is clear that we need three, not two, independent variables to describe colour appearance. Thus, a third channel is necessary. What does this channel signal? The answer is luminance. The signals from the R and G (but probably not B) cones are added, and the information is transmitted as luminance. But again, it is opponent coded. The channel signals 'brighter' or 'darker', but with respect to what? Simply with respect to other parts of the picture, or retinal image. The luminance channel signals comparative information, not about absolute local luminance but about how the local luminance compares with the rest of the scene. Comparisons are made not across colour but across space. The visual system places heavy emphasis on comparison across space. The impressive colour effects demonstrated by Edwin Land (see RETINEX THEORY AND COLOUR CONSTANCY) are a powerful example of longrange interaction in the visual system.

An analogy with colour television. Why should opponent coding of colour have evolved? It may be useful to draw analogies with colour television. About 1950, television engineers started looking for a means of transmitting an acceptable colour picture efficiently. This meant transmitting as little information as possible (i.e.

keeping the bandwidth low), with a high level of resistance to extraneous noise, and in a way that was compatible with monochrome receivers, i.e. capable of giving an acceptable blackandwhite picture.

Obviously this analogy cannot be pursued too far, since colour television aims to provide an image that is a good substitute for the original object; the visual system of each member of the audience must then get to work on the picture. However, the choice of how much importance to attach to different aspects of the information contained in the picture, and how to transmit the information most efficiently, seems to raise interesting questions for visual science.

The simplest system would 'look at' the original scene through three primary filters, transmit the three pictures separately, and recombine them in the receiver. Since the G primary is most similar to the luminance signal, this would be the one that monochrome receivers would receive. But errors would result, reds being too dim and greens too bright. More importantly, three times as much information would have to be transmitted (so the bandwidth would be trebled) in comparison with monochrome transmission. This would be expensive, and impossible where many broadcasts must share a limited range of radio frequencies.

At the time when colour television was being developed, it was known that visual acuity was worse for colour than for brightness contrast. Since it was desirable to separate colour and luminance anyway (to allow monochrome sets to receive a true luminance signal) there now appeared a way of reducing the total transmission bandwidth: give the colour information less bandwidth than the luminance information. But how could colour and luminance be separated? A neat mathematical solution presented itself: opponent coding. If R , G and B are the signals from the red, green, and blue receivers respectively, then we can define luminance, L , as The weightings given to the R , G and B signals are commensurate with the relative contributions of the three primaries to luminance.

We can now derive two 'colour difference equations':

Equations (2) and (3) give 'chrominance' information. If $R = G = B$, then both chrominance signals are zero. Since the viewer's visual acuity is less for colour, less bandwidth need be used to transmit (2) and (3) than (1) (Sims, 1969).

There are other consequences of the colour difference operation that hold advantages for both television and the visual system. If three trichromatic signals were transmitted untransformed, then redundant information would be carried in the transmission. For the three signals would be correlated: they would necessarily be correlated because the spectral sensitivities of the three receptors overlap and because objects in the world have broad spectral reflectances. To avoid waste of valuable channel capacity the three signals should be orthogonal, i.e. should not be correlated with

Page 152

each other. By transmitting a luminance signal and two difference signals, visual systems may approach this ideal of communications engineering (Fukurotani, 1982).

Another advantage of the difference operation may lie in the preservation of neutral colours. Imagine that a television camera is looking at a neutral object. There will be a luminance signal, but the two chrominance signals will be zero, since the camera is set so that $R = G = B$. The chrominance signals are thus zero: all is well. But now imagine that the gains of the two chrominance channels are altered

—that is, the $R L$ and $G L$ signals are each multiplied by a different number (as might arise from drift in the electronics). The two channels will still be signalling 'zero' for neutral scenes, since a product of any number and zero is still zero. The resistance of the neutrality of neutral objects to drifts in the gains of opponent channels is likely to be an important consideration in our visual system as well.

Cortical analysis of colour. A question of great interest, and still unsettled, is that of the extent to which colour is analysed separately from other attributes of the retinal image, such as form and movement. S. Zeki has identified in the rhesus monkey two adjacent regions of the prestriate cortex that he suggests are specialized for the analysis of colour: these regions (denoted ' $V 4$ ' and ' $V 4 A$ ') lie on the posterior bank of the lunate sulcus and the anterior bank of the superior temporal sulcus (Zeki, 1977). He suggests that colourspecific cells are here more frequent than in other prestriate regions and, most interestingly, that the cells show colour constancy (see RETINEX THEORY AND COLOUR CONSTANCY) when one patch of a complex, multicoloured array falls within their receptive field; that is to say, they respond to the colour seen by a human observer despite large changes in the local spectral flux that falls on their receptive field. But as yet we have little idea of how the colour constancy is achieved or of how the hue of an object is referred to its other attributes, such as movement, shape, and distance.

COLOUR VISION: EYE MECHANISMS. When things are seen, it is usually because light enters the eye and is focused upon the retina, that sensitive membrane at the back. Light consists of electromagnetic vibrations of minute wavelengths—one million waves to the half metre for green light.

Isaac*Newton, by his famous prism experiment, showed in 1666 that sunlight consists of a mixture of rays, each bent to a different degree in traversing the prism and thus falling at a different place upon the far wall. He showed that each ray was elementary in the sense that it could not be changed into a ray differently bent. Each elementary ray had a different colour, and the colour of objects depended upon the copiousness with which the various coloured rays were reflected or transmitted from the object to the eye.

Newton's conclusions, though true, met with fierce opposition. To*Goethe it was absurd to assert that the mere mixing of all the rainbow colours could appear white since white is without colour. And artists had long known that it was not necessary for them to have a set of seven rainbow paints; a judicious mixture on the palette of a few bright paints—perhaps only three—was sufficient for masterpieces of natural representation.

A person's perception of everything in the world outside him depends upon three factors: (i) the physical stimulus, such as vibrations of light or sound, (ii) the sense organs that respond to particular stimuli in special ways, and send corresponding messages along their nerves to the brain, and (iii) the mind that creates perception out of brain activity. Newton analysed correctly the diversity of light rays that constitute sunlight. But he did not consider the limitations of the eye in responding selectively to these divers rays. This was done by the physician Thomas*Young in 1801, at St George's Hospital, London. He saw that human perception of fine detail implies a

'fine grain' of photoreceptors in the retina, and thought it unlikely that each 'grain' would be selectively responsive to every wavelength of light. Nor was this necessary to explain colour discrimination. Young suggested that each grain consisted of a triad of resonators each thrown into vibration by light waves. The 'green receptor' was moved chiefly by waves from the middle of the spectrum (which looks green), though neighbouring spectral waves also acted upon it less vigorously. The 'red receptor' and the 'blue receptor' respond likewise to waves near either end of the spectrum. Thus light of any composition falling upon the eye will throw these three resonators, R , G , and B , into determinate amplitudes of vibration. Their sum, $R + G + B$ defines the brightness, and their ratio $R : B$ defines the colour.

This view, which is essentially what is believed today, is seen not to question Newton's physics but, by taking into account the limited discrimination of the eye, to explain the painter's experience that mixing a few paints will give the whole range of colour. Young's explanation should lead

to a simple and striking result. Every colour (including white) should excite the R , G , and B receptors in a characteristic set of ratios. Consequently, a mixture of red +

green + blue lights, adjusted to produce this same set of ratios, should appear white, or whatever the initial colour was. In 1854 this was systematically tested by James Clerk Maxwell (1831-79), the great physicist, while a student at Trinity College, Cambridge. He showed that every colour can be matched by a suitable mixture of red + green + blue 'primaries', although sometimes it is necessary for the experimenter to mix one of his three primaries with the colour to be matched rather than with the other primaries. This *trichromacy* of vision was confirmed by Hermann von*Helmholtz in Heidelberg

and later measured with spectral lights and great accuracy by W. D. Wright at Imperial College London and independently by W. S. Stiles at the National Physical Laboratory, London.

Visual pigments. What does light do to the photoreceptors of the retina to make them send nerve messages to the brain? Willy Kühne (1837-1900), professor of physiology at Heidelberg, observed in 1877 that a dark-adapted retina removed from a dead frog in dim light and then observed in daylight, was initially pink, but bleached to pale yellow upon exposure to light. This showed that the retina contains a photosensitive pigment, i.e. one that changes its chemical constitution on exposure, as does a photographic film. This pigment, 'visual purple' or 'rhodopsin', is present in the photoreceptors called 'rods' that serve deep twilight vision, which is without colour. Therefore the pigments serving colour vision must lie not in the twilight receptors but in the daylight receptors called 'cones'. And Young was correct in supposing that these are of three types.

Researchers in Cambridge were the first to measure the visual pigments in the living human eye, applying the familiar observation that if at night a cat's eye is caught in the beam of a car's headlamps it shines back with reflected light (Rushton and Campbell, 1954). By knowing the incident light and measuring the reflected light, it is found what light has been absorbed in the eye. And if these measurements are made before and after the visual pigment has been bleached away with strong light, the change in absorption, resulting from the change in amount of visual pigment present, is learnt.

The same measurements may be made in human eyes, though here there is a very black surface behind the retina instead of the cat's shining *tapetum lucidum*. Since the measuring light sent in may not be made very strong (or it will bleach away the pigment that is being measured), the great sensitivity of a photomultiplier tube is needed to measure the faint light that emerges from the eye. Using this technique, it has been possible to measure the spectral sensitivity and kinetics of bleaching and regeneration in the living human eye, first of rhodopsin, then of the red and the green cone pigments. There was never sufficient blue light reflected to measure the blue cone pigment.

This work has been confirmed and extended by Marks, Dobelle, and MacNichol at Johns Hopkins University, Baltimore. They used fresh retinas from monkeys' and human eyes removed at operation, and with superb technique measured the visual pigments in single cones. They found Young's three types of cone and specified the visual pigment in each, confirming the measurements made in Cambridge on living colourblind subjects who possessed only one of the two cone pigments measurable by the Cambridge technique.

Colourblindness. Almost all so-called colour defectives have some appreciation of colour, and generally resent being called colour *blind*. The common defective cannot distinguish well between red and green. This is a hereditary defect, something wrong with a gene carried on one (or rarely both) of the sex chromosomes in the female or on the single active sex chromosome in the male. If in the male the gene is missing or abnormal, colour vision will be defective; and 8 per cent of all males exhibit some defect. But in the female it needs *both* chromosomes to suffer the loss before her defect will show, and of course the probability of the double event is much smaller than that of the single one. In fact only 0.4 per cent of females show some abnormality. Even so, women who are abnormal in only one chromosome, though showing perfect colour vision themselves, have a fifty-fifty chance of

transmitting their weakness to their children; and half their sons will be 'colourblind', since the (normal) father holds his normal gene on the one sex chromosome that will make his child a daughter, and he has none for his sons.

Dichromacy. In the extreme conditions of the redgreen defect, the subject cannot tell red from green and can match every colour of the rainbow exactly with a suitable mixture of only *two* coloured lights, for example red and blue. Such subjects are called dichromats, to distinguish them from ordinary people (trichromats) who need also a green primary if every colour is to be matched.

The cone pigments in the redgreen spectral range of dichromats have been measured by a reflection technique. It has been shown that instead of the red *and* greensensitive cone pigments of normal vision, these subjects have only the red *or* the green. They lack one dimension of colour vision because they lack one kind of cone pigment.

Anomalous trichromacy. The majority of colour defectives are not true dichromats, but anomalous trichromats: like normal subjects, they require three variables in a colourmatching experiment, but the matches they make are different from those of the normal. Thus, in matching a monochromatic Page 154

yellow with a mixture of red and green, some ('protoanomalous') observers require more red than normal in the match, whereas other ('deuteranomalous') observers need more green. Usually, though not necessarily, the abnormality of matching is associated with a reduced capacity for discriminating colours. It is thought that anomalous trichromacy arises when one of the cone pigments is displaced from its normal position in the spectrum.

Adaptation. Newton's physics of colour was inadequate because it did not take into account the selective physiological action of Young's three cone types. We are now on the way to understanding their selectivity and the sort of nerve signals they generate. But though light waves and nerve signals are factors that lead to colour vision, there is still the miracle of how some nerve signals generate a sensation in the mind. This sensation certainly does not depend exclusively upon the $R: G: B$

excitation ratios of the three cone types. We all know how adaptation to any strongcoloured light leaves the eye, as it were, fatigued to the colour so that some extra light of this colour must be added to any presentation if its appearance is to be the same as it was before adaptation. This adaptation is often called 'successive contrast' to distinguish it from the rather similar 'simultaneous contrast', where two differentcoloured objects seen close together have their differences enhanced through their proximity. Some of these effects can be objectively measured by recording from nerves in the visual pathways of animals.

Psychology. Colours are so gay that those with total colour loss cannot but be pitied; and it must be wondered what it is that makes red produce the wonderful red sensation most people perceive. What has been said here explains only what cannot be discriminated, and nothing has been said about how sensations arise from what is seen. Let it be concluded that Newton ended his first paper with these strong words: 'But to determine . . . by what modes or actions light produceth in our minds the

phantasms of colours is not so easie. And I shall not mingle conjectures with certainties.'

COMMON SENSE. The original meaning is a 'common centre', or neural pool into which all the five senses were supposed to contribute to give coherent perceptions, though the various senses are so very different. René*Descartes (1596/1650) used the term *le siège du sens commun* in this way. There is indeed still a problem over the coordination of the senses and just how the different sources of information are pooled (see, for example, SPATIAL COORDINATION OF THE SENSES AND CHANNELS).

Nowadays 'common sense' generally refers to practical attitudes and widely accepted beliefs which may be hard to justify but which are generally assumed to be reliable. Extreme deviations from commonsense beliefs may be evidence of psychological disturbance, but may, on the other hand, be the products of genius, sometimes becoming accepted later as common sense. Thus, although it is now common sense that the earth is round, only a few centuries ago a man believing this might have been regarded as mad.

There is indeed a vast body of unquestioned assumptions which is seldom questioned. Common sense is, however, frequently questioned by philosophers—with a curious ambiguity, for at least linguistic philosophy tends to assume that the 'common sense' of normal language is philosophically significant. This is discussed critically by Ernest Gellner (1979).

Gellner, E. (1979). *Words and Things*. Cambridge.

COMPATIBILISM. Traditionally, those who maintain the truth of determinism and believers in the freedom of the will have been regarded as taking up incompatible positions. Thus from one side it is argued that since all events, including human actions, are causally determined, the belief that we are free is an illusion; from the other side it is argued that we know we are free, and hence universal determinism must be false. Compatibilists maintain that both these arguments are invalid: since a free action is simply one that is not constrained by external forces, there is a perfectly ordinary and proper sense in which we act freely when we do what we want to do;

and the existence of such freedom need not presuppose that determinism is false, or that human beings possess some contracausal power. Defenders of the compatibilist or 'reconciliationist' position have

included Leibniz and Hume. See DETERMINISM AND FREE WILL.

J.O.C.

COMPLEX. In experiments using the association method, C. G. Jung observed that there are stimulus words about which the subject does not think quickly and surely. He attributed this disorder to a concealed cluster of ideas and feelings, which he called a complex, such signs as repetitiveness, uncommonness of the response word, and delay in responding, being complex indicators. He showed also how these may reveal guilt over, say, having stolen. The complex indicators on which the 'liedetector', used in some courts in the USA, depends are the changes, recorded on a polygraph, produced by stimulus words or questions on the electrical resistance of the skin, the pulse rate, and the rate and pattern of respiration (see ELECTRODERMAL ACTIVITY).

The term is also applied to the cluster of child

Page 155

hood fantasies underlying a neurosis. The Oedipus complex has been said to be the 'nucleus complex' in neurosis in males, the Electra complex in females (see INFERIORITY COMPLEX).

COMPULSIONS. See OBSESSIONS AND COMPULSIONS.

COMPUTED TOMOGRAPHY (CT). See IMAGES OF THE BRAIN IN ACTION.

COMPUTER CHESS is pursued in some cases for sport and in others to deepen scientific understanding of the kinds of knowledge that support mental skills. From specialized activities in both the sport and the science category, artificial intelligence scientists have obtained insights of general relevance to cognition and its computer simulation, including topics such as the following. How is a causal model of some problem domain to be exploited in solving particular problems within it? What principles characterize knowledgebased planning? What are the tradeoffs between the use of calculation and the use of stored patterns during problemsolving? Can the fruits of past calculations be turned into summarizing patterns for future use; and can the fruits of past miscalculations also be utilized, and if so how? What are the limits to human codification of a skill, and can these limits be overcome in any way? What makes a pattern-directed representation intelligible, and what makes such a representation also executable 'in the head'?

The properties of chess which make it especially suitable for computer-based approaches to such questions are that the domain can be fully and exactly defined; it overextends the best human intellects; it demands calculation, learning, concept-manipulation, analogical thinking, and long-term

judgement. Moreover master skill at chess is measurable on a universal scale, and over the centuries players and scholars have built a vast incremental literature of chess knowledge, as apprehended and improved by each generation.

In the theory of games chess is a twoperson game with perfect information: both players have full sight of the board and of every move made. It is also zerosum, i.e.

what is good for one player is bad in precisely equal measure for the other. Further, the rule which declares a draw when 50 moves have passed without castling, captures, or pawn moves ensures that the game is finite. The space of legal positions is, however, rather large, having been estimated as exceeding 10 to the power of 46 .

The fraction of these which a chessmaster would regard as capable of occurrence in serious play, and hence meaningful, is infinitesimal. Yet the number of distinct positions contained in that infinitesimal fraction has been estimated as exceeding 10 to the power of 23 . This is still many billion times too many for complete solution by computer search and enumeration. Such an enterprise would also require mechanizable representations of chess meaning, in a language whose most primitive expressions would denote basic features from which the master builds his mental picture of a chess position.

Only a few descriptive clichés of the hypothesized language have been uncovered to date. The 'chunks' involve such relations as mutual defence between pieces, cooperation in attacking a common target, certain types of pawn chain, *characteristic* castledking patterns, and the like. Relevant investigations began a century ago with Alfred*Binet's studies of chess memory in simultaneous blindfold chess, and were extended in the 1940s by Adriaan de Groot's analyses of players of varying strengths, including former world champions, 'thinking aloud' about given positions. More recent work by Herbert Simon and by Jorg Nievergeldt has yielded in addition estimates of the number of chunks, or basic patterns, stored by a master in longterm memory. (See CHUNKING.) This number, thought to lie between 30,000 and 50,000, corresponds to the size of the vocabulary employed by the hypothesized language. Little use has so far been made of studies of chess cognition by the mechanizers, who have mainly been content to apply brute force along lines mapped out, although not particularly recommended, by Claude Shannon in 1950.

Current highwater marks are reviewed below.

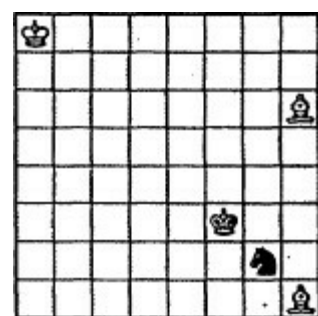

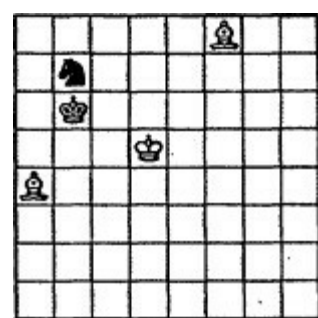

Brute force: tournament play. The first world computer chess championship in 1974 was won by a program authored by M. Donskoy and V. L. Arlazarov of the USSR. It performed at the level of mediocre club play. Programs for playing under tournament conditions have concentrated on wringing the most out of the concurrent rapid advance of computing technology together with the use of shortcut tricks of programming technique (such as 'alphabeta'—see below). The Shannon paradigm of searching large trees of possibilities, guided by simplistic but fast means of evaluating each possibility as it is thrown up, has dominated.

The principle of machine search resembles the strenuous 'thinking ahead' of an ambitious beginner,

enhanced with miraculous speed, completeness and accuracy.

Tens, or even hundreds, of thousands of variations per second are scored for features generally correlated with a position's strength, such as piece scores, mobility, control of centre, king safety, and pawn structure. From the positions located along the furthestmost boundary of the forward search, position values are backed up the levels of the lookahead tree by a method known as minimaxing, until the immediate successors of the position under consideration have received backedup values.

Choice of the highestscoring of these determines the machine move. A refinement of minimax known as alphabeta prun

Page 156

ing almost doubles the depth of analysis obtainable for given computational cost: modern tournament programs regularly search three to four moves ahead (six to eight

'ply'), pursuing capturerecapture or other unstablelooking sequences to as much as twice this depth.

As early established by de Groot, the chess mind follows a diametrically opposite regime. When asked how many moves ahead he looked, the great grandmaster and theorist Richard Reti replied 'One, the right one'. Even in correspondence chess forward calculations are highly selective, pruned and guided by criteria of strategic meaning not yet seriously addressed by the mechanizers.

In 1985 the strongest programs had reached the borderline of international master strength, as judged by their showing in regular human tournaments. When, however, obliged to play the same opponent repeatedly, they tend to fall to the human's ability to learn his enemy's weak points and exploit them. No tournament program of today has the power to learn from experience. Yet the final of the 1985 North American computer chess championship, in which Hans Berliner's 'Hitech' defeated Robert Hyatt's 'Cray Blitz', was recognizably master level. Both programs searched 2030 million lookahead positions per move. The equivalent figure for de Groot's grandmasters was 2030 positions.

Brute force: endgame analysis. Given today's fast processors and large computer memories, exhaustive computation can be performed so as fully to solve and tabulate subgames of chess which are not understood by grandmasters, or even (a taller order) by endgame specialists. The first such feat, by T. Strohle in 1970, fully analysed the fourpiece ending king and rook versus king and knight, thought until then to be in the general case a drawn game. Of the 1,347,906 legal rook's side to move positions (neglecting positions equivalent under rotations and reflections of the board), almost half (651,492) turn out to be winnable by correct (though for the most part protracted) play. The two longest wins are represented by positions 27 moves from checkmate or knight capture. Aided by knowledge that it could be done and by samples of the computer generated material itself, the leading endgame scholar A. J. Roycroft was able to acquire and demonstrate complete mastery of optimal play of positions won for the rook's side (contrast the KBBKN case, below).

Kenneth Thompson has completed exhaustive data bases for all the interesting fourpiece and fivepiece pawnless endings. Of his factual discoveries one of the most spectacular has been the status of king and two bishops versus king and knight (KBBKN), previously believed to be drawable provided that the knight's side can attain the 'Kling & Horwitz' position (Fig. 1a). The position dates from 1851. The verdict that the defending side can draw positions like this (based on the Fig. 1a.

Either side to move.

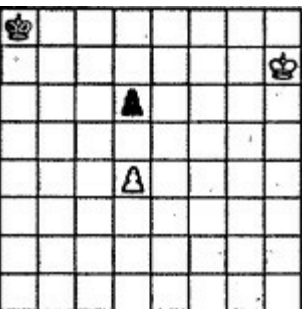

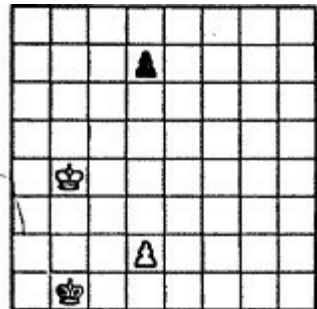

Fig. 1b.

White to move.

placing of the two black men and largely ignoring the white placement) is repeated in all relevant chess endgame textbooks. In 1983 Thompson's exhaustive solution demonstrated the general win of this endgame in at most 66 moves, and the particular win in Kling & Horwitz positions in about 4045 moves. Cases of this kind have led to a growing number of *ad hoc* modifications by the World Chess Federation of the 50move drawing rule.

Not only does the Thompson data base, comprising some two hundred million legal positions, show that the bishops' side can win from all but a few freak starting positions, but its manner of doing so passes the comprehension of the ending's dedicated human students. The critical fourth stage of a 5stage win from the starting position shown in Fig. 1b involves a procedure 'not to be found in any book and characterized by excruciating slowness and mystery' (Roycroft). Moreover, following a year's study by Roycroft and others, involving availability of a variety of computer aids, it seems that human mastery (as opposed to machine mastery) of this ending may never be attainable.

Data bases generated in this style can also be searched for positions which a master or endgame scholar would recognize as 'studies' or 'compositions'. Here a unique winning (or in appropriate cases drawing) line of play must exist, coupled with properties of elegance, surprise, didactic value and

even wit, not easy to define in programming terms. M. R. B. Clarke has conducted selective trawls with some success: two of his discoveries for kingpawn—kingpawn (KPKP) are shown as Figs. 2a and 2b.

Automation of chess knowledge. In addition to purely factual discoveries, computer programs could help the chess expert fill the gaps of which codified chess knowledge is now seen mainly to consist. Knowledgedirected programs can support his endeavours to outline the missing framework and by semiautomatic generation of descriptions from expertsupplied examples to fill empty slots in the framework as it takes shape. Using a technique of Alen Shapiro and Timothy Niblett known as

'structured induction', Shapiro was able to generate a complete humanreadable codification for adjudicating positions in the kingpawn—kingrook ending (pawn's side to move, pawn on a7) where none preexisted. A sidebenefit subsequently extracted from this phenomenon was endowment of the program with the ability to document its own adjudications on demand with explanatory notes.

In the abovementioned work the induction process was fuelled by handsupplied examples. In some other cases success has been reported where the examples have been quarried by the program itself from large precomputed data bases. A recent *de novo* synthesis of knowledge in clinical cardiology by Ivan Bratko and colleagues employed just such an alternation between (i) exhaustive derivation of brute facts from a logical model and (ii) induction from these of an operational theory.

Sparked initially by the chess work, application is beginning to place emphasis on factual compilations as raw materials for automating the codification of new knowledge as a commercial product. The need to better understand the cognitive invariants with which the designer of codification languages must now come to terms is also leading to closer involvement of professional students of mind.

COMTE, AUGUSTE (17981857). French philosopher and sociologist, and the founder of positivism. His main work is *Philosophie Positive* (6 vols., 183042), which was freely translated into English and condensed into three volumes by Harriet Martineau: *The Positive Philosophy of Auguste Comte* (1896).

Comte tried to organize knowledge of society and technology into a consistent whole. He argued that

all human conceptions pass through a theological and then a metaphysical stage, and then into a positive or experiential form. The abstract sciences form a hierarchy, with mathematics at the top, then astronomy, physics, chemistry, biology, and finally sociology. Sociological development is from militarism to industrialism. Positivism is an expression of*humanism, in which there is no deity and the emphasis is entirely on man and on intellectual conceptions of the world and man's place in it.

CONCEPT. An abstraction or general notion that may serve as a unit (or an 'atom') of a theory. Some concepts can be powerful thinking tools even when they are not at all fully understood. Thus even simple concepts or procedures in mathematics

Page 158

(such as 'dividing by x ', or 'taking the square root of x ') allow problems to be solved even though they, or even the questions addressed, are not understood.

Concepts may be more or less clear, and a major part of philosophy is to clarify them. This can be extremely difficult: what is our concept of time—or of mind?

Perhaps most concepts are components of theories or explanations. At least they seem to give fairly direct insight into the nature of things. For example, the astronomer Johannes Kepler's concept of the planets moving in elliptical orbits was essential for*Newton's great synthesis in his *Principia*, which went virtually unchallenged as an account of the universe until Einstein's Special and then General Theory of Relativity. Evidently changes of theory change concepts; and new concepts, or revisions of old ones, can change theories —and so how we understand and see.

In psychology, concepts of mind must be invented or discovered, much as in physics, for we cannot see at all clearly into our own minds by introspection. So we need experiments in psychology; they sometimes suggest concepts far removed from*common sense, or what we *seem* to be like. If we could see 'directly' into our own minds by introspection perhaps we would not need explanatory concepts for understanding at least our own psychologies. But as it is, introspection tells us virtually nothing about how our minds work, or what they or we are. So we need experiments and concepts for psychological understanding. In this way concepts of mind are not so different from concepts of physics, except perhaps for concepts such as purpose: for both underlie appearances and are moreorless helpful tools for thinking and understanding.

CONCUSSION can be defined as a clinical syndrome characterized by immediate and transient impairment of mental functions such as alteration of*consciousness, and disturbance of*vision or equilibrium, due to mechanical forces. Such results follow all but the mildest blows to the head. In the majority of instances loss of consciousness is of short duration, but severe injuries result in periods of unconsciousness varying from hours to weeks or even months. The greater the duration of unconsciousness and the subsequent posttraumatic*amnesia, the greater will be the period of postconcussional disability. Consequently it is important to record the duration of loss of memory

following head injuries, not only as an index of severity but also as a guide to ultimate recovery.

It has been estimated that about 150,000 patients in England and Wales are admitted to hospital each year following head injuries. About 7 per cent of these cases are classed as severe, and the majority of severe cases are the consequences of road traffic accidents. Falls in the home make a significant contribution to the number of elderly cases, and injuries from violent assault have become increasingly common.

The cerebral damage is caused by rotational stresses within the brain, and is likely to be the more severe if the head is in motion at the time of impact. This causes minute haemorrhages and neuronal changes throughout the brain which may be of aetiological importance for the so-called postconcussional syndrome. At the same time it is clear that the principal features of concussion are caused by interference with vital centres in the brainstem. If unconsciousness lasts more than a few hours, it is likely that permanent brain damage has been sustained, with the risk of major psychological disabilities and personality changes that may prevent the patient returning to his former employment or even living equably with his family. The premorbid qualities of the individual will greatly influence his capacity for attaining full recovery, but even the most stable of individuals may suffer to some extent from postconcussional symptoms. These may include headache, dizziness, fatigue, and intolerance of noise, as well as emotional instability and impaired memory and concentration.

Chronic psychological impairment is sometimes seen in professional boxers who have sustained repeated blows to the head without necessarily losing consciousness.

In recent times a good deal of attention has been focused on this 'punchdrunk' syndrome, which has led to proposals that boxing should be banned. This is unlikely to happen but greater protection of the head and face of boxers and medical control of those taking part in the sport may do something to minimize the frequency of punchdrunkenness.

F.A.W.

CONDILLAC, ÉTIENNE DE (1715-80). Born of an aristocratic family at Grenoble, Condillac was a proponent of the philosophy of sensationalism—that all knowledge is based on the senses. He was also one of the first to realize, after the discovery of the retinal image (suggested by the astronomer Johannes Kepler in 1604, and observed in the ox eye by C. Scheiner in 1625), that we do not *see* retinal images (as we see optical images): what we see are external objects. The eye is not like a camera. Retinal images are just one cross-section of the visual channel, and are not objects of perception (except for the special case of looking at the image in another's eye with an ophthalmoscope). Condillac concludes that perceptions are inferences from data from retinal images. This is the basis of current representational theories of perception, following Hermann von Helmholtz, who stressed the importance for perception of 'unconscious inference'.

CONDITIONED REFLEX. See PAVLOV.

CONDITIONING. The rudiments of conditioning are familiar to most people. After experiencing a number of pairings of a signal, for example a tone or light, and a reinforcer, in this case food, Ivan*Pavlov's (1927) dogs came to salivate to the signal much as they did to the food. Similarly, B. F. Skinner's (1938) rats (see SKINNER BOX) would readily perform some action, such as pressing a lever, that procured food.

Clearly, both these behaviours depend upon*learning, in that their development requires the animal to experience a relationship or association between the signal and food in the case of Pavlovian or classical conditioning, and between the action and food in instrumental or operant conditioning. Although the empirical phenomena themselves are not a matter of dispute, the significance of this type of learning is contentious. Traditionally, conditioning represented the cornerstone of the*behaviourist's analysis of learning, but with the increasing focus on*cognition and information processing, the study of this form of learning has been consigned to a backwater of psychology.

The current neglect seems to be based largely upon the assumption that conditioning is a simple, automatic, and unconscious form of learning that underlies the acquisition of relatively trivial behaviour. Following a thorough survey of human conditioning studies, W. F. Brewer (1974) concluded that there was no good evidence for conditioning in human beings. This surprising claim was based not on our failure to show the appropriate behavioural changes, but on the observation that whenever conditioninglike effects occur, we are aware of the association between the signal or action and the reinforcer. Underlying this argument there appears to be the assumption that, by definition, conditioning must be an unconscious process. But neither the empirical effect itself nor its associated terminology imply such an assumption. Pavlov referred to the signal and its associated response as a 'conditional stimulus' and a 'conditional response' respectively, simply because the acquisition of this reaction was conditional or dependent upon having experienced the relationship between the signal and the food. Similarly, the food can be identified as a reinforcer because, at an empirical level, it appears to be an important agent for strengthening, or reinforcing, the conditional response. However, this terminology has undergone a subtle change in the West, so that one now finds statements to the effect that people and animals can be 'conditioned' and 'reinforced'. Obviously such statements are a travesty of the Pavlovian terminology: a person cannot be conditioned or strengthened, at least not by a conditioning experience. These distortions are important, however, for they reveal a fundamental and widespread belief about the nature of conditioning, namely that it is a passive process to which a person or animal is subjected.

The origin of this belief lies not in the conditioning phenomenon itself, but rather with the initial behaviourist explanations of this type of learning. For instance, E.

L.*Thorndike (1911) in his famous 'law of effect' argued that following an action by a reinforcer simply strengthens a connection between the stimuli present when the action is performed and the action itself, so that the action reoccurs as a response to these stimuli when they are again presented. This stimulus-response theory has at least two features that bolster the idea that conditioning is a simple and passive process. First, the conditions for learning, and by implication the process underlying such learning, appear simple: in essence, successful conditioning depends just upon the temporal contiguity between the response and reinforcer. Secondly, a conditional response occurs because it is automatically elicited by the appropriate conditional stimulus. Thus, a trained rat presses the lever not because it knows about the relationship between its action and the occurrence of the reinforcer, but rather because the sight of the lever automatically triggers leverpressing. Both these claims turn out to be incorrect on further analysis.

It is a relatively easy matter to show that instrumental conditioning does not necessarily establish a simple habit released by the appropriate stimulus. Stimulus-response theory, by denying the animal any knowledge about the consequences of its actions, implies that conditional behaviour, once established, should be insensitive to any subsequent changes in the value of the reinforcer. We can test this claim by training an animal to perform an action for a particular food before devaluing the food, for example, by establishing quite separately an aversion to the food. This is readily done by inducing nausea shortly after consuming the food. If we now give the animal the opportunity to perform the action that had previously procured the food, stimulus-response theory would anticipate that the vigour of the action should be unaffected by the devaluation of the reinforcer. Not surprisingly, however, the animal is reluctant to perform this action (Adams and Dickinson, 1981), indicating that simple instrumental conditioning reflects the acquisition of knowledge about the relationship between an action and the occurrence of the reinforcer rather than establishing a reflexively elicited habit. The deployment of this knowledge in controlling behaviour can then be modified by other relevant information, such as the current value of the reinforcer. Given this perspective, instrumental conditioning can be seen to represent a relatively simple procedure for investigating learning about the consequences of our actions and general purposive and goal-directed behaviour.

Just as our view of the knowledge underlying conditioning has changed from that specified by Thorndike's 'law of effect', so have our theories about the conditions for the acquisition of this knowledge. The 'law of effect' states that simple

Page 160

temporal contiguity between an action and a reinforcer is sufficient for instrumental conditioning, and Pavlov himself argued that a classical conditional stimulus also acquires its properties as a result of contiguous pairings with a reinforcer. It has long been recognized that a system sensitive only to temporal contiguity would often fail to distinguish real causal and predictive relationships from purely fortuitous and coincidental conjunctions, and thus be prone to the development of superstitious beliefs and behaviour. It is now clear, however, that the conditioning mechanisms embody a number of subtle and complex processes designed to counteract the formation of superstitions. For instance, conditioning depends not only upon the temporal relationship between the conditional stimulus or action and the reinforcer, but also upon whether or not the occurrence of the reinforcer is surprising

or unexpected. The role of surprise is demonstrated by L. J. Kamin's (1969) 'blocking effect'. If an animal receives conditioning trials in which a conditional stimulus, A, is paired with a reinforcer, it will subsequently show little conditional responding to a second stimulus, X, when a compound of A and X is reinforced. In the initial stage the animal learns to expect the reinforcer following stimulus A, so that its subsequent presentation following the AX compound is fully predicted by stimulus A and hence unsurprising. As a result, minimal conditioning accrues to stimulus X. Conversely, if stimulus A is initially established as a predictor of the nonoccurrence of the reinforcer, the presentation of the reinforcer following the AX compound is very surprising and leads to enhanced conditioning to stimulus X (Rescorla, 1971). This sensitivity to the surprisingness of the reinforcer will serve to protect us and other animals against the formation of superstitious beliefs and behaviour. Effectively, the conditioning mechanism appears to embody an assumption of minimum sufficient causation;

an animal is less likely to attribute the contiguous occurrence of a reinforcer to the presence of a stimulus or the execution of an action if another adequate cause or signal for this reinforcer is also present.

In conclusion, the contemporary view of conditioning is considerably more complex and subtle than that expounded by the early behaviourists. We should not overplay, however, the importance of conditioning as a general model for all learning. There are many examples of nonassociative learning that lie outside the scope of conditioning theory. Even so, conditioning studies appear to reveal universal mechanisms by which we and other animals intuitively detect and store information about the causal structure of our environment.

CONFUCIAN IDEAS OF THE MIND. See CHINESE IDEAS OF MIND.

CONSCIOUSNESS is both the most obvious and the most mysterious feature of our minds. On the one hand, what could be more certain or manifest to each of us than that he or she is a subject of experience, an enjoyer of perceptions and sensations, a sufferer of pain, an entertainer of ideas, and a conscious deliberator? On the other hand, what in the world can consciousness be? How can physical bodies in the physical world contain such a phenomenon? Science has revealed the secrets of many initially mysterious natural phenomena— magnetism, photosynthesis, digestion, even reproduction— but consciousness seems utterly unlike these. For one thing, particular cases of magnetism or photosynthesis or digestion are in principle equally accessible to any observer with the right apparatus, but any particular case of consciousness seems to have a favoured or privileged observer, whose access to the phenomenon is entirely unlike, and better than, anyone else's, no matter what apparatus they may have. For this reason and others, not only have we so far no good theory of consciousness, we lack even a clear and uncontroversial pretheoretical description of the presumed phenomenon. Some have gone so far as to deny that there is anything for the term to name.

The mere fact that such a familiar feature of our lives has resisted for so long all attempts to characterize it suggests that our conception of it is at fault. What is needed is not just more evidence, more experimental and clinical data, but a careful rethinking of the assumptions that lead us to suppose there is a single and familiar phenomenon, consciousness, answering to all the descriptions licensed by our everyday sense of the term. Consider the baffling questions that are inevitably raised whenever one turns one's attention to consciousness. Are other animals conscious? Are they conscious in the same way we are? Could a computer or robot be conscious? Can a person have unconscious thoughts, or unconscious pains or sensations or perceptions? Is a baby conscious at or before birth? Are we conscious when we dream? Might a human being harbour more than one conscious subject or ego or agent within one brain? Certainly good answers to these questions will

Page 161

depend heavily on empirical discoveries about the behavioural capacities and internal circumstances of the various problematic candidates for consciousness, but about every such empirical finding we can ask: what is its bearing on the question of consciousness, and why? These are not directly empirical but conceptual questions, and answering them is not an alternative or competitor to answering the empirical questions, but an essential preliminary—or at least accompaniment.

Our ordinary concept of consciousness seems to be anchored to two separable sets of considerations that can be captured roughly by the phrases 'from the inside'

and 'from the outside'. *From the inside*, our own consciousness seems obvious and pervasive: we know that much goes on around us and even inside our own bodies of which we are entirely unaware or unconscious, but nothing could be more intimately known to us than those things of which we are, individually, conscious. Those things of which I am conscious, and the ways in which I am conscious of them, determine *what it is like to be me*. I know in a way no other could know what it is like to be me. From the inside, consciousness seems to be an allornothing phenomenon—an inner light that is either on or off. We grant that we are sometimes drowsy or inattentive, or asleep, and on occasion we even enjoy abnormally heightened consciousness, but when we are conscious, *that* we are conscious is not a fact that admits of degrees. There is a perspective, then, from which consciousness seems to

be a feature that sunders the universe into two strikingly different kinds of things: those that have it and those that do not. Those that have it are *subjects*, beings to whom things can be one way or another, beings it is like something to be. It is not like anything at all to be a brick or a pocketcalculator or an apple. These things have insides, but not the right sort of insides—no inner life, no point of view. It is certainly like something to be me (something *I* know 'from the inside') and almost certainly like something to be you (for you have told me, most convincingly, that it is the same with you), and probably like something to be a dog or a dolphin (if only they could tell us!), and maybe even like something to be a spider.

When one considers these others (other folk and other creatures), one considers them perforce *from the outside*, and then various of their observable or determinable features strike us as relevant to the question of their consciousness. Creatures react discriminatively to events within the scope of their senses: they recognize things, avoid painful circumstances, learn, plan, and solve problems. They exhibit*intelligence. But putting matters this way might be held to prejudge the issue. Talking of their 'senses' or of 'painful' circumstances, for instance, suggests that we have already settled the issue of consciousness—for note that if I had described a robot in those terms, the polemical intent of my choice of words would have been obvious (and resisted by many). How do creatures differ from robots, real or imagined? They are organically and biologically similar to *us*, and we are the paradigmatic conscious creatures. This similarity admits of degrees, of course, and one's intuitions about which sorts of similarity count are probably untrustworthy. Dolphins' fishiness subtracts from our conviction, but no doubt should not. Were chimpanzees as dull as seaslugs, their facial similarity to us would no doubt nevertheless favour their inclusion in the charmed circle. If houseflies were about our size, or warmblooded, we'd be much more confident that when we plucked off their wings they felt pain (*our* sort of pain, the kind that matters). What makes us think that some such considerations ought to count and not others?

The obvious presumption is that the various 'outside' indicators are more or less reliable signs or symptoms of the presence of that whateveritis each conscious subject knows from the inside. But how could this be confirmed? This is the notorious 'problem of other minds'. In one's own case, it seems, one can directly observe the coincidence of one's inner life with one's outwardly observable talents for perceptual discrimination, introspective avowal, intelligent action, and the like. But if each of us is to advance rigorously beyond solipsism, we must be able to do something apparently impossible: confirm the coincidence of inner and outer in others. Their *telling us* of the coincidence in their own cases will not do, officially, for that gives us just more coincidence of outer with outer: perceptual capacities and so forth normally go hand in hand with capacities for 'introspective' avowal. If a cleverly designed robot could (seem to) tell us of its inner life (could utter all the appropriate noises in the appropriate contexts), would we be right to admit it to the charmed circle? We might be, but how could we ever tell we were not being fooled? Here the question seems to be: is that special inner light really turned on, or is there nothing but darkness inside? And this question looks unanswerable. So perhaps we have taken a misstep already.

My use of 'we' and 'our' in the last paragraph, and your unworried acquiescence in it, reveals that we don't take the problem of other minds seriously—at least for ourselves and the human beings with whom we normally associate. The temptation then is to decide that, in so far as there is a serious,

coherent question yet to be answered about the imagined robot (or about some problematic creature), it will turn out to be answerable by straightforward empirical means once we have better theories of the organization of our brains and their role in controlling our behaviour. This is to suppose that somehow or other the facts we individually get 'from the inside' reduce to facts publicly obtainable from the outside. That is to say, enough of the right sort of outside facts *will settle* the question of whether or not some creature is conscious. For instance, a recent attempt to define consciousness in objective terms is E. R. John's: Page 162

a process in which information about multiple individual modalities of sensation and perception is combined into a unified multidimensional representation of the state of the system and its environment, and integrated with information about memories and the needs of the organism, generating emotional reactions and programs of behavior to adjust the organism to its environment ... (Thatcher and John, 1977, p. 294).

Determining that this internal process occurs in a particular organism is presumably a difficult but clearly empirical task. Suppose that with regard to some creature it were completed successfully: the creature is, by this account, conscious. If we have understood the proposal correctly, we will not find any room to wonder further.

Reserving judgement here would be like being shown in detail the operations of an automobile engine and then asking, 'But is it *really* an internal combustion engine?

Might we not be deluded in thinking it was?'

Any proper scientific account of the phenomenon of consciousness must inevitably take this somewhat doctrinaire step of demanding that the phenomenon be viewed as objectively accessible, but one may still wonder if, once the step is taken, the truly mysterious phenomenon will be left behind. Before dismissing this sceptical hunch as the fancy of romantics, it would be wise to consider a striking revolution in the recent history of thinking about the mind, a revolution with unsettling consequences.

For John*Locke and many subsequent thinkers, nothing was more essential to the mind than consciousness, and more particularly selfconsciousness. The mind in all its activities and processes was viewed as transparent to itself; nothing was hidden from its inner view. To discern what went on in one's mind, one just 'looked'—one

'introspected'—and the limits of what one thereby found were the very boundaries of the mind. The notion of *unconscious* thinking or perceiving was not entertained, or, if it was, it was dismissed as incoherent, selfcontradictory nonsense. For Locke, indeed, there was a serious problem of how to describe all one's memories as being continuously in one's mind, when yet they were not continuously 'present to consciousness'. The influence of this view has been so great that when Sigmund*Freud initially hypothesized the existence of unconscious mental processes, his proposal met widely with stark denial and incomprehension. It was not just an outrage to common sense, but even selfcontradictory, to assert that there could be unconscious beliefs and desires, unconscious feelings of hatred, unconscious schemes of selfdefence and retaliation. But Freud won converts. This

'conceptual impossibility' became respectably thinkable by theorists once it was seen that this way of thinking permitted one to explain otherwise inexplicable patterns of psychopathology. The new way of thinking was also supported by a crutch: one could cling to at least a pale version of the Lockian creed by imagining that these 'unconscious' thoughts, desires, and schemes *belonged to other selves* within the psyche. Just as I can keep my schemes secret from you, my id can keep secrets from my ego. By splitting the subject into many subjects, one could preserve the axiom that every mental state must be someone's conscious mental state, and explain the inaccessibility of some of these states to their putative owners by postulating other interior owners for those states. This move was usefully obscured in the mists of jargon so that the weird question of whether it was like anything to be a superego, for instance, could be kept at bay.

It is easy to speculate, but hard to confirm, that Freud's expansion of the bounds of the thinkable was a major precondition for a much more pervasive, and much less controversial, style of theorizing in experimental, and especially cognitive, psychology in recent years. We have come to accept without the slightest twinge of incomprehension a host of claims to the effect that sophisticated hypothesis testing, memory searching inference—in short, information processing—occurs within us even though it is entirely inaccessible to introspection. It is not repressed unconscious activity of the sort Freud uncovered, activity driven out of the 'sight' of consciousness, but just mental activity that is somehow beneath or beyond the ken of consciousness altogether. Freud claimed that his theories and clinical observations gave him the authority to overrule the sincere denials of his patients about what was going on in their minds. Similarly the cognitive psychologist marshals experimental evidence, models, and theories to show that people are engaged in surprisingly sophisticated reasoning processes of which they can give no introspective account at all. Not only are minds accessible to outsiders; some mental activities are more accessible to outsiders than to the very 'owners' of those minds!

In the new theorizing, however, the crutch has been thrown away. Although the new theories abound with deliberately fanciful homuncular metaphors—with subsystems sending messages back and forth, asking for help, obeying, and volunteering—the actual subsystems are deemed to be unproblematically *nonconscious* bits of organic machinery, as utterly lacking in a point of view or inner life as a kidney or kneecap. (Certainly the advent of 'mindless' but 'intelligent' computers played a major role in this further dissolution of the Lockian view.)

But now Locke's extremism has been turned on its head; if, before, the very idea of unconscious mentality seemed incomprehensible, now we are losing our grip on the very idea of *conscious* mentality. What is consciousness *for*, if perfectly unconscious, indeed subjectless, information processing is in principle capable of achieving all the ends for which conscious minds were supposed to exist? If theories of cognitive psychology can be true of us, they could also be true of zombies, or robots, and the theories seem to have no way of distinguishing us. How could any amount of mere

Page 163

subjectless information processing (of the sort we have recently discovered to go on in us) add up to or create that special feature with which it is so vividly contrasted? For the contrast has not disappeared. Karl*Lashley once provocatively suggested that 'no activity of the mind is ever

conscious', by which he meant to draw our attention to the inaccessibility of the processing that we know must go on when we think. He gave an example: if asked to think a thought in dactylic hexameter, most of us can readily oblige; but how we do it, what goes on in us to produce the thought, is something quite inaccessible to us. Lashley's remark might seem at first to herald the demise of consciousness as a phenomenon for psychological study, but its true effect is just the opposite. It draws our attention unmistakably to the *difference* between all the unconscious information processing—without which, no doubt, there could be no conscious experience—and the conscious thought itself, which *is* somehow directly accessible. Accessible to what or to whom? To say that it is accessible to some subsystem of the brain is not yet to distinguish it from the unconscious activities and events which are also accessible to various subsystems of the brain. If some particular and special subsystem deserves to be called the *self*, this is far from obvious. What feature of its particular traffic with the rest of the nervous system would make it a thing it was like something to be?

Strangely enough, this problem is the old chestnut, the problem of other minds, resurrected as a serious problem now that psychology has begun to analyse the human mind into its functional components. This comes out most graphically in the famous splitbrain cases. (For details, see SPLITBRAIN AND MIND.) There is nothing very problematic in granting that the people who have undergone severing of the corpus callosum have two somewhat independent minds. It is not problematic because we have grown used to thinking of a person's mind as an organization of communicating subminds. Here the lines of communication have simply been cut, rendering the mindlikeness of the individual parts particularly salient. But what remains entirely problematic is whether both subminds 'have an inner life'. One view is that there is no reason to grant (full, 'innerlife') consciousness to the nondominant hemisphere, since all that has been shown is that that hemisphere, like many other unconscious cognitive subsystems, can process a lot of information and intelligently control some behaviour. But then we may ask what reason there then is to grant consciousness to the dominant hemisphere, or even to the whole intact system in a normal person. We had thought that question was frivolous and not worth discussing, but this avenue forces us to take it seriously again. If, on the other hand, we grant full, 'innerlife' consciousness to the nondominant hemisphere (or, more properly, to the newly discovered *person* whose brain is the nondominant hemisphere), what will be said about all the other informationprocessing subsystems posited by current theory? Is the Lockian crutch to be taken up again, at the expense of populating, quite literally, our heads with hosts of subjects of experience?

Consider, for example, the striking discovery by J. R. Lackner and M. Garrett of what might be called an unconscious channel of sentence comprehension. In dichotic listening tests, subjects listen through earphones to two different channels, and are instructed to *attend* to just one channel. Typically they can report with great accuracy what they have heard through the attended channel, but can say little about what was going on concomitantly in the unattended channel. Thus, if the unattended channel carries a spoken sentence, the subjects typically report that they heard a voice, and even a male or female voice. Perhaps they even have a conviction about whether the voice was speaking in their native tongue, but they cannot report what was said. In Lackner and Garrett's experiments, subjects heard ambiguous sentences in the attended channel, such as 'He put out the lantern to signal the attack'.

In the unattended channel one group of subjects received disambiguating input (e.g. 'He extinguished the lantern'), while another group had neutral or irrelevant input. The former group could not report what was presented through the unattended channel, but they favoured the suggested reading of the ambiguous sentences significantly more than the control group did. The influence of the unattended channel on the interpretation of the attended signal can be explained only on the hypothesis that the unattended signal is processed all the way to a semantic level—that is, the unattended signal is comprehended—but this is apparently unconscious sentence comprehension! Or should we say it is evidence of the presence in the subjects of at least two different and only partially communicating consciousnesses? If we ask the subjects what it was like to comprehend the unattended channel, they will reply, sincerely, that it was not like anything to them—they were quite unaware of that sentence. But perhaps, as is often suggested about the splitbrain patients, there is in effect someone else to whom our question ought to be addressed: the subject who consciously comprehended the sentence and has relayed a hint of its meaning to the subject who answers our questions. (See also ATTENTION; SUBLIMINAL PERCEPTION.) Which should we say, and why? We seem to be back to our unanswerable question, which suggests we should find a different way of looking at the situation. Let us then entertain the hypothesis that what we had taken to be one phenomenon is actually two quite different phenomena: the sort of consciousness that is intrinsically connected to the capacity to say in one's natural language what is going on; and the sort of consciousness that is just a matter of intelligent information processing. On this proposal, adding the capacity to make 'introspective reports' *changes the phenomenon*, so when we wonder what a dolphin or dog could tell us, or what a nondominant hemisphere could tell

Page 164

us, if only they could talk, we are wondering about a radically different phenomenon from the phenomenon that exists in the absence of such a linguistic capacity.

It is a familiar theme in discussions of consciousness that human consciousness is somehow tied to our capacity for language, and is quite different from animal consciousness. Developing this idea in a cognitivist model of linguistic production and comprehension should clarify the conditions of this dependence of human consciousness on language. Of course many perplexities must be confronted along the way. How should we conceive of the gradual acquisition of language by children (or chimpanzees, perhaps!—see PRIMATE LANGUAGE), and what should we say about the 'experience' (conscious or unconscious) of the preverbal Helen Keller? A theory of consciousness that does justice to the variety of complications will almost certainly demand of us a revolution in our habits of thought about these issues, but we have already partially absorbed the first shocks of that revolution in the overthrow of the Lockian vision of the transparent mind.

THEBODY EXPERIENCES; PSYCHOPHARMACOLOGY.

CONSCIOUSNESS AND CAUSALITY. The difference between mind and matter and how the two interrelate has challenged and baffled human understanding ever since man first began to reflect on his nature and the meaning of existence. The common, naive impression that we use the mind to initiate and control our physical actions has long been rejected almost universally in science, following the doctrine of scientific materialism, which predicates that a full account of brain, behaviour, and reality is possible in terms purely physical without reference to conscious, mental, or subjective agents. The more progress neuroscience achieved in explaining the electrophysiology, chemistry, and anatomy of brain activity, the greater became the apparent dichotomy between mind and brain, and the more inconceivable that the course of brain function could be influenced in any way by the subjective qualities of inner experience.

In the 1950s materialistic philosophy was carried to a new extreme in the so-called 'psychophysical (or mindbrain) identity theory'. By involved semantics it was affirmed that no difference exists at all between mind and brain, that they are one and the same, and only seem like two different things because we have used different languages and perspectives in our objective and subjective descriptions. According to this identity theory, there is no mindbrain relation; only a pseudoproblem remains that allegedly can be resolved with a proper linguistic approach. The materialist position as developed through the late 1960s was expressed by D. M.

Armstrong, a leading proponent, as 'the view that we can give a complete account of man in purely physicochemical terms', in a 'purely electrochemical account of the workings of the brain'. 'The mind is nothing but the brain.' 'Life is a purely physicochemical phenomenon.' 'It seems that man is nothing but a material object having none but physical properties.' (Armstrong, 1968). The accepted superfluosness of consciousness for neuroscience was expressed by Nobel laureate Sir John Eccles in 1964:

We can, in principle, explain all our inputoutput performance in terms of activity of neuronal circuits; and consequently, consciousness seems to be absolutely unnecessary! ... as neurophysiologists we simply have no use for consciousness in our attempts to explain how the nervous system works.

In direct reaction against the materialist view, a modified, mentalistic concept of consciousness and

the mindbrain relation emerged in the mid 1960s. In the course of attempts to account for the observed unity and/or duality of conscious experience following surgical disconnection of the cerebral hemispheres (see SPLITBRAIN

AND MIND), favour was given to an interpretation of conscious mind in which subjective unity and subjective meaning generally were conceived to be primarily operational or functional derivatives. It was posited that a brain process acquires subjective meaning by virtue of the way it operates in the context of brain dynamics, not because it is a neural copy, transform, or an isomorphic or topological representation of the imagined object. This operational concept of subjective meaning necessarily involved a functional, and therefore *causal*, impact of subjective phenomena in the dynamics of brain control. Conscious phenomena were interpreted to be dynamic emergent properties of brain activity. The subjective phenomena by definition were 'different from, more than, and not reducible to' the neural mechanisms of which they are built.

The neural infrastructure of any brain process mediating conscious awareness is composed of elements within elements and forces within forces, ranging from subnuclear and subatomic particles at the lower levels upward through molecular, cellular, and simple to complex neural systems. At each level of the hierarchy, elements are bound and controlled by the enveloping organizational properties of the larger systems in which they are

embedded. Holistic system properties at each level of organization have their own causal regulatory roles, interacting at their own level and also exerting downward control over their components, as well as determining the properties of the system in which they are embedded. It is postulated that at higher levels in the brain these emergent system properties include the phenomena of inner experience as high order emergents in the brain's hierarchy of controls.

Interpreted as holistic high level dynamic properties, the mental phenomena are conceived to control their component biophysical, molecular, atomic, and other subelements in the same way that the organism as a whole controls the course and fate of its separate organs and cells, or just as the molecule as an entity carries all its component atoms, electrons, and other subatomic and subnuclear parts through a distinctive timespace course in a chemical reaction. As is the rule for part-whole relations, a mutual interaction between the neural and mental events is recognized: the brain physiology determines the mental effects, as generally agreed; but also the neurophysiology, at the same time, is reciprocally governed by the higher subjective properties of the enveloping mental events. These interact at their own level and correspondingly move their subsidiary constituents in brain processing. Although determined in part by the properties of their neural components, the subjective properties are also determined by the spacing and timing of the components. Thus the critical, multinested spacetime pattern properties of the neuronal infrastructure, as well as the mass-energy elements, must also be included in the causal account.

The resultant mindbrain model, in which mind acts on brain and brain acts on mind, is classified as being 'interactionist' in contrast to mindbrain 'parallelism' or mindbrain 'identity'. The term 'interaction', however, is not the best for the kind of relationship envisaged, in which mental phenomena are described as primarily *supervening* rather than *intervening*, in the physiological

process. Mind is conceived to move matter in the brain and to govern, rule, and direct neural and chemical events without interacting with the components at the component level, just as an organism may move and govern the timespace course of its atoms and tissues without interacting with them.

In the revised mindbrain model consciousness becomes an integral working component in brain function, an autonomous phenomenon in its own right, not reducible to electrochemical mechanisms. Exerting top-level causal influence in the direction and control of behaviour, the conscious mind is no longer something that can be ignored in objective neuroscience wherever an explanation of conscious activity is concerned. Subjective experience is given a use and reason for being as having a central, ineliminable causal role in brain function. A rationale is thus provided for the evolution of mind in a physical world.

The new mentalist view of consciousness as causal stands in direct opposition to the founding precepts of the behaviourist-materialist philosophy. The two explanatory frameworks are diametrically opposed and mutually exclusive. During the 1970s in the so-called 'consciousness' or 'mentalist' revolution (referred to also as the

'cognitive', 'humanist', or 'third' revolution) the new mentalist interpretation gained acceptance over behaviourism as the dominant paradigm of psychology. The shift from behaviourism to mentalism, or cognitivism, represents a shift to a fundamentally different form of causal determinism. The traditional microdeterminism of the materialist-behaviourist era emphasizing causal control from below upward, gave way to a paradigm in which primacy is given to emergent top-down control, exerted by the higher, more evolved forces in nature over the less evolved. In the brain this means a downward control of the mental over the neuronal. However, the principle of emergent downward control (referred to also as 'emergent interaction' or 'emergent determinism') applies, to all hierarchic systems in all science.

The new mentalism, combining tenets from previously conflicting views, tends to reconcile polar opposites of the past such as mind and matter, the physical and metaphysical, determinism and free choice, as well as 'is' and 'ought' and fact and value, in a unifying view of mind, brain, and man in nature. The new position appears metaphysical in its recognition of mental events as realities existing in their own form different from neural events, in endowing subjective phenomena with causal influence and in placing mind in a control role above matter in the brain. At the same time, the interpretation appears to be materialistic in defining mental phenomena as being built of physical elements and being inseparable from the neural substrate. Because it is neither traditionally dualistic nor physicalistic, the new mentalist paradigm is taken to represent a distinct third philosophic position. It is emergentist, functionalist, interactionist, and monistic.

In the new mentalist terms, science no longer postulates that all operations of the brain and behaviour are determined mechanistically or physiochemically as in traditional materialist philosophy. Although the neuroelectrochemical mechanisms sustain and help determine any given course of action, the choice of action is determined largely at higher levels by conscious mental events. Willed choice involves the causal influence of subjective value priorities wherein one's personal wishes, feelings, and other *mental* factors override the subsidiary forces of the neural substructure. In other words we

do what we *subjectively wish* to do. Freewill decisions are still caused or determined in the new scheme but acquire degrees of freedom and of selfcontrol far above those of classic mechanistic determinism.

The shift of the 1970s in the scientific status and treatment of conscious experience carries far

Page 166

ranging philosophic and humanistic, as well as scientific, implications. The mind has been restored to the brain of experimental science. The qualitative, colourful and valuerich world of inner experience, long excluded from the domain of science by behaviouristmaterialist doctrine, has been reinstated. The subjective is no longer outside the mainstream of objective science, nor something that will eventually be reducible in principle to neurophysiology. A logical determinist framework is provided for those disciplines that deal directly with subjective experience such as cognitive, clinical, and humanistic psychology. Scientific theory has become squared finally with the impressions of common experience: we do in fact use the mind to initiate and control our physical actions.

CONTINGENT PERCEPTUAL AFTEREFFECT. A distortion occurring after prolonged sensory stimulation by alternating patterns. While there are early reports of effects which with hindsight we can see were contingent aftereffects, there has been a growth in interest due to a paper published by Celeste McCollough in 1965.

She presented human subjects with two alternating visual patterns: a grating of blue and black vertical stripes, and a grating of orange and black horizontal stripes.

After her subjects had gazed at these alternating, adapting patterns for a few minutes (and so adapted to them), they were shown a test field of black and white stripes of the same size. In one part of the field the stripes were vertical, in the other horizontal. However, to the subjects the stripes did not

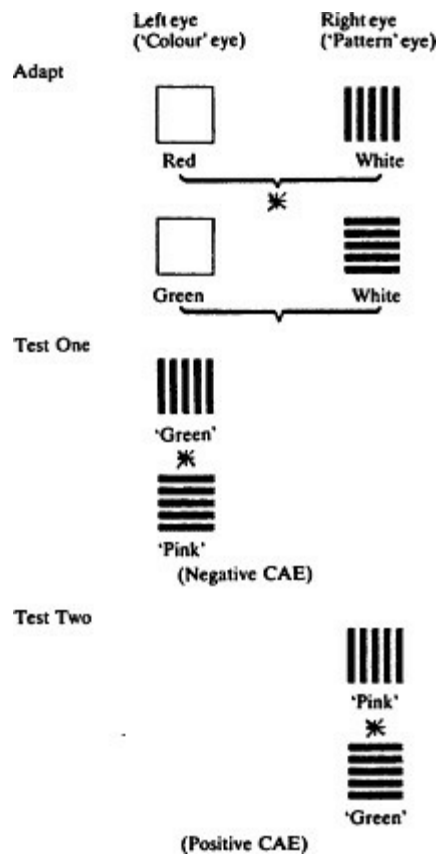

appear black and white: where vertical they appeared pinkish and where horizontal they appeared bluish. This is now called the 'McCollough effect'.

Such effects are different from simple*afterimages produced by staring at a bright, coloured surface. If one looks for half a minute or so at an unpatterned red field, for a few moments all subsequently viewed white objects will appear tinged with green. But in the McCollough effect, although the perceived colours are also the approximate complementaries of the adapting colours, they depend (or are contingent) upon the orientation of the stripes of the adapting and test fields. It is the orientation with respect to the retina which is important. McCollough's subjects were adapted and tested with their heads upright; but if while looking at the test field they tilted their heads sideways, by 45 degrees, the apparent colours disappeared, even though the stripes in the test field still looked horizontal and vertical. If they tilted their heads through 90 degrees the effects reappeared, though now the stripes which had appeared pinkish with the head vertical appeared bluish, and vice versa.

Interest in the McCollough effect, and related effects, has generated a large volume of research. It is worth asking why. The original interpretation of the effects seems to have been right for the *Zeitgeist* of the late 1960s. It was becoming clear from the discoveries of the neurophysiologists that cells in the visual cortex of the brains of cats and monkeys are specialized to respond to rather specific features of the sensory input. Aftereffects seemed to suggest a similar organization in man. For example, the movement aftereffect (apparent motion of a stationary field in one direction, following prolonged viewing of real motion in the other) is consistent with the idea that there are specific*channels sensitive to particular directions of motion, whose outputs are reduced by prolonged stimulation and are compared to give perceived motion. The McCollough effect, as a complicated aftereffect, might reveal how the human brain processes more complex patterns. This hope has, however, not been realized. Contingent aftereffects have revealed little about how a face is recognized. Like other aftereffects they seem to tell us only about the organization of early stages of visual processing.

Many other contingent aftereffects (or CAEs) have been discovered since Celeste McCollough's original report. For example, coloured aftereffects can be made contingent on the width of stripes, as well as on their orientation. Another effect, reported by H. J. Wyatt, is the size aftereffect contingent upon orientation. After adaptation to coarse horizontal stripes, alternating with fine vertical stripes, medium stripes appear fine when horizontal, and coarse when vertical.

There are several ways for finding out where in the brain a particular effect is occurring (see Julesz, 1971, for a discussion of them). One trick is to induce a visual effect with one eye, and then see if it can be obtained with the other eye. For example, for the aftereffect of movement: if one gazes for a time with one eye at a moving display, which is then stopped, the now stationary display will appear to move in the opposite direction—and this apparent motion can be seen not only with the eye which inspected the moving display but also with the other eye, when the adapted eye is closed. This phenomenon is known as interocular transfer. It implies (provided there is no activity from the closed eye) that the anatomical site of the aftereffect lies at a point at or after the combination of the two optic tracts. Some CAEs transfer between the eyes; for example, the movement aftereffect contingent on the orientation of a superimposed

Page 167

grating. However, the McCollough effect exhibits little, if any, transfer. It used to be thought that it was a purely monocular effect, whose site lay peripheral to binocular combination; but more recent studies have found evidence for binocular effects. One way to do this is to divide up colour and pattern information between the eyes so that, instead of coloured gratings, the subject sees a plain coloured field with, say, his left eye, and a black and white grating with his right eye. The alternate adapting stimulus used is another colour, seen by his left eye, and a grating at 90 degrees to the first, seen by his right eye. (These adapting conditions are shown diagrammatically in Fig. 1.) McCollough effects are then found, but they are of opposite sign in each eye. So when the subject views the test field with the eye that has seen colour, the perceived colours are the complementary colours to those paired with a particular orientation during adaptation. This is the normal relationship between the colours seen during adaptation and those which appear during testing. But, when the eye which has adapted to black and white stripes is tested, the perceived colours are the same as those with which that orientation was paired during the adaptation. Here the normal relationship is reversed. Perhaps when the left eye is flooded with green light while the right sees a black and white grating, the visual system treats the colour input as 'left eye greener than right'. At any rate, the apparently simple scheme suggested by the early interocular transfer results has now been complicated by such later work.

Although most work on contingent aftereffects has been done in vision, they can be found in other sensory modalities such as touch. For example, contingent tactile adaptation can be obtained with a wedged shaped block of wood, held with the tips of forefinger and thumb. If your hand moves from left to right as the finger and thumb slide from the thick to the thin end of the wedge, then, after some moments of sliding the hand right to left, and left to right, a rectangular block of wood will feel deformed. As the finger and thumb of the adapted hand are moved from left to right the block will feel

to be getting thicker, and for the reverse direction of movement it will seem to be getting thinner. Here the tactile adaptation is dependent upon the direction of movement of the hand.

Although it is easy to generate CAEs within several (perhaps all) sensory modalities, no one has succeeded in generating CAEs across modalities. For example, the author failed to find a coloured aftereffect contingent upon the frequency of sound, after staring at a red field while listening to a high tone, and alternating with a green field accompanied by a low tone. Absence of crossmodal links suggests that the underlying mechanisms lie peripheral to the site(s) where information from different modalities is combined. However, although vision and hearing have not been linked, different parts of the visual field will cooperate to give CAEs. For example, Michael

Fig. 1.

Diagrammatic representation of the dichoptic induction

of the McCulloch effect, reported by D. M. and

V. MacKay. During adaptation, the subject's left eye

always sees colour, and his right eye always sees black

andwhite stripes. The colour and stripe orientations are

systematically paired so that, say, red and vertical are

always seen together, though by different eyes, and

similarly green and horizontal. The pairs of stimuli

alternate every 10 seconds or so during adaptation. To test for

an aftereffect, the subject views a blackandwhite grating

with one eye. if this is the eye that is adapted to colour, the

aftereffects are negative, but if it is the eye that is adapted

to the gratings the aftereffects are positive.

Potts and the author found that a movement aftereffect contingent on colour can be obtained when the coloured adapting stimuli are not superimposed on, but surround the moving stimuli, so that no area of retina sees coloured moving patterns. This suggests some spatial spread of the mechanism linking colour and motion.

What do these striking and robust effects tell us about the brain? At present, there is still no generally accepted explanation for CAEs; but current theories are of two main types. One view likens CAEs to

channels. So, orientation would be coded by a number of neural channels: some tuned preferentially to vertical, some to, say, 10 degrees from vertical, and so on round the clock. Each group of channels tuned to a particular orientation would have members also tuned for red as well as vertical; others for green and vertical, and so on. During McCollough-type adaptation, gazing at a red vertical grating would reduce to below normal the output of channels tuned for both red and vertical. When the test grating is presented, channels tuned for vertical and other colours would give their usual output; but the red/vertical channels would be less active than normal.

This imbalance in favour of the other channels would add an apparent green tinge to the vertical stripes. This is sometimes called a 'builtin' theory, since the mechanism producing the CAE is supposed already to exist in the subject's visual system before adaptation. It can be contrasted with a group of 'builtup' theories which propose that some kind of link is forged during the adaptation period, between previously separate mechanisms for processing colour and orientation. Different kinds of link have been proposed: some authors have suggested that an association is made like that in classical (Pavlovian)*conditioning (in which, after a bell has been presented together with food on several occasions, the bell alone comes to elicit salivation); others that a neural inhibitory link is formed, so that activity in, say, the orientation system reduces activity in the colour system. However, despite numerous attempts, no experiment has yet been reported which convincingly decides between 'builtin' and 'builtup' theories.

There are several important characteristics of CAEs which a successful theory will have to explain. First, the effects are usually 'negative'. That is, the value taken by a sensory quality in the aftereffect is opposite to or shifted further away from the value of that quality during adaptation. So, in the McCollough effect the colour seen on a particular orientation (say, red) in the test field is the complementary to that viewed on that orientation during adaptation (in this case, green). Second, CAEs can be very longlived. McCollough effects have been reported six weeks after adaptation; and reports that they can be reevoked days after adaptation are common in the literature. Third, they do not decay during sleep. Indeed, there is some evidence that to remove the effects one has to look at the usual test field.

It is interesting to ask what the role is in normal perception of the mechanisms that produce the McCollough effect. Presumably, they do not exist simply to provide amusing perceptual demonstrations! One possibility is that if indeed the initial stages of human perception consist of banks of filters tuned to particular features of the sensory input, then there will be a need to keep the outputs of these filterchannels calibrated. For example, the gain of a particular sensory channel (that is, how much output it produces for a given input) might be subject to unwanted drifts, or fluctuations, as, say, a blood vessel narrowed which supplied that area of cortex. The brain could attempt to distinguish between such internal changes and those introduced by stimuli in the external world, by sampling over time the outputs of all channels. On the assumption that red vertical stimuli are about as likely to occur on average as green vertical stimuli, it would turn down the gain of a channel whose output was abnormally high for a long period; or turn up the gain of one which was correspondingly low. Such an automatic gain control system would act to keep the gains of sensory channels roughly

equal despite biological drift. It could also remove from the neural image false signals—such as colour fringes introduced by chromatic aberration in the optics of the eye—since these constant errors would be treated in the same way as the unvarying colour/orientation combination in the McCollough effect. But such a system would be misled by prolonged exposure to stimuli exciting only a very few channels. It would surely mistake the activity in these channels for internal drift, rather than external stimulation, and turn down their gain. This would give negative aftereffects, since these channels would contribute less than their appropriate share to the final percept. The system would also require evidence that the gains of the adapted channels were too low before readjusting them. The best evidence of this would be for the subject to inspect (in the case of the McCollough effect) black and white gratings. Thus presenting the test field should cause CAEs to decay, but withholding it should produce longlasting aftereffects, as is found. CAEs may, therefore, reflect the brain's usually efficient but sometimes erroneous attempts at selfcalibration.

CONTINGENT PROPERTY. 'Contingent' (sometimes 'accidental') is applied to certain properties of a thing to suggest that they do not necessarily belong to that thing, either because of their dependence on some further cause, or simply to indicate that the thing need not have those properties to be the thing that it is. Thus a piece of wood may have the contingent property of being stained; however, the property of having been produced from a tree is necessary to its being a piece of wood.

The distinction between contingent and necess

Page 169

ary properties is broadly the Aristotelian distinction between what a thing is in virtue of itself (*kath' hauto*) and what it is by accident (*kata sumbebekos*). To sustain the distinction requires, on the one hand, a recognition that the very identity of a thing may be bound up with its being of a certain kind; otherwise all its properties are contingent (e.g. it would be thinkable that something which is a piece of wood might not have been a piece of wood). On the other hand, it must be allowed that a thing can

alter some of its properties without changing its identity; otherwise all its properties are necessary (e.g. a piece of wood could not be stained without becoming a completely different thing).

COORDINATION BETWEEN DIFFERENT SENSES. See SPATIAL COORDINATION OF THE SENSES.

CORNEA. The transparent window of the eye. It is the main imageforming structure in air-living vertebrates. (In fish, however, the crystalline lens produces the refinal image.) The cornea has no blood vessels, receiving its nutrients by absorption. It is for this reason that corneas can be transplanted without rejection.*Astigmatism is generally due to the cornea having a nonspherical surface.

CORPUS CALLOSUM. The very large bundle of fibres connecting the two cerebral hemispheres in the brain. It is occasionally sectioned as a treatment for*epilepsy, and the results have been used for 'split-brain' experiments, particularly associated with the American neurophysiologist Roger Sperry, who holds that the patient may then have two minds, or two selves. See NERVOUS SYSTEM; SPLITBRAIN AND MIND.

CORRELATION. An observed association between events (for example, that smoking is associated with lung cancer). It is not possible to assign causes directly from correlations: there must always be an underlying theory, or explicit or implicit assumptions, to set the causal 'arrow'. Discovering correlations is a principal aim of most scientific experiments, and much of learning may also be thought of as discovering correlations, which are useful when predictive.

CORTICAL MAPS. See LOCALIZATION OF BRAIN FUNCTION AND CORTICAL MAPS.

COUÉ, EMILE (1857-1926). French lay psychotherapist who founded a therapeutic method based on autosuggestion (self-induced suggestion) that won considerable popularity in its day. He gained fame with his maxim 'day by day and in every way I am getting better and better'.

COURAGE. See FEAR AND COURAGE.

COVERANT.*Behaviourists have long relied on the concept of 'operant' or 'instrumental' behaviour: that is, behaviour which is modified by its consequences. The concept was applied almost exclusively to overt, observable behaviours such as speaking, walking, and leverpressing, each of which may be considered 'operants'.

But some behaviourists, such as B. F. Skinner, maintained that covert, unobservable behaviours—what most people would call 'thoughts', 'images', and other 'mental'

events—work in the same way as overt behaviour. That notion eventually led to the concept of the

'coverant' (a contraction of 'covert' and 'operant'), which was introduced by the psychologist Lloyd Homme (1965). Homme suggested various means for controlling coverants as an aid to therapists dealing with problems such as obsessive thoughts. Control was said to be accomplished, for example, by training a patient to punish himself after an inappropriate thought. Though the theoretical underpinnings of this approach to therapy have been challenged, the coverant concept helped stimulate widespread interest among therapists in a behaviouristic approach to both selfcontrol and cognition. See BEHAVIOUR THERAPY.

CRAIK, KENNETH JOHN WILLIAM (191445). British psychologist, educated at the Edinburgh Academy and the University of Edinburgh, where he graduated with firstclass honours in philosophy. He then deviated to psychology, working for a year in Edinburgh under Professor James Drever, Sen., before moving on to Cambridge, where he became a research student in the psychological laboratory under Professor F. C. (later Sir Frederic)*Bartlett. Craik was awarded his Ph.D. in 1940 and elected to a fellowship at St John's College, Cambridge, in the following year.

During the Second World War, Craik was heavily engaged in applied research work on behalf of the Medical Research Council and the armed services, especially the Royal Air Force. In 1944 he was appointed the first director of the Medical Research Council's applied psychology unit at Cambridge and seemed well set for an active and productive postwar career. Unfortunately, his premature death in a road accident at the age of 31 deprived British psychology of one of its most promising figures. It can hardly be doubted that had he survived he would have become one of the ablest experimental psychologists of his time.

Craik's early work was concerned almost wholly with problems of vision. He was particularly interested in the adaptation of the eye to changes in the level of illumination and in the effects of such adaptation on visual efficiency. In a series of published papers, he described the effects of various levels of adaptation on differential brightness sensitivity, visual acuity, and subjective

Page 170

brightness, concluding that the efficiency of the eye was highest when at a level of illumination roughly equal to that to which the eye had been preadapted (see VISUAL ADAPTATION). In general, he viewed adaptation as a kind of 'rangesetting' adjustment of the visual system and saw in it the first stage of the process whereby a degree of constancy is achieved in the apparent brightness of objects despite wide variations in the general level of illumination. Although he may have underrated the specificity of tuning of the adapted eye, his attempt to establish some general principles of perception on the basis of the simpler mechanisms of physiological response held high promise.

Craik was always much interested in the nature of dark adaptation, and some of his work in this field

found important application during the war, particularly in relation to night flying. He also did important work on glare as a factor limiting visual efficiency in locating submarines from the air. On the basis of his impromptu experiments, he was able to evolve a simple experimental law relating intensity of glare to angle of light source and size of target. This led him to suggest a much improved method of visual scanning which was immediately adopted. Studies of anoxia (oxygen deficiency) in relation to aviation medicine stimulated him to undertake experiments, with himself as subject, on temporary blindness induced by mechanical pressure on the eyeball. In the course of these somewhat hazardous experiments, he established very convincingly not only that both light and dark adaptation are essentially retinal processes but that visual*afterimages are likewise of peripheral origin.

Although vision may well have been Craik's foremost scientific interest, he shook off his earlier preoccupations with philosophy only with difficulty. In 1943 he published *The Nature of Explanation*, his only completed study of any length. Although this was in principle an essay in philosophy, it embodies a highly original attempt to develop a theory of thought along mechanistic lines. His point of departure is that thinking is undeniably predictive and that this predictive capacity is also characteristic of calculating machines, antiaircraft predictors, and other devices which, at all events to this extent, can be said to operate in essentially the same manner as man himself. Craik therefore postulated that the brain makes use of mechanisms similar in principle to many of the artefacts of modern technology and that these mechanisms can model, or parallel, phenomena in the external world, just as a calculating machine can parallel the development, say, of strains in a bridge of given design and hence predict whether it will stand or fall. On such a view, Craik contends, our thought has objective validity because it is not fundamentally different from external reality and is especially suited to imitating it.

In assessing Craik's theory, it is important to bear in mind that modern computer technology was virtually in its infancy at the time that he was writing and that his model leans heavily on the principles of analogue devices. Had he been alive in the era of digital computers and lived to read A. M.*Turing's famous paper on *Computing Mechanisms and Intelligence*, which appeared five years after Craik's death, he might well have put forward a model of thought more in keeping with the capacity of digital computers to mimic any discrete state machine. None the less, Craik's theory, and his concept of internal models in the brain, have had considerable influence on psychologists and neurophysiologists seeking mechanical analogues of intelligent behaviour in animals and man (see ARTIFICIAL INTELLIGENCE).

Craik's wide knowledge of general experimental psychology and the physiology of the senses had been appreciably expanded by his wartime work on human factors in tank and antiaircraft gunnery. This work also fostered a lively interest in servomechanisms and automatic control principles, as is well shown in his two posthumous papers (1947, 1948) on the theory of the human operator in control systems. As the war neared its end, Craik began work on a systematic treatise on the mechanisms of learning and human action. This was never completed, although several chapters survived and have been edited for publication by Stephen Sherwood. They are to be found in a volume of Craik's essays, notes, and papers assembled by Sherwood on the initiative of Warren*McCulloch under the title of *The Nature of Psychology* (1966). As Sherwood rightly points out, Craik's draft embodies some of the earliest references to the relationships between learning, cyclical events in the nervous system,

and servomechanisms. Indeed it foreshadows many of the arguments later developed *in extenso* by the mathematician Norbert*Wiener in his famous book on *Cybernetics* (1948) (see CYBERNETICS; INTERACTIONAL APPROACH).

His scientific talents apart, Kenneth Craik was an accomplished designer of technical equipment and derived enormous enjoyment from mechanical invention of all kinds. He was a skilled craftsman, and the set of miniature steamengines, each one smaller than the last, which he made when still a schoolboy are now in the Royal Scottish Museum in Edinburgh. He was also an accomplished amateur violinist and had some talent for poetry.

Page 171

CREATIVITY is one of those terms (*intelligence is another) that psychologists use as though they refer to single human characteristics, but which direct us in practice to a number of concerns that are rather separate. Some of these, like 'innovation' and 'discovery', have a bearing on the ideas or objects that people produce;

some, like 'selfactualization', refer more to the quality of the life an individual leads; and some, like 'imagination' and 'fantasy', point us, in the first instance, to what goes on inside a person's head. Despite its air of vagueness, the notion of 'creativity' has none the less served an important function among psychologists and teachers, acting as a banner under which ideological battles have been fought; and indicating, too, a somewhat disparate body of research, some of which is of real value.

What is now thought of as the 'creativity movement' had its first stirrings in America in the years after the Second World War. At one level, it was psychology's response to the challenge of Sputnik, and to the fact that little of the best space research was being done by homegrown American scientists—the implication being that there was something deadening about the education that clever young American scientists had received. At another level, it represented a liberal reaction, within psychology, against

values which were seen as excessively manipulative and bureaucratic. Translated into the classroom, this concern for creativity expressed itself in a desire to shake education free of rote learning and the set syllabus, multiple choice examinations, and the IQ test, and to give children the opportunity to make discoveries for themselves.

Although hints of its existence were detectable as early as 1950, this movement was not in full swing until the early 1960s. It seems, in other words, to have been a portent of the liberal and antiauthoritarian mood that dominated university life towards the end of the 1960s, and which, in its turn, provoked its own reaction. By the early 1970s, the more selfconsciously scientific psychologists had already begun to reassert the virtues of the IQ test, and to argue in favour of genetic rather than cultural explanations of individual and racial differences.

This symbolic war between 'soft' and 'hard' psychologists has tended to obscure genuine advances in our understanding of the ways in which the human imagination works. The founding fathers of psychology were keenly interested, Francis*Galton no less than Sigmund*Freud; and research has proceeded quietly for a hundred years or more. Two sorts of enquiry have been especially fruitful: straightforwardly descriptive studies of the lives that highly original men and women have led; and research on the processes of thinking itself.

In a sense, the evidence of the biographical studies has been largely negative. It has been found, time and again, that those who display great originality as adults were often, like Charles*Darwin, only mediocre as students. British scientists who become Fellows of the Royal Society show roughly the same distribution of good, mediocre, and poor degree results as do those who go into research but achieve little. The same holds for intelligence test scores: above a surprisingly low level, there is little or no relationship between IQ and achievement in any sphere of adult endeavour yet studied. As a result, we would expect future Nobel prize winners to show roughly the same distribution of IQ scores as their fellow students at university. In the American context, the budding scientist of high renown seems typically to be a

'B+' student: one who works hard when a topic captures his (or her) imagination, but otherwise does the bare minimum. Science springs to life for such individuals when they discover that instead of assimilating knowledge created by others, they can create knowledge for themselves—and are hooked from that moment onwards.

It is the more detailed studies of thinking that indicate the tensions which underlie such creative effort. Some of the most vivid have concerned mathematicians; and a feature of them is the stress they place on the process of 'incubation'. Often, having struggled with a problem and then put it aside, mathematicians find that the solution comes to them quite unexpectedly, in a flash. The clear implication is that our brains are at their most efficient when allowed to switch from phases of intense concentration to ones in which we exert no conscious control at all.

There are many instances of such 'unconscious' work, one of the more dramatic being that of the German poet Rainer Maria Rilke. In 1912, in the midst of a long poem, the *Duino Elegies*, Rilke ran out of inspiration, and lapsed into a long period of frustrated depression. Interrupted in any case by the First World War, he was able to write little for a decade. When 'utterance and release' came to him in 1922, it took the shape of a series of poems, the *Sonnets to Orpheus*, that he had no intention of writing whatever. Eighteen days later, when he had finished both these sonnets and the *Duino Elegies*, he had produced some 1,200 lines of the pithiest and most carefully poised poetry ever written, and had done so largely without correction, as if taking dictation.

Such evidence encourages us to reconsider the popular idea that*genius and madness are closely allied. It is not true, of course, that great poets, painters, scientists, and mathematicians are mad; far from it. On the other hand, it may well be that they work as intensely and imaginatively as they do in order to remain sane; that they have access to aspects of the mind's functioning from which those who live more staid and conventional lives are excluded, and that it is this access which gives their work both its flair and its sense of risk. Rilke's lengthy depression may well have been necessary for the extraordinary burst of creative but also highly disciplined work that followed it.

It is such tensions as these which explain a remark once attributed to Einstein. He suggested Page 172 that the creative scientists are the ones with access to their*dreams. Occasionally, a dream will actually provide the solution to a problem—as in the case of the chemist August Kekulé and his dream of the snake swallowing its own tail, the clue to the nature of the benzene ring. Einstein's point was less specific, though. As Freud realized, in establishing his distinction between primary and secondary process thought, the mind is capable of functioning both intuitively and according to the dictates of common sense. The implication of Einstein's remark is that, in order to innovate, the scientist, like anyone else, must break the grip on his imagination that our powers of logicalseeming storytelling impose. We must be willing to subvert the conventional wisdom on which our everyday competence depends.

It is here that the research done by the advocates of creativity in the 1900s now seems most relevant. Rather than straining to see whether tests of creativity can be devised, to stand side by side with IQ tests (a largely barren exercise, it seems), we can concentrate on an issue that Francis Galton ider

tified over a century ago: the extent to which each individual can retrieve apparently irrational ideas, sift them, and put them to some constructive use. We know that individuals differ in their ability to*free associate, to fantasize, and to recall their dreams. We also know that these differences have a bearing on the kinds of work people find it comfortable to do: among the intelligent, it is those who are relatively good at free associating (the 'divergers') who are attracted towards the arts, while those who are relatively weak in this (the 'convergers') are drawn towards science and technology. What we do not yet know is how the abilities to think logically and to free associate combine to produce work of real value: what qualities of mind, for example, a genuinely imaginative solution to an engineering problem demands, or how a sustained contribution to one of the arts is actually achieved.

CRETINISM. Impaired physical and mental development due to lack of thyroid development. Appearing in early childhood, the problems can be largely avoided by treatment with thyroid extract—if diagnosed and treated sufficiently early in infancy.

CRIMINOLOGY, like medicine, is an amalgam of disciplines. In popular usage it even includes scientific methods of identifying criminals, although nowadays this is distinguished as 'forensic science' or—less elegantly—'criminalistics'. In stricter modern practice criminology comprises four kinds of study: descriptive, explanatory, penological, and nomological.

Descriptive studies are concerned with the frequencies of the various sorts of lawbreaking; the situations in which they are most likely to occur; the kinds of people who are most likely to commit them; and the extent of the harm done. In the past such studies have relied chiefly or entirely on official statistics and police files. More recently, 'selfreport' studies, in which samples (usually of teenagers) have told interviewers about their behaviour, have provided less superficial data, as have 'victim surveys'. These studies and surveys have yielded more valid estimates of the real incidence of

violence, thefts, robberies, burglaries, and sexual crimes (but not yet of serious traffic offences, or of rare crimes such as homicide). They have shown that victims are selective in what they report to the police; that police are selective in what they regard as worth recording; and that fluctuations in recorded crimes can result from, or be greatly exaggerated by, changes in people's willingness to report them, as well as from variations in the interest which the police take in them.

Explanatory studies need to be subdivided into those which seek to offer explanations of particular breaches of law and those which try to account for especially high (or low) frequencies of lawbreaking (or, better, of certain kinds of lawbreaking), whether in different countries, in different social groups, or during different periods in their histories. Explanations of particular breaches usually attach importance to the disposition of the individual lawbreaker, whether this is attributed to upbringing, to the influence of associates, or—less commonly nowadays—to genetic or perinatal misfortunes. Explanations of differing frequencies emphasize economic conditions, subcultural values that are in conflict with law, or inequalities of opportunity for legitimate acquisition or enjoyment. 'Histories' may figure in both kinds of explanation, whether they take the form of narratives about individuals or trace the origins of, say, violence in a country's past. Most explainers are highly selective, either because they are searching for some factor which can be manipulated so as to reduce the frequency of lawbreaking, or because they want ammunition to support political or moral attacks on the current state of their society. What should not be overlooked, however, is the relevance of explanations when courts are trying to assess the culpability of an individual offender.

Penological research is concerned mainly with the effects of what is officially done to identified offenders, although it has also taken an interest in

the social consequences of being labelled as an offender of one kind or another. Until recently most penologists concentrated on assessing the extent to which *desired* effects were achieved: reform, deterrence, rehabilitation, incapacitation. There have always been critics, however, who emphasized the unwanted sideeffects of sentences; and when it became clear that the wanted effects were confined to a small minority of offenders (who could seldom be identified in advance) the importance of unwanted effects began to be appreciated. These too, however, have been exaggerated; and it is only in the last decade that attempts have been made to define and measure the sorts of damage which incarceration (for example) inflicts, and determine whether it is transient or lasting.

Nomological studies. What can be called 'nomological' studies—for want of a better term—concentrate on lawenforcement itself. Some offer answers to the question 'What kinds of conduct should be prohibited by the (criminal) law?' The kinds most frequently discussed are consensual sexual deviations, contraception and abortion, euthanasia, drug abuse, and obscene entertainment. Others are concerned with compulsory benevolence such as requirements to wear seatbelts in motor vehicles. Nomological work is also undertaken into the ways in which the criminal law as it stands is administered. Since police have to be selective—both because of limitations on resources and for the sake of good relations with the public—their selectivity has been subjected to very critical scrutiny in Britain and the USA, though much less in 'police states' for obvious reasons. Public prosecutors, who exercise considerable discretion in bringing people to court and in framing the charges against them, are also a subject of study. Another favourite subject is the criminal courts: chiefly summary

courts and appeal courts. Where higher courts are concerned, it has been the jury which has been the focus of the spotlight. The behaviour of prison staff and administrators has also received much attention. Less attention has been paid to the behaviour of probation officers, hostel wardens, and other social workers, chiefly because their roles are seen as less coercive. Furthermore, penologists have interested themselves in 'theories of punishment': more precisely in the differing aims which are held to justify penalizing offenders. Until fairly recently this was regarded as a subject for moral philosophers; but penologists have been able to show that some philosophers' assumptions about the practicability of achieving their aims have been unrealistic.

CRITICAL PERIODS. Walking, language, sensorimotor coordination, and other skills are best learnt at certain 'critical periods' in the development of children, and similarly with other animals. Once the critical period is lost, it may be very difficult or impossible to learn the skill with full effectiveness. (See SPATIAL CO

ORDINATION OF THE SENSES; VISUAL SYSTEM: ENVIRONMENTAL INFLUENCES.) A major skill in teaching children is to recognize the advent of each critical period. Jerome Brunet speaks of readiness to learn, and Jean*Piaget has attempted to determine the ages at which various lessons are appropriate.

CROSSMODAL SENSORY INTEGRATION. To the ordinary observer it is selfevident that an object he perceives remains unchanged even when on different occasions the same object is, say, seen (but not touched, heard, or smelled), or touched (but not seen, heard, or smelled). or heard (but not seen, touched, or smelled). Psychologists have increasingly during the recent past been posing questions with regard to skills of crossmodal recognition. Were*Berkeley,*Leibniz, and*Piaget correct in their supposition that at birth the perceptual systems relating to each sense modality are independent? Then, during development, do the perceptual systems become integrated, and does the infant learn through the experience of stimulus correlations that equivalences between sensory systems exist? Or, are others (e.g. Werner, Bower) right in arguing that babies have a primitive unity of the senses, so that early perception is 'supramodal' (i.e. the sense modality of the inflow is disregarded)? Then, during development, are the senses increasingly differentiated and does the child learn that the senses are distinct?

In addition, psychologists have been asking questions with regard to special populations. Is crossmodal recognition immediately proficient in patients whose sight has been restored at a later age after being virtually blind from birth on account of cataract (a question first raised by*Locke)? Is there evidence, from neurological patients, of a special brain area that acts as a structural bridge between the separate senses? Does language mediate crossmodal skills: and how do mammals lacking language but with their highly proficient perceptual capacities fare on crossmodal tasks?

Unfortunately, we have no certain answers to most of these questions. The originally posed issue (Piaget versus Bower) seems too broad to answer directly. In accordance with the particular task (which might involve objects or temporal sequences), and depending on the subject's prior experience and individual capacities, codes of processing are flexibly selected, irrespective of modality. Distinctions such as 'separateness' and Page 174

'unity' (of the senses) have no general validity: the particular task at a particular time is allimportant. Moreover, demonstration of certain relatively primitive crossmodal skills in preverbal human infants, or in nonhuman animals, should not imply that symbolic coding is not the normal or preferred human strategy for processing information crossmodally once language has developed. The crossmodal capacities of the human infant (Meltzoff and Borton, 1979) and baby monkey (Gunderson, 1983) seem extremely crude in comparison with the skills shown (not in all tasks or comparisons, but none the less quite frequently) by children over the age of 8, or by adults.

A broad view of the current evidence suggests that a primitive kind of 'supramodal' perception is structurally given at birth in human infants (and also in apes and monkeys), possibly at a 'low' (subcortical) level of the brain. This system may be involved in stimulusobject identification and reidentification (i.e. recognition), but cannot serve when features of an object, as opposed to the identity of the object *per se*, have to be analysed (i.e. discriminated) and then recognized. Apes and monkeys have not progressed far beyond this stage (so that crossmodal 'transfer of learning' does not occur even in apes capable of immediate crossmodal

'recognition', and the greater the amount of experience given in the first sense modality, the poorer the crossmodal recognition in the second). With increasing age, the human child resorts to new strategies: it learns from lawful correlations (e.g. bimodal exposure, when the stimuli are perceived simultaneously through different senses, so that feature analyses via different senses become possible); and even physically quite dissimilar properties can be assigned to the same stimulus on a conditional basis (e.g. the sound of the word 'apple' associated with the seen object 'apple'). (Such crossmodal conditional learning is also laboriously possible for nonhuman animals.) Finally, increasing through childhood, man tends to have recourse to symbolic mediation, where language serves as a crossmodal bridge, allowing for greater flexibility in judging equivalence. This tentative schema may well need to be revised as new evidence becomes available.

CULTURAL DIFFERENCES IN PERCEPTION. See PERCEPTION: CULTURAL DIFFERENCES.

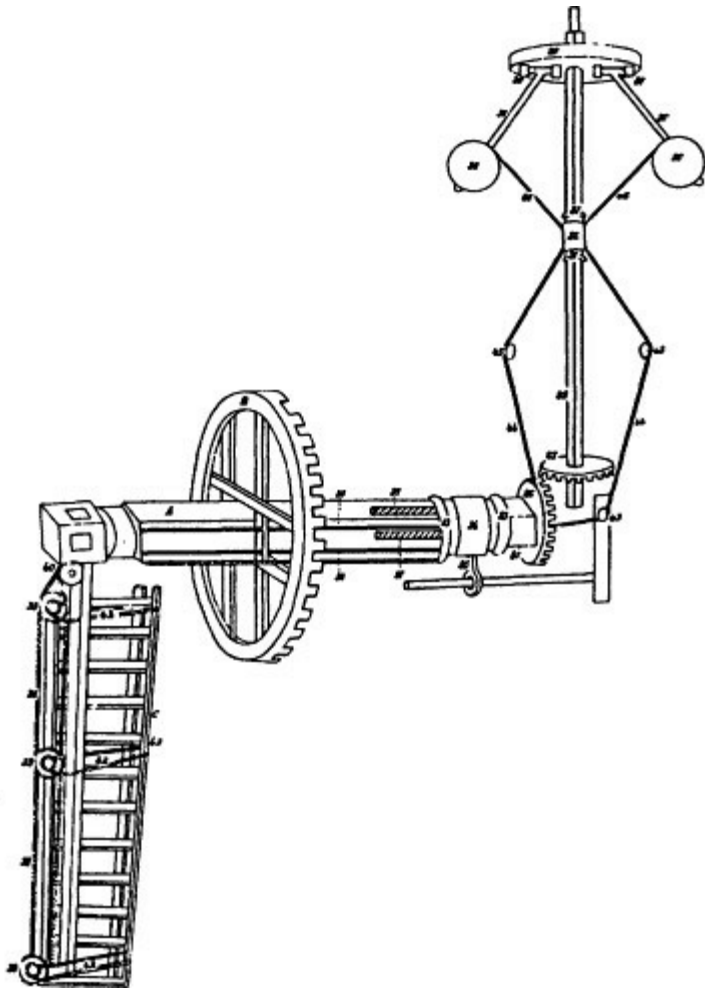

CYBERNETICS, HISTORY OF. The word 'cybernetics' was introduced by Norbert*Wiener (1894-1964), the distinguished mathematician. It was the title of a book, *Cybernetics, or Control and Communication in the Animal and the Machine*, published in 1948. The word is formed from the Greek *kubernetes*,

'steersman'. As Wiener explained: 'What recommended the term cybernetics to me was that it was the best word I could find to express the art and science of control over the whole range of fields in which this notion is applicable.' These words can also be used as a definition of cybernetics. It is a theory of*feedback systems, i.e.

self-regulating systems, the theory being applicable to machines as well as to living systems. Today, after the introduction of computers, theoretical aspects of control analyses have become so sophisticated and their application to engineering, biomedicine, and economics so firmly rooted and self-evident that it is difficult to recapture the intellectual excitement brought about by Wiener and his publications. The roots of the application of control theory or feedback in engineering reach far back; so too, it was noticed by certain biologists that control or the maintenance of equilibrium is one of the basic properties of life. However, the unifying theory of control and communication as applicable both to living systems and to machines built by man was first generally recognized only in 1948 with the publication of Wiener's book.

It is not certain who was the first person to apply a feedback mechanism to regulate or control a machine. There is evidence that certain kinds of regulating devices, such as for regulating the level of oil in an oil lamp or the outflow of water reservoirs, were already being used more than 2,000 years ago, and were known in the Middle Ages and the Renaissance. However, knowledge was transferred orally from craftsman to craftsman, and only a few written descriptions exist, none of which treat the theoretical aspects of mechanical engineering. In the seventeenth century, machines that developed great power, like windmills and steam engines, were first used. It then became essential to provide some mechanism to limit or control their power, so that it would not finally destroy the machine which produced it. One of the first patents granted to a feedback mechanism was for a 'whirling regulator' which controlled the speed of rotation in windmills by means of a centrifugal pendulum (T. Mead: Regulator for Wind and Other Mills, patent no. 1628, London 1787). The engineer James Watt (1736-1819) adapted it and used it as a 'governor' to regulate the velocity of rotation in steam engines, where the output (i.e. the velocity of rotation) regulated the input (i.e. the steam). During most of the nineteenth century, although regulating devices were widely used in engineering, there were no clear concepts of the dimensions and mechanical properties they should have.

They were built and simply had to be tried out—and often failed. There was no theoretical framework which allowed the performance of a given regulator to be calculated. Then James Clerk Maxwell (1831-79), a physicist, reduced the problems to mathematical formulae. However, it was not until the end of the nineteenth century that there became available the mathemat

Page 175

Fig. 1.

Original figure from T. Mead, patent 1628, 1787:

'A regulator on a new principle for wind and other mills,
for the better and more regular furling and unfurling the
sails on windmills without the constant attendance of a
man, and for grinding corn and other grain, and dressing
of flour and meal, superior in quality to the present
practice, and for regulating all kind of machinery where

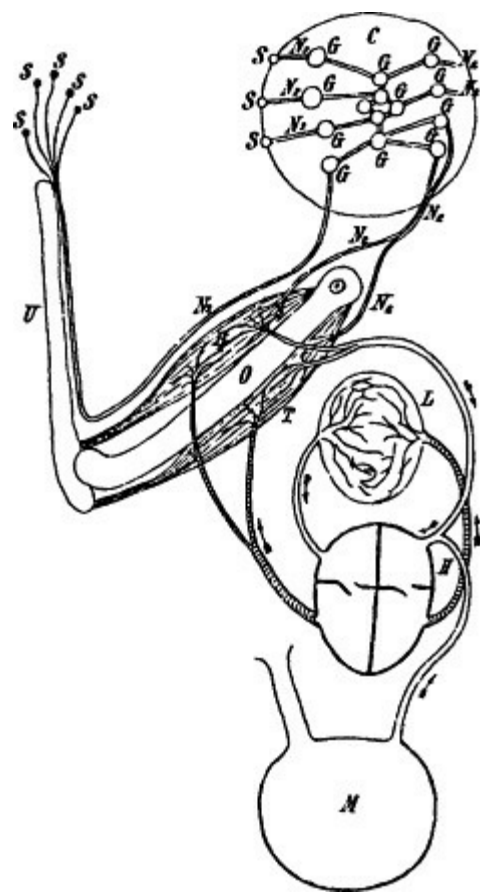

the first power is unequal.' Right up one sees a speed regulator. During rotation centrifugal forces will lift the two spherical weights. They pull on strings which then furl the sails so that the effective area exposed to the wind is reduced.

ical tools for giving easy and practical solutions to the equations suggested by Maxwell. Only then did the theory of feedback regulation become an established discipline that could be applied to all fields of engineering.

Similarly, in biology, the idea of control cannot be traced to a single person. Several steps, each focusing on special aspects, were important and necessary until it became apparent that the theory of feedback as applied to biological systems is structurally and mathematically the same as that used in engineering. Three physiologists of the nineteenth century deserve to be mentioned, because each of them drew attention to one important aspect of feedback control. The three aspects are the complex organization of organisms, the relative constancy of certain physiological parameters, and the description of animal behaviour using teleological terms.

In 1828 Charles*Bell, the Scottish anatomist and surgeon, published *Animal Mechanics, or Proofs of Design in the Animal Frame*, in which he discussed the complex organization of organisms. He compared the structure which gives stability to bones with elements of architecture and building engineering. Similarly he compared the mechanism and efficiency of the heart and vascular system with pumps and pipes used in engineering. Although he did not go as far as actually to describe feedback mechanisms, by systematically comparing organisms with machines, and by using the same terminology, he was the first to widely use the concept of models. Models have since been generally employed, and have become an important element in biological cybernetics. One of their purposes is to isolate certain functional aspects of behaviour and to study their logic and limits of operation in order to better understand the mechanisms of biological design and development.

Claude Bernard (181378), a French physio

Page 176

Fig. 2.

Original figure from F. Lincke: Das mechanische Relais (the mechanical relay) VDI Zeitschrift 23, 50924, 577616 (1879). The 'indicators' are sensory nerves (*S*, *N_s*), the 'executive' organ (motor nerves *N_e* and muscle *B*), the 'transmitter' (brain with ganglion cells *G*), and 'motor' (stomach *M*, heart *H*, lung *L*). 'The activity we use to direct our human "machine" to its goal results from the difference between the will and the observed or imagined reality, i.e., the difference between the intention and the result of the execution.'

logist, introduced the concept of the constancy of the *milieu intérieur*. By that he understood that within certain limits blood, for example, has a constant composition independent of environmental

changes. If the glucose level in the blood falls, animals as well as humans get hungry, eat, and by doing so raise the glucose level again.

Bernard saw the results of feedback mechanisms and explored several examples, like the regulation of body temperature as well as glucose levels in the blood. In his book *Lessons on Phenomena of Life in Animals and Plants* (1878) he extended these experimental results and developed a general theory of how animals are able to maintain the constancy of their *milieu intérieur* (see HOMEOSTASIS).

The German physiologist Eduard Pflüger (1829-1910) considered the goal-directed behaviour of feedback mechanisms in biology. In 1877 he published a paper, *The Teleological Mechanics of Nature*. Teleology is defined as the study of final causes. Feedback mechanisms are characterized by the fact that the input is controlled by the output, and thus stabilizes the output, or makes the performance relatively independent from disturbing influences. One can consider the stability of the output as the 'goal' of the system. To turn the argument round, whenever a behaviour in biology is encountered that can be described as goal-directed, i.e. teleological, it is very likely that a feedback mechanism is involved.

The next step in combining biology and technology was taken by Felix Lincke (1840-1917), professor of mechanical engineering at the Institute of Technology at Darmstadt, Germany. He was probably the first who saw the outlines of a unifying theory of feedback control that is applicable to machines as well as to organisms. In 1879 he published a lecture, *The Mechanical Relay*, in which he classified the different feedback mechanisms used in mechanical engineering and listed the necessary elements of any feedback loop. These are: (i) the 'indicator', which continuously measures the output, (ii) the 'executive organ', which modifies the input of the feedback loop, (iii), the 'transmitter' which connects the 'indicator' and the 'executive organ', and (iv) the 'motor', which supplies the energy. Applied to an arm movement, the 'indicator' is the sensory nerve endings that sense the position of the arm, the 'executive organ' is the motor nerves with the muscles that perform the movement, the 'transmitter' is the brain which establishes a connection between the sensory and motor nerves, and the 'motor' is the alimentary tract supplying the energy for the whole system. The action of the indicator, executive organ, transmitter, and motor in a feedback loop can be described in the same way whether they are identified in biological systems or in machines. It is always the difference between the intended goal and the measurement given by the indicator that modifies the input to the feedback loop and thus brings the output of the system nearer to its goal. Although Lincke's paper was published in a widely recognized journal of engineering (*Zeitschrift des VDI*), and also as a book, nobody picked up his ideas and he was virtually unknown until well after Wiener's success in 1948.

In 1940, sixty years after Lincke's lecture, another engineer, Hermann Schmidt (1894-1968), a professor at the Institute of Technology in Berlin, published a series of papers in which he independently developed ideas similar to those of Wiener. Wiener focused his ideas more on the mathematical problems involved, while Schmidt based his theory more on the historical development of engineering. First, with primitive tools like an axe, man determines the exact action. In a Page 177 second phase, energy is provided, but man still has to control the action by constantly monitoring the

state of the machine, as in an automobile. In a third stage, energy *and* control over that energy is provided, as in aeroplanes with automatic landing control. (The pilot approaching the airfield makes only the decision to land; the exact monitoring of height, velocity, etc., is taken over by a computer). In this third stage of development, energy and the immediate control over it are transferred to a machine, even though man still has to determine the goal of action for the machine. Only in science fiction, like Samuel*Butler's novel *Erewhon* (1872), is a fourth stage envisioned in which machines would develop to such a stage that they would determine their own goals—be it to the benefit of humans or not.

For a discussion of the application of cybernetics to human social behaviour, see also INTERACTIONAL APPROACH.

D

DALTON, JOHN (1766-1844). British chemist born in Cumberland, the son of a Quaker hand loom weaver. At the age of 15 he was teaching at the Quaker school in Kendal and in 1793 he moved to Manchester, where he remained for the rest of his life, supporting himself by teaching and tutoring. His atomic theory provided an explanation of the behaviour of elements and compounds and became one of the foundations of modern chemistry. He was also a keen meteorologist (recording over 200,000 observations), and a collector of butterflies and plants.

As a young man he discovered that a geranium appeared to him 'sky blue' by daylight but 'red' by candlelight. Finding that his friends did not experience this striking change (although his brother did), he came to realize that he had unusual colour vision. His detailed observations, reported to the Manchester Literary and Philosophical Society in 1794, suggest that he suffered from the type of dichromacy in which the longwavelengths receptor is missing (see COLOUR VISION). His report excited widespread interest in Daltonism, as colourblindness came to be known for many years.

DANGER RECOGNITION. Recognition of danger in animals requires that they distinguish dangerous stimuli from others, and distinguish among different sorts of danger that may require different escape responses. In many species there is a close relationship between fear and curiosity: confronted with a novel stimulus, or a change in environment, most animals respond first with flight and then with approach and investigation. The degree of novelty is crucial in determining which response will be given: familiar stimuli evoke little response, whereas a moderate degree of novelty elicits curiosity and approach, and fear is shown, by either freezing, flight, or alarm signals, when the

stimulus is extremely novel. Thus, for a wide variety of stimuli the relation between stimulus novelty and response takes the form of an inverted U: positive interest is high at intermediate levels of stimulation, and fear responses, or the recognition of danger, appear only when stimuli are very unusual.

With many species certain sights, sounds, and smells are particularly effective in eliciting escape behaviour, and different stimuli may elicit different sorts of escape.

Many birds and small mammals give acoustically distinct alarm calls when ground or aerial predators appear, and respond differently to each call type. In East Africa, vervet monkeys are preyed upon by leopards, two species of eagle, and pythons. Alarm calls given for leopards cause other monkeys to run up into trees; the different calls given for eagles cause animals to look up into the air or run into bushes; and those for pythons, acoustically distinct from both leopard and eagle alarms, cause animals to stand on their hind legs and peer into the grass around them (Seyfarth, Cheney, and Marler, 1980).

In some species, these highly specific responses appear fully formed, even when a stimulus is encountered for the first time: many birds give aerial predator alarm calls on their first encounter with such predators, and chicks of the same species freeze in their nests when they first hear the alarm. In other cases, recognition of specific classes of danger emerges gradually, apparently requiring some experience. While adult vervet monkeys restrict their alarmcalling to particular species, infants often make 'mistakes' and give alarms for objects that pose no danger to them. These calls are not entirely indiscriminating, however: leopard alarms are given for many animals other than leopards, but only for terrestrial animals; and eagle alarms are given for many nonpredators, such as pigeons and geese, but only for objects flying in the air. Despite such early classification, however, the monkeys' use of warning calls does not emerge fully formed but requires further sharpening with experience.

Parallels in the way humans and other animals recognize danger are most evident in development. Upon first exposure to a novel stimulus, most animals exhibit fear, followed by curiosity and inspection, and then by disinterest. For each species some stimuli are particularly alarming, and faced with these an animal readily develops an ability to recognize different kinds of danger. Similarly, human infants are frightened by a variety of general stimuli, such as loud noises, bright lights, and being left alone; later, distress is caused only by more specific stimuli, such as separation from a particular person. Thus children learn to distinguish between different classes of danger.

DARK ADAPTATION. See VISUAL ADAPTATION.

DARWIN, CHARLES ROBERT (1809-1882). British naturalist, born at Shrewsbury. His grandfather was Erasmus Darwin, his father, Robert Waring Darwin, was a distinguished physician, and his mother was a daughter of Josiah Wedgwood. Charles studied medicine at Edinburgh, but, finding the operating procedures of that time extremely distasteful, went up to Christ's College, Cambridge, in 1828 in order to enter the Church. However, he was befriended by the botanist Professor J. S.

Henslow, and his interests moved to botany and zoology. He graduated in 1831, and with Henslow's recommendation became naturalist to the survey ship HMS

Beagle, bound on a voyage of scientific discovery. This changed the course of his life and the science of natural history.

Darwin sailed on 27 December 1831, and returned on 2 October 1836, after exploring Tenerife, the Cape Verde Islands, Brazil, Tierra del Fuego, the Galápagos Islands, New Zealand, Tasmania, and the coral reefs of the Keeling Islands. During the voyage he stocked his mind with knowledge, questions, and a hunch that species could not be separately created but must have evolved. He attributed the insight that evolution proceeds by selection of the fittest to reading the *Essay on Population* (1798, 1803) by Thomas Malthus, which gave the pessimistic prediction that competitive society declines in spite of the individual's struggle for existence.

Curiously, this same book later triggered the same concept of evolutionary development by natural selection (a phrase coined by Herbert Spencer) in the mind of Alfred Russel Wallace. The theory was presented jointly by Darwin and Wallace (though neither was present) at the Linnean Society in London, on 1 July 1858. It was received in silence, with no questions; and the president of the Linnean summed up 1858 as a year that 'has not been marked by any ... striking discoveries'.

Darwin showed remarkable character in maintaining friendship with Wallace and giving him due credit, though, unlike Wallace, he had spent twenty years collecting notes. He finally published *On The Origin of Species by Means of Natural Selection*, with the spur of Wallace's independent discovery, in November 1859. The entire printing of 1,500 copies was sold out in a day.

It was the science of geology that first cast serious doubt on the biblical account of special creation for each animal species, as it became clear that there had in the past been great changes in rocks, and so in the environment, and yet animals were adapted to the present environment. It also became clear that the age of the earth was very much greater than the biblical account taken literally allows; and, perhaps most important, unknown forms of life were discovered as fossils. These facts were set out in detail by Charles Lyell (1797-1875) in *Principles of Geology* (1830). Darwin began to develop an evolutionary theory with such thoughts in mind, and his first theory was very different from natural selection. He first thought (in the summer of 1837) that species must change in order to remain adapted; and that, as species change, old species must die out, for the number of species to remain nearly constant. He supposed that simple living forms ('monads') appeared through spontaneous generation from inanimate matter, and evolved by direct environmental influences. The monads, he supposed, had a limited lifespan, as do individuals, though presumably for different reasons. (See

Gruber, 1974, ch. 5.) Although he soon abandoned this theory, he retained the notion of a continuous branching tree of evolutionary development, with the implication that we should not expect any simple sequence of evolving lifeforms to be found in the fossil record. There were enormous gaps in the fossil record that was available in his time, and this is still so, with controversial implications (See EVOLUTION: NEODARWINIAN

THEORY.)

Darwin also made specific contributions to human psychology, tracing the origins of emotional responses and facial expressions from prehuman species, in *The Expression of the Emotions in Man and Animals* (1872). This still unrivalled work contains accounts of the experiments he carried out on his own children, including—in spite of his extreme affection and gentleness—inducing fear to establish their responses.

He studied behaviour not only in animals and man (*The Descent of Man*, 1871, explicitly places man in the evolutionary sequence) but also in plants: *Climbing Plants* (1875), and especially *The Power of Movement in Plants* (1880), which describes not only elaborate movements of tendrils but also their selective sensitivity to appropriate or inappropriate stimuli. Darwin saw this as a precursor to control of animals by the nervous system, an idea yet to be followed up in detail.

Darwin's life after the voyage was spent with his talented family at Downe House, some twenty miles south of London, with its splendid garden and greenhouses in which he carded out many experiments while writing his books. Here he worked incessantly though dogged by ill health, possibly sleeping sickness (trypanosomiasis) contracted by an insect bite. The house and garden, with its famous walk, are preserved as a Charles Darwin museum. One can still see the study chair with wheels, in which he used to push himself around when too tired to stand among his zoological and botanical specimens and his books.

Darwin's principal regret was the pain his theory caused those of religious persuasion, including his beloved wife Emma. He was personally shy of controversy and debate, and T. H.*Huxley was his champion in public, disarming even the formidable Bishop of Oxford, Samuel Wilberforce, at a celebrated meeting of the British Association for the Advancement of Science, at Oxford, on 30 June 1860, when Wilberforce ('Soapy Sam') asked Huxley: 'Is it on his grandfather's or his grandmother's side that the ape ancestry comes in?' Huxley replied (in a verbal battle during which Page 180

Lady Brewster fainted) that 'a man has no reason to be ashamed of having an ape for his grandfather', and, 'if there were an ancestor whom I should feel shame in recalling, it would be a man of restless and versatile intellect who ... plunges into scientific questions with which he has no real acquaintance, only to obscure them by an aimless rhetoric, and distract the attention of his hearers from the point at issue by eloquent digressions and skilled appeals to religious prejudice' (as reported by the historian J. R. Green twentytwo years later).

In addition to Darwin's books published in his lifetime, there are the notebooks that he kept to record and develop his ideas. Those named 'M' and 'N' record his growing ideas on mind, and man's place in

nature. He was well aware that evolutionary accounts implied, or at least strongly suggested, that man's origin is in the animals that one may see in zoos. He ends the *Descent of Man*: 'with all his exalted powers—man still bears in his bodily frame the indelible stamp of his lowly origin'.

Realizing that mental characteristics can be passed on through generations, and assuming that only physical structures can be inherited, Darwin was forced to conclude that mind has a physical basis. On this ground he became a materialist— while aware that this would be painful to his wife Emma, to his friends, and more widely to all he would influence. He postponed for as long as possible his conclusions on the origin of man.

In Notebook 'N', writing at the time of his marriage, Darwin puts forward his theory of*blushing: that it depends on the person's awareness of the thought, or opinion, of another person. It is restricted to humans: 'animals, not being such thinking people, do not blush'. Darwin accepts blushing as evidence of*consciousness, and especially selfconsciousness; but he rejects the notion of free will, saying that although we experience ourselves as causal agents, desires and purposes do not arise from some special endowment but only from natural laws of thought, as we would see if only we could stand outside ourselves. We cannot stand outside ourselves, so, 'on my view of free will, no one could discover he had not it' (N 49). The notebooks are fascinating both for their insights and as documents of the slow, painful development of Darwin's thought: for here are the germs of most of the ideas worked out often much later in his books.

R. L. G.

There is an enormous literature on Darwin's life and work. See his *Life and Letters* (1887) and *More Letters* (1903), edited by his son, Sir Francis Darwin, and his autobiography edited by his granddaughter, Lady Nora Barlow (1958). The voyage of the *Beagle* is described in Darwin's own words in *Charles Darwin and the Voyage of the Beagle*, ed. Nora Barlow (1945), and with many illustrations in Alan Moorhead, *Darwin and the Beagle* (1969). An interesting account of Darwin's mental development (together with the previously unpublished notebooks) is Howard E. Gruber, *Darwin on Man: a psychological study of scientific creativity* (1974). An excellent general study of his work and its implications is Gertrude Himmelfarb, *Darwin and the Darwinian Revolution* (1962).

DARWIN, ERASMUS (1731-1802). British physician and scientist, the grandfather of both Charles*Darwin and Francis*Galton. He was born near Newark in Nottinghamshire, studied at Cambridge and Edinburgh, and became a successful physician at Lichfield in Staffordshire. He was well known for his radical opinions, his eight-acre botanical garden, and for his books, including the long poem *The Botanic Garden* which appeared in two parts, *The Loves of the Plants* (1789) and *The Economy of Vegetation* (1791). His most important work was *Zoonomia, or The Laws of Organic Life* (1794), in which he anticipated*Lamarck's theory of evolution by the inheritance of acquired characteristics, and also, though somewhat vaguely, Charles Darwin's theory of evolution by natural selection. He was a founder member of the Lunar Society of Birmingham, the leading intellectual society of the Midlands, whose members included James Watt and Josiah Wedgwood.

DEDUCTION. In the more general sense any process of reasoning by means of which one draws conclusions from principles or information already known. Thus Isaac Newton talks of making deductions from his experiments with prisms, and G. K. Chesterton's Father Brown, after visiting the scene of the crime, deduces that Flambeau was responsible. But within logic and philosophy deduction is contrasted with*induction. Frequently the contrast is made by use of a directional metaphor: by induction one moves from particular to general and from the less general to the more general, ascending the theoretical ladder which terminates in first principles; by deduction one moves from more general to less general and from general to particular, descending the theoretical ladder which terminates in facts about particular individuals or events. This image of the ascent and descent of reason is to be found in*Plato,*Aristotle, in many medieval treatises on logic, and also in the works of Francis*Bacon.

In the logic of scholastic tradition, deduction is equated with syllogistic inference, for it was by means of the definition and study of syllogisms and their possible forms that Aristotle introduced a framework for both a codification and a theoretical discussion of the principles of valid deductive
Page 181

inference, the kind of inference that can be accepted as providing proofs or demonstrations. The central idea here is that in a valid deductive argument the truth of the premisses guarantees the truth of the conclusion; in some sense the conclusion is already contained in the premisses. Thus Aristotle defined a syllogism as 'a discourse in which, certain things being stated, something other than what is stated follows of necessity from their being so. I mean by the last phrase that it follows because of them, and by this that no further term is required from without in order to make the consequence necessary.' (*Prior Analytics*, 24b, 1823.) But the further idea underlying the study of deductive inference, and indeed behind the notion of logic generally, is that this is a study of the principles of correct reasoning and that as such it must be independent of any particular subjectmatter about which we might want to reason. The laws of logic, if they are to be universally applicable, must thus concern the forms or structures of arguments only, omitting all reference to content. On Aristotle's account, which was dominant for 2,000 years, all deduction is a matter of establishing connections between general terms. He defines a proposition as 'a statement affirming or denying something of something' (24a, 16). In other words, a (categorical) proposition is thought of as a statement that a certain relation holds between its subject *S* and its predicate *P*. Propositions are then classified according to the relation asserted to hold: Universal Affirmative—'All *S* are *P*' (*SaP*), Universal Negative—'No *S* are *P*' (*SOP*), Particular Affirmative—'Some *S* are *P*' (*SiP*), Particular Negative—'Some *S* are not *P*' (*SOP*). A syllogism is the making of a new connection between terms which goes via a third, or middle term.

Syllogisms were traditionally classified into four figures according to the arrangement of their terms (although only the first three of these were recognized by Aristotle, who did not regard the fourth as a distinct figure). The figures are:

(2)

(3)

(4)

(1)

$S — M$

$M — S$

$S — M$

$M — S$

$M — P$

$M — P$

$P — M$

$P — M$

$S — P$

$S — P$

$S — P$

$S — P$

Thus an example of a valid firstfigure syllogism would be:

(All) whales are mammals.

SaM

MaP

(All) mammals are warmblooded.

SAP

(All) whales are warmblooded.

An example of a plausible but invalid firstfigure syllogism would be:

(All) larches are conifers.

SaM

MiP

Some conifers are deciduous.

SiP

Some larches are deciduous.

The invalidity of this form becomes obvious if 'Scots pine' is substituted for 'larch'. Any valid deduction will then be required to be reducible either to a syllogism or to a sequence of syllogisms which traces a chain of connections between the subject and predicate terms of its conclusion.

In the seventeenth and eighteenth centuries, partly as a result of the increased hold of nominalism, partly as a result of the dominance of a (Cartesian) thinking subject centred approach to philosophy, the Aristotelian view of deductive reasoning was internalized. Instead of referring to classes or to universals, general terms were taken as standing for ideas (mental representations). (Categorical) propositions are thus interpreted as assertions about the relations between ideas, and deductive reasoning becomes a matter of perceiving the relations between ideas. From this perspective the laws of logic become the laws of thought, laws basic to the structure of the human intellect and constitutive of its rationality.

This conception finds perhaps its clearest expression in Immanuel* Kant's *Critique of Pure Reason*. But it is here also that the seeds are sown of the fundamental revisions both in logic and in conceptions of the nature and structure of thought which were brought about as a result of the work of Gottlob Frege and others working in the late nineteenth and early twentieth centuries. For Kant, in spite of his use of a very traditional Aristotelian framework for the construction of his table of judgements, (i) places primary emphasis on judgements as cognitive acts, rather than on ideas as the referents of general terms, and (ii) sees judgement as a matter of the application of a concept to an object according to a rule.

Frege strenuously rejected the idea that laws of logic are laws of thought. It was his view that if a valid deductive argument is to be one where the *truth* of its premisses guarantees the *truth* of its conclusion, the laws of logic must be laws of truth, founded on the way in which language represents reality, not on the nature of the psychological processes by means of which human beings represent reality to themselves and then manipulate these representations. But Frege did retain and build on the Kantian emphasis on judgement which gives logical priority to propositions rather than to terms. Deductive argument is now seen to depend on establishing relations between the possible truth values

of propositions (thoughts) expressed by (indicative) sentences; the proposition becomes the basic logical unit and truth the fundamental semantic notion. The simplest (atomic) propositions are regarded as expressing the application of a concept to an object (symbolized as '*Fa*'), where there is a fundamental asymmetry at both logical and ontological levels between concepts and objects. Concepts are treated by analogy with mathematical functions.

This allowed Frege to develop a logical framework of much greater power and flexibility than Aristotle's. In particular it enabled him to incorporate arguments where the propositions involve relations and where the validity of the argument depends on the characteristics of the relation concerned, as, for example: '*A* is heavier than *B*. *B* is heavier than *C*. Therefore *A* is heavier than *C*.'

In addition, by the device of introducing quantifiers and bound variables, Frege was able to treat such statements as 'Every natural number has a successor' and 'There is no largest natural number'. Present logical systems all exploit the basic Fregean innovations.

DÉ JÀ VU. 'It happened on my first visit to Paris. I was walking along one of those little streets in Montmartre, when I suddenly had the feeling that I'd been there before. It was all happening again ...'

This is a characteristic account of *déjà vu* (literally: 'already seen')—the experience that one has witnessed some new situation or episode on a previous occasion.

Perception of the scene is accompanied by a compelling sense of familiarity. Usually the sensation lasts only for a few seconds, but in some pathological cases it may be much more prolonged or, indeed, continuous. It is often accompanied by a conviction that one knows what is about to happen next—'When I reached the square, I knew what I was about to see ...'

The *déjà vu* experience is often reported by patients suffering from psychiatric disorders. It is known to be associated with temporal lobe lesions, and is one of the

'dreamy state' experiences characteristic of focal*epilepsy. But the phenomenon seems also to be experienced occasionally by the majority of normal people. Most commonly it occurs in youth, or under conditions of fatigue or heightened sensitivity.

Understandably, the sensation of having previously experienced the event in question suggests to the individual that he is recalling a previous occurrence. The present event is taken to be a 'second' occurrence; mystification and interest is thus focused upon the 'first' one. As the crucial aspect of *déjà vu* is that the individual knows that he has not in fact previously experienced the event, lay explanations often posit psychic or magical processes. Such 'explanations' usually attribute unusual talents or powers to the individual concerned. Thus, one obvious 'explanation' is that the event has been 'revealed' to the individual prior to its occurrence. In that case he has demonstrated precognition, and is the fortunate possessor of the 'sixth sense' or the power of prophecy. More commonly, lay explanations make the presumption that the event has, in fact, occurred on a previous occasion, and focus on how the individual could have gained his knowledge of that 'first' occurrence. A common explanation is that the individual experienced the 'first' event in a previous life. His *déjà vu* sensation may thus be taken as evidence for reincarnation. An associated view is that the 'first' event was witnessed by the individual but *through the eyes of another person*. He is therefore taken to possess telepathic gifts. The other witness may be hypothesized to have existed at another period in time. In that case the present individual is presumed to have mediumistic powers. A somewhat more subtle hypothesis is that the 'first' experience took place in a dream, a proposition which accords well with the dreamlike quality of the *déjà vu* experience itself. The individual himself may feel, not that he has previously witnessed the event, but that he has previously *foretold* it. But there is never any evidence of his actual foretelling, nor does he recall ever having done so. Thus he may speculate that the events were revealed to him in a dream, which would explain his failure to recall consciously his presentiment in the interim. Technically, this feeling is a *pseudopresentiment*, so termed because the belief is held only at the moment that he witnesses the event. A number of serious writers have maintained this 'dream' hypothesis.

As noted above, the last four explanations presuppose that *déjà vu* is attached to a *second* experiencing of the situation in question—in other words, that the individual is *remembering*. Several psychological and psychiatric authorities have also taken this view, classifying *déjà vu* as an example of paramnesia. For them the question becomes one not of how the individual could remember something which he has not experienced before, but of why he should *think* he has not experienced it before. The obvious assumption is that the original experience aroused distress in the individual, so that its recall would prove painful to him. The standard psychoanalytic explanation of *déjà vu* is that the original experience has been repressed and so, by definition, is no longer accessible to memory. Any repetition of the experience cannot elicit conscious recall of the original occurrence. But it does constitute a 'reminder' to the ego, and it is this which is reflected in the *déjà vu* feeling.

A more prosaic explanation of *déjà vu* is that, although the overall situation is novel, a number of its component features have in fact been experienced before. For example, the observer may know for certain that he has never walked along this particular street before—indeed, he may never previously have visited the town or even the country in question. But there are many features which all streets have in common, and it is the combination of these specifics which brings some familiarity to this newly visited street. However, this suggestion applies more directly to what has been termed 'restricted paramnesia'. (An everyday example of 'restricted paramnesia' is the frustrating experience of being unable to identify a person whom one knows but in some other context.) There are

which accompanies a restricted paramnesia and the *déjà vu* experience. In the formers one is well aware of those aspects of the situation which have been experienced previously (such as the other person's facial features, expression, and voice). The perplexity arises from the inability to reconstruct the totality of the previous experience (for example, the circumstances and context of previous encounters). In *déjà vu*, the *whole* of the new experience seems familiar, and so does the ensuing progression of events. Typically, the paramnesia experience is described in terms such as: 'I knew that I had met him before, but for the life of me I couldn't remember who he was ...' Whereas *déjà vu* is described as: 'I felt that I had lived through it all before, but knew that I hadn't.'

Two other suggestions should be mentioned. The first one, once held by psychologists, stresses the affective component and classifies *déjà vu* as a paradoxical emotional experience. The argument would be that the sense of familiarity has reference, not to the characteristics of the situation, but to the observer's feelings. It is postulated that these are a carryover of the emotional state associated with the preceding situation. The second suggestion is of more recent origin and focuses upon neurological function. Here the argument is that the two hemispheres of the brain may temporarily lose synchronicity. Thus the anomalous feeling of familiarity may be due to the fact that one side of the brain is receiving input a fraction of a second after the other.

A more fruitful psychological approach to the consideration of *déjà vu* may be to deemphasize the recall aspect, with its presumption of a 'previous event', and approach the experience in terms of its other name: *fausse reconnaissance* (false recognition). Instead of 'Why is the observer unable to remember the previous situation?' the question now becomes: 'Why does the observer feel that he recognizes the present situation?' This, indeed, was the approach taken by Pierre*Janet, who was one of the first psychologists to identify, describe, and analyse the experience. He considered *déjà vu* to be one outcome of the obsessional incapacity for active and adequate response to the pressures of reality. The essence of *déjà vu*, he suggested, is not the 'affirmation of the past'; it is the 'negation of the present'. It is not a question of how the observer *remembers* a previous event, but how he *perceives* the present one.

At first sight, the classification of our topic as an anomaly of recognition rather than one of recall does not seem to offer any easier road to explanation. Certainly, conventional laboratory studies of recognition would seem to offer nothing which might throw light upon the *déjà vu* experience. However, consideration of the views of F. C.*Bartlett, as presented in his classic work, *Remembering*, may yield some dues. Bartlett's central point, which has been reemphasized by contemporary cognitive theorists, was that longterm memory is a dynamic, constructive process. We do not recall an event in its original form, nor even in a merely attenuated version. We *reconstruct* it, drawing upon the*schematas or cognitive structures into which the perceived components of the event were organized. Thus, what is reconstructed during recall or reproduction shows not only omissions and abbreviations but elaborations and distortions.

On each occasion that we recall any given event, further distortions or elaborations are introduced. It could be said that in a series of recollections we are not recalling the original event at all, but our last recollection of it. The longer the series the more the remembered version will differ from the original, because each further recollection will involve distortions of distortions and elaborations of elaborations. If this line of argument (for which there is considerable experimental as well as observational evidence) is applied to the examination of recognition, some interesting implications emerge. Basically, recognition involves the acceptance of a 'good fit'

or match of currently perceived material with recalled, imagined material. The better the level of match, the more pronounced will be the accompanying sense of familiarity. In the case of personal experiences, the familiarity includes an added dimension of personal identification. Clearly, the more often an original event has been recalled, the more modifications will have been introduced, and the weaker the subjective fit between our current recollection and any representation of the actual original material. Conversely, the sense of familiarity may now be evoked by the perception of material which differs considerably from the actual original, given that the differences are in line with the distortions and elaborations present in our recollection. If we have good reason to believe that it would be quite impossible for us to have actually experienced this new material previously, then our feeling of familiarity is naturally highly perplexing. It may well be that this perplexity, resulting from the discrepancy between objective knowledge and subjective feeling, constitutes what is termed *déjà vu*. In that case, why is the experience so rare? Perhaps the problem is not why *déjà vu* occurs, but why it does not occur more frequently. There are several possible answers. One is that perhaps it does occur commonly, but that we only register it under certain conditions. But at the same time, it is probable that there are relatively few occasions when we can be objectively certain that we have not experienced the criterion situation previously. A first visit to a geographic area is one such example. Other cases where the total situation may be labelled emphatically as a personal 'first time' event are often ones of a heightened emotive nature, where we are likely to be more sensitive to our subjective state and more vulnerable to feelings of anxiety and perplexity. It should be noted that while we may be acutely aware that a given situation is a personal 'first', we have almost

Page 184

certainly experienced it at second hand, through descriptions, literary accounts, or films. Perhaps the obvious examples are marriage ceremonies, job interviews, and funerals. And it is of interest that, after the 'strange town' example, these are the very situations in which people most commonly report experiencing *déjà vu*.

Purely psychological explanations of the kind discussed are hardly sufficient when the *déjà vu* experience is part of an epileptic aura. In this situation one might presume that the spontaneous electrical discharge in an area of the brain (the temporal lobe) particularly concerned with memory has reactivated a distant memory from the memory store, which is now perceived as something the patient has previously experienced—as, indeed, he probably has.*Penfield's brainstimulation studies on patients undergoing neurosurgical operations might be considered as supportive of such an explanation of the *déjà vu* phenomenon, at least in cases when it is associated with temporal lobe*epilepsy.

G. F. R.

DELIRIUM. A grossly disordered state of brain function characterized by restlessness, incoherent speech, and*hallucinations. Delirium is, as a rule, of toxic origin and is best known to the layman in its not infrequent link with delirium tremens, a condition resulting from chronic alcoholism. It may, however, also result from a wide variety of febrile conditions, or from drugs such as mescal, Indian hemp, cocaine, and bromide.

Hallucinatory states associated with toxic delirium are of considerable psychological interest. First, they may on occasion be associated with distortions of space and time; and secondly, they may give rise to*synaesthesia—a term first introduced by Sir Francis*Galton to denote phenomena such as 'coloured hearing', which is experienced from time to time by wholly healthy individuals.

The possible incidence of hallucinations in toxic delirium and in*schizophrenia has also been widely discussed, though it should be borne in mind that delirium is a wholly organic manifestation.

O. L. Z.

DELUSION. A delusion is a fixed, idiosyncratic belief, unusual in the culture to which the person belongs. Unlike normal beliefs, which are subject to amendment or correction, a delusion is held to, despite evidence or arguments brought against it. Delusions are usually taken to indicate mental illness, but something akin to them is occasionally to be observed, at a meeting of scientists, for instance, when a person insists on the correctness of an idea he overvalues, and denies any significance to evidence appearing to refute it. There is a difference: usually he gets angry, whereas in mental illness the patient's emotional response when a delusion is challenged tends to be bland or otherwise inappropriate.

Extravagant ideas are relatively common at times of frustration. A driver, frustrated when his car does not start, may allege serious deficiencies in all the cars made in the same country as his. This is to overgeneralize from the particular. Similarly, a student who has failed a test may feel for a while that he has failed as a student or, more generally still, as a person. Such feelings if they persist would amount to a delusion of unworthiness. Or he may conclude that his teachers are hostile to him, or that the world is against him. A persistent idea of this kind, especially if a person believes that there is a conspiracy or concerted action against him, is a delusion of persecution. A fixed belief that he is physically ill or, more extreme, that his organs are rotting or are destroyed, is a hypochondriacal delusion; that he does not exist or is nothing, a nihilistic delusion; that he has an exalted position or powers, a delusion of grandeur.

There is often sense in delusions, although it may be expressed extravagantly or confusingly. A man who declares that his wife is persistently unfaithful to him may be understood to mean that she has had sexual intercourse on many occasions with others. He is deluded if he insists unreasonably that this is so, in which case he is probably an example of the morbid jealousy syndrome; but he may only wish to convey his feelings that she no longer shows love or concern for him, feelings for which there might be some justification.

A delusion may persist because it explains what would otherwise cause*anxiety. Soldiers serving under stressful conditions occasionally express the belief that 'they'

are putting bromide into the soup. The meaning of this belief emerges when added to it is the belief that aphrodisiacs are being put into the soup of other units. It serves to explain, for those who hold it, the changes produced by the stressful conditions in the pattern of occurrence of penile erections. Some bizarre delusions are unlabelled metaphors. A mentally ill girl says that she is the Virgin Mary. What perhaps she means is that she feels that she is still a virgin although she fears she is pregnant. The delusion, with its implication of her essential goodness, mitigates the intense anxiety which being seduced and becoming pregnant would otherwise evoke.

Why are delusions resistant to modification in the light of other evidence? In this respect they are similar to the behaviours, characteristic of neurosis, which persist although they appear to be maladaptive. It is supposed that they persist because, being instrumental in reducing anxiety, they are reinforced.

This is only part of an explanation of delusions, which, with*hallucinations, are the cardinal symptoms of some forms of mental illness. In cases of paranoid*schizophrenia, the patient may reveal, as well as hallucinations, a more or less coherent system of delusions of persecution and grandeur, without showing any awareness of how abnormal the ideas he expresses are. In other cases of schizophrenia, the delusions may be contradictory and incoherent. Severely disabling are Page 185

hypochondriacal delusions, especially when they are associated with symptoms of*depersonalization, the patient then feeling that he has changed in personality with loss of his sense of identity; this may amount to a nihilistic delusion. Delusions of unworthiness occur in depressive illnesses in association with misery and hopelessness.

D. R. D.

DEMENTIA is defined by W. A. Lishman (1978) as 'an acquired global impairment of intellect, memory, and personality but without impairment of consciousness'.

Although often considered to be an irreversible condition, recent studies have shown that about 10 per cent of patients with dementia have conditions for which treatment can reverse the otherwise inexorable decline of mental function. The progressive dementias are most often diagnosed in the elderly under the headings of senile dementia of the Alzheimer type and multiinfarct dementia. The former is caused by widespread degeneration of nerve cells in the brain and their replacement by elements known as plaques and neurofibrillary tangles. Postmortem studies of the brains of patients who have died from senile dementia have enabled correlation of the numbers of these elements with the degree of mental impairment shown by psychometric testing during life. Multiinfarct dementia, which is less common than senile dementia, is caused by loss of brain substance following repeated closure of small or large blood vessels, incidents which cause minor or major strokes. The older

term, arteriosclerotic dementia, has now been superseded.

These areas of degeneration may be widespread and scattered, or concentrated in certain areas of the brain. If the latter, the mental changes will be much more severe in some functions than in others. For instance, the person may lose his speech (developing*aphasia) but not his memory, or vice versa. One of the last things usually to be affected is his basic personality, and some of the last skills to be lost are the social ones. Hence some demented persons will retain the major features of personality, remaining wellmannered, considerate, and responsive if these were the former characteristics. On the other hand, blunting of emotion and loss of control of social behaviour may lead to episodes of petulant and irritable behaviour or tactless and inappropriate remarks which would not have been uttered before the onset of the illness.

The difference between dementia and the more limited losses of mental ability due to focal injuries is that the demented person can seldom make compensations for his disabilities in the way the others do; and, indeed, very often seems to be unaware of them. He tends to live his life entirely for the present moment, although the present for him may be an era from his own distant past.

Although it is characteristic of the truly demented person that he has little insight into his defects, inability to cope with his environment may make him severely perplexed, or trigger off a condition described by Kurt*Goldstein and called by him the 'catastrophic reaction'. The individual becomes tearful and angry; he may repeat nonadaptive stereotyped movements in a repetitive manner, or start sweating and becoming restless. The 'emotional lability' that accompanies dementia is one of its outstanding characteristics and helps to differentiate it from true*depression, in which the individual remains sad and retarded no matter how his circumstances alter. Dementia must also be differentiated from another, much less common form of emotional disorder: that accompanying bulbar palsy, in which the individual may respond to any sudden stimulus or strong effort by screwing up his face and bursting into tears, without any of the unhappiness which usually causes such outbursts. 'I just can't help crying,' he may be able to tell you between spasms. 'Don't pay any attention to me.' In contrast to both of these, the emotional state of the demented person seems to reflect exactly the situation of the moment. If he is faced with a problem too difficult for him to solve, he shows all the signs of distress, but if this is removed and he is presented with a simpler one, the next moment he will be laughing and cheerful. It follows that even severe dementia may not necessarily cause its sufferer any personal pain, depending on where and how he is cared for. If his environment is simple, cheerful, and constant (i.e. unchanging) he may to all outward appearances (and on his own admission) be perfectly cheerful and contented.

It is important to distinguish dementia from the other disorders which commonly affect the elderly, as although there is, as yet, no known method of retarding or reversing dementia, many of the other conditions are fully treatable. In the speech disorders of dementia, comprehension is usually just as badly affected as expression, whereas in the aphasia due to focal lesions this is very rare. Moreover, the errors made when trying to name objects are rather different. The aphasic person usually manages to indicate that he knows perfectly well what the object is even though he cannot find its name, but the demented person often seems to fail to recognize the object too. If asked to name different parts of his body, the aphasic person can usually name those parts which are commonly mentioned (such as feet,

hands, and arms) but not those less frequently so (knuckles, eyebrows, ankles); in the demented there is seldom any difference.

The failure of memory seen in senile dementia is also different from that seen in normal old age (see AGEING) or in the organic*amnesic conditions. In the latter, cues or prompts very often help, but in the demented they seem rather to do the opposite. If one considers recall as being like searching for an item in a vast territory, a cue for the amnesic narrows the field of search and directs his attention to a specific area; for the demented, it seems to direct him to a new part of the field. For instance, if the target is the word 'cart', a useful cue for an

Page 186

amnesic would be the words 'Horse and ———'. A case of senile dementia might respond by saying, 'Horse? Yes, I remember we had many horses when I was a child, one particular one ...'

The ability to handle and manipulate objects is usually little impaired in dementia. Those motor skills which were learned in the past are well retained, but since he is inclined to forget what he is aiming to achieve before he has half done it, the demented person gets himself into difficulties. At first appearance he may seem to be suffering from apraxia (the loss of such skills due to focal lesions), but closer study will reveal differences. For example, both apraxic and demented individuals often have difficulty dressing themselves, but in the case of the apraxic the difficulty is due to 'forgetting' how to tie knots, do up buttons, or put an arm into a sleeve; in the demented it is due to forgetting whether he is supposed to be getting dressed or undressed at the time. When preparing meals—even such a simple task as making a pot of tea—the apraxic forgets how to put tea into the pot or stir it with a spoon; the demented can do all these things, if reminded constantly of the task in hand, but if distracted at all is liable to lose track of how far he has got and start from the beginning again.

Finally, there are two conditions which may be easily mistaken for dementia. The first is a severe depressive illness which may produce the condition sometimes called*pseudodementia which only a skilled psychiatrist can distinguish from true dementia, but which responds to appropriate antidepressant treatment. The second is a delirious state, triggered off in an old person by physical disorder such as pneumonia, a heart attack, or hypothermia. Unlike dementia, which usually comes on slowly over a long period, delirious states are likely to appear suddenly and will be accompanied by severe disorientation and even*hallucinations. These symptoms, however, clear up completely once the underlying physical disorder is rectified, and in former days it was quite common for an old person to 'wake up' after such an illness and find himself in a mental hospital labelled, to his great consternation, a case of senile dementia.

DENDRITE. One of the branching small neural processes carrying signals to the cell body of a neurone (nervecell). See NERVOUS SYSTEM.

DENOTATION is one of several words (the most common alternative is 'reference') used by logicians and philosophers for the relation between a fragment of language and that part or aspect of the world which it is used to introduce into discourse. The paradigm of the relation is that of a proper name to its bearer, but it is a matter of dispute what to say about proper names (and other grammatical subject expressions) which lack a bearer; and it is a matter of dispute whether and how the relationship applies in the case of predicate expressions. It is common to identify the denotation (reference) of a predicate expression with its extension, i.e. the class of all things to which it applies. Those who are prepared to recognize the existence of universals are often inclined to treat predicate expressions as denoting these. For J.

S.*Mill a general term like 'man' names the class of men, and denotes the indefinite number of individuals who belong to that class, while it *connotes* the attribute which is signified by 'humanity' (cf. 'white' connotes what 'whiteness' signifies), as well as any attributes implied by this, such as animal life and rationality. All such attributes comprise the connotation of 'man'.

Mill's distinction between denotation and connotation is often confused with Frege's distinction between reference (*Bedeutung*) and sense (*Sinn*); but for Frege the sense of an expression is the manner in which it refers, and this made it possible for him to hold that proper names have a sense, whereas Mill denied that proper names have a connotation.

DEPERSONALIZATION. A term applied in psychiatry to a complaint made by a patient that he feels himself to be changed, that the world appears different or unreal because he is different. If the world is seen as if in a dream, vague or unreal or, although familiar, as having no reference or significance to him, the state is called derealization. The essence of depersonalization is loss of identity or of the sense of the reality of one's self, accompanied usually by a sense of being divorced from one's body or having*outofbody experiences.

Depersonalization and derealization may be experienced by healthy persons who have been going through periods of intense excitement in the face of danger. The onset is usually when they begin to relax as the danger recedes. In wartime, for instance, such states are occasionally reported by the crews of aircraft who have flown a sortie over enemy territory. Subsequently memory of the action

has a dreamlike quality.

Depersonalization and derealization tend to occur together, sometimes without, but more often with, other symptoms of mental illness, especially depression but also obsessional neurosis. Both depersonalization and derealization may be experienced in conjunction with the* *déjà vu* phenomenon, as part of an epileptic aura, especially in patients afflicted with temporal lobe*epilepsy. When associated with*hallucinations and*delusions, especially hypochondriacal delusions, Page 187

depersonalization has been regarded as characteristic of true*schizophrenia and as a warning of disintegration of the personality. When combined with guilt, depersonalization and derealization may be ominous symptoms because they enable the patient to take coldblooded steps to destroy himself without normal awareness of the significance and consequences of what he does.

'Depersonalization' has been used in a broader sense by psychiatrists who have come under the influence of existentialism. To depersonalize then means to negate another person by ignoring his feelings or by treating him as an object or thing. Depersonalization was experienced in an extreme form by inmates of the concentration camps in the Second World War. The passive, 'ontologically insecure' person, in R. D. Laing's phrase (1965), may feel under threat of being depersonalized or of losing his autonomy when he enters into a cooperative relationship with another person. Natural science depersonalizes when it adopts a determinist view of a person as a component of a system or as composed of a complex of organs or functions. In contrast is the existentialist view that each person is a free and responsible agent determining his own development by making choices, great or small. However, a healthy person accepts that his autonomy is limited by his responsiveness to the social and physical demands made on him.

DEPRESSION Psychiatry shares with general medicine a tendency to adopt words with commonly understood meanings and give them specialized, unfamiliar interpretations. Obsession, conversion, pervert, and depression are psychiatric examples of such words. In everyday language we speak of feeling depressed, thereby indicating a transitory downturn in mood whose origin can usually be traced to some setback, even to the prospect of returning to routine living after too convivial a weekend. On the other hand, depression as an illness signifies a severe emotional disturbance whose source may or may not be traceable to external causes—

misfortunes, bereavements, financial loss, illness, etc. Emil*Kraepelin distinguished two major psychotic illnesses under the headings of *dementia praecox* (*schizophrenia) and manicdepressive psychosis (see MENTAL DISORDERS: CLASSIFICATION). The latter condition takes the form of alternating periods of extreme melancholia and equally extreme periods of elation and excitement.

But, as time has gone by, this relatively clear description has been complicated by the inclusion of persons suffering from recurrent bouts of severe depression without any periods of mania or, for that matter, major psychotic symptoms—the so-called endogenous depression. In addition, there are individuals who experience less intense attacks with less clearly demarcated changes in mood, whose depression appears to be an understandable response in a vulnerable personality to lesser or greater degrees of adversity—a reactive or neurotic depression.

This simple dichotomy is unfortunately beset with difficulties. Indeed, the very terminology invites—and gets—criticism. To say that somebody has sunk into the depressive phase of a manicdepressive psychosis overlooks the obvious fact that many such cases do not develop psychotic symptoms. Delusions, hallucinations, and bizarre hypochondriacal beliefs about one's bodily functions may be, but often are not, present. More frequently the sufferer will manifest a state of deep despondency and hopelessness coupled, in some instances, with selfaccusations and guilt over trivial misdemeanours previously ignored. The term *endogenous* depression seems to imply that the victim has some innate predisposition to this variety of mood disturbance; and there may be genetic evidence for such a predisposition, adding emphasis to the aetiological significance of the word 'endogenous'. On the other hand, speaking of *neurotic* (reactive) depression is probably saying as much about the quality of the symptoms as about their origin. To use more than one base for a classification hardly makes for clarity, and the word 'reactive' signifies that some external event is responsible for the onset of the individual's state of gloom. However, as some indubitable cases of endogenous depression and the depressive phase of manicdepressive psychosis can be preceded by psychological stresses such as bereavement and serious ill health, the distinction between endogenous and reactive depressions becomes distinctly blurred; and it would be erroneous to assume that in all persons with reactive depressions one can delineate external events determining the quality and time of onset of the illness.

For at least fifty years there has been controversy over whether endogenous and neurotic depressions are distinct and separate illnesses or merely alternative terms for severe and milder forms of mood change lying at the ends of what is essentially a continuum of affective disorder. Numerous attempts have been made to settle this dispute, with powerful statistical techniques being employed in the hope that mathematics will decide once and for all a debate which, some might think, has taken up more research time than the facts warrant. In the end the question of whether a person is suffering from a reactive or an endogenous depression will be decided on clinical grounds without recourse to statistics; and treatment will be given according to the judgement made at the time.

Numerous typologies aiming at a better classification of depression have been devised, but possibly a dimensional rather than a categorical approach to the problem is the most appropriate way of overcoming the difficulty of finding clearcut natural boundaries between one type of depres

sion and another. It is a fact that between patients with endogenous and reactive depressions lies a group with atypical symptoms who fail to fit neatly into one category or the other. This seems to presuppose a continuum of depressive disorders rather than a set of distinct classes of illness. But, as Kendell has written (1976): The attempt to resolve our classification problems by the statistical

analysis of clinical data has failed up to now and may continue to do so. We may have to live with our uncertainties and disagreements until we understand enough about the physiological or psychological basis of depression to construct a new classification on that basis.

Does it matter? Yes, but in all probability not so much as the protagonists in this debate might wish us to believe. The diagnosis of depression rests on consideration of the patient's symptoms, his previous history, and the course of his illness. Simple rating scales can be used, if required, to permit a fairly accurate diagnosis to be made.

Treatment will depend on this clinical decision, for what may be appropriate in one type of depression may be ineffective in another. Electroconvulsive therapy (ECT) may be lifesaving for patients with severe endogenous depression, when the risk of suicide can be high. But ECT rarely benefits those with neurotic depression, for whom drugs and psychological treatments are usually more effective. In recent years prominence has been given to a form of behaviour therapy, cognitive therapy; but it is clear that although this may be beneficial for neurotic depression, its impact on the symptoms of endogenous depression will be slight (Williams, 1984).

There is another complication introduced into the classification of depression that has a bearing on treatment. Persons with recurrent attacks of mania and depression (bipolar affective disorder) are more responsive to treatment with lithium salts than are those with recurrent attacks of depression only (unipolar affective disorder).

Opinions differ on this point, but for the most part those with repeated attacks of endogenous type depression appear to react best either to ECT or to tricyclic antidepressants, or to a combination of both. Neurotic (reactive) depression, on the other hand, is probably best treated with other types of drugs in conjunction with psychological methods designed to help the patient take a more realistic view of his situation.

In the end, in spite of many refined arguments, it appears that there are individuals who become severely depressed, sometimes losing touch with reality to a degree that warrants the label 'psychotic'; and there are those whose depressions are of a milder nature but, none the less, are sufficiently troublesome to interfere with enjoyment of life. One can for convenience designate the former as 'endogenous' and the latter as 'reactive' or 'neurotic'; but such labelling does not say as much about the origins of these mood disturbances as the terms themselves suggest. In both cases we are faced by illnesses requiring far more help than will be derived from the admonition 'pull yourself together and snap out of it'. Although such advice may be beneficial for individuals with mild degrees of cyclothymia and an overdeveloped sense of selfpity, it is worse than useless for those whose depressed mood has gone beyond the limits of normal human variation.

Finally, one point of singular importance must be mentioned. All persons suffering from depression should be adequately assessed for the risk of suicide. Relatives, and some physicians, sometimes hesitate to enquire directly about suicidal thoughts lest such questions prompt the actions they are most anxious to prevent. This is not so.

Most depressed patients answer truthfully to enquiries of this kind, and may even be relieved by the opportunity to discuss their innermost feelings of despair and dread of the future. It is sometimes believed, however, that those who mention suicidal thoughts never put them into practice. This is quite incorrect, and all mention of suicide by a depressed person must be taken with the utmost seriousness so that prompt admission to hospital for treatment can be arranged.

DEPTH PERCEPTION. The seeing of objects in three dimensions, although*retinal images are only twodimensional. Depth is seen even with one eye by

'monocular depth cues'. These are the partial hiding of further by nearer objects, loss of fine detail through haze and the limited resolution of the eye with increasing distance ('aerial perspective'), geometrical perspective (especially the converging of parallel lines as optically projected on the retina),*accommodation of the lens of the eye (the anterior surface of the lens becoming more convex for near vision), and motion parallax (when the observer moves, objects are displaced according to his movements, the visual world rotating round the point of fixation in the direction opposite to his motion). We may say, following Hermann von*Helmholtz, that depth is unconsciously inferred from these cues, or clues; or, following J. J.*Gibson, that we 'pick up' depth information from these features.

*Stereoscopic depth is given by the comparison of 'corresponding points' of the retinal images in the two eyes. This requires remarkably powerful neural computation, which can now be carried out with computer programs, though far more slowly.

Page 189

When depth cues are misleading, distortions of size can be generated. See ILLUSIONS.

DESCARTES, RENÉ (1596-1650). Descartes was a pivotal figure in the great seventeenth-century revolution that marked the emergence of modern philosophical and scientific thinking. He was born at La Haye near Tours, and educated at the Jesuit college of La Flèche. He travelled in Germany during 1619, and on the night of 11 November he had a series of dreams which inspired his vision of founding a completely new philosophical and scientific system. In 1628 he moved to Holland, where he lived, with frequent changes of address, for most of the rest of his life. His philosophical masterpiece, the *Meditations on First Philosophy* appeared in Latin in 1641; and his *Principles of Philosophy*, a comprehensive statement of his philosophical and scientific theories, also in Latin, in 1644. He died of pneumonia in Stockholm, where he had gone to act as tutor to Queen Christina of Sweden.

Descartes made important contributions in many areas of human knowledge. His early work was in mathematics, and his *Rules for the Direction of the Understanding* (1628) provided a general account of scientific knowledge that was strongly influenced by mathematical models. His *Geometry* (published 1637) lays the foundations for what is now known as analytical*geometry. In the *Discourse on Method*, a popular introduction to his philosophy, published in French in 1637, Descartes developed his celebrated 'method of doubt': 'I resolved to reject as false everything in which I could imagine the least doubt, in order to see if there afterwards remained anything that was entirely indubitable' (see DOUBTING). This led to the famous affirmation 'I think, therefore I am' (*je pense, donc je suis*). On the basis of this 'Archimedean point' Descartes erected a comprehensive philosophical and scientific system which was to include both a general theory of the structure and working of the physical universe, and many detailed explanations of particular phenomena, such as the mechanics of human and animal physiology. Although the metaphysical foundations of his system depend heavily on the existence of an omnipotent, benevolent and nondeceiving God, Descartes aimed, in all areas of natural science, to provide explanations in terms of strictly mechanical models and mathematical principles. All phenomena, whether celestial or terrestrial, were to be explained ultimately by reference to the shapes, sizes, and motions of bits of matter: 'I freely acknowledge that I recognize no matter in corporeal things apart from that which the geometricians call "quantity" and take as the object of their demonstrations' (*Principles*, Part II).

Descartes's theory of the mind stands out as a striking exception to his general insistence on mechanical and mathematical explanations. Mental phenomena, for Descartes, have no place in the quantifiable world of physics, but have a completely autonomous, separate status. 'I am a substance the whole nature or essence of which is to think, and which for its existence does not need any place or depend on any material thing' (*Discourse*, Part IV). Developing the theory later known as

'Cartesian dualism', Descartes maintains that there are two radically different kinds of substance: physical, extended substance (*res extensa*)—i.e. that which has length, breadth, and depth and can therefore be measured and divided—and thinking substance (*res cogitans*), which is unextended and indivisible. Thus the human body—including the brain and entire nervous system—belongs in the first category, while the mind—including all thoughts, desires, and volitions—belongs in the second.

One of Descartes's reasons for supposing his mind to be essentially nonphysical is that in his *Meditations* he found himself able to doubt the existence of all physical objects (including his body), but was unable to doubt the existence of himself as a thinking being. And from this he concluded that having a body was not part of his essential nature. But, as some of his contemporary critics pointed out, this argument seems invalid: ability to doubt that some item X possesses some feature F does not prove that X could in fact exist without F. Descartes also argued that the essential indivisibility of the mind proves its noncorporeality; but this seems questionbegging, since the premiss that the mind is indivisible would be disputed by those who maintain that the mind is some kind of physical system. Despite the shakiness of some of Descartes's arguments, his dualistic approach has continued to exert a dominantly powerful influence on theories of the mind. As recently as 1977, for example, we find the eminent neurophysiologist Sir John Eccles and the famous philosopher Sir Karl Popper maintaining that Descartes was fundamentally correct.

According to Eccles and Popper, the 'self'—the conscious being that is 'me'—is essentially nonphysical. The self may make use of the brain in its operations, but its operations have separate and independent status over and above the occurrences in the brain.

As Descartes himself recognized, however, dualism faces considerable philosophical difficulties. The chief of these is the problem of 'causal interaction'. We know from experience that mind and body do not operate in total isolation, but interact with each other: if there is a physical change (e.g. my hand touches a hot stove), a mental change (e.g. pain) results; and, conversely, a mental event (a volition to raise my arm) leads to a physical event (my arm going up). Descartes acknowledges these facts by saying that in many cases mind and body 'intermingle' to form a kind of unit. Thus, sensations like hunger and thirst are, he maintains, 'confused perceptions' resulting from

Page 190

the fact that 'I am not merely lodged with my body, like a sailor in a ship, but am very closely united and as it were intermingled with it' (*Meditations*, VI). But exactly how there can be such a 'union' or 'intermingling' between two allegedly quite distinct and seemingly incompatible substances is left something of a mystery. Elsewhere (e.g. in the *Passions of the Soul*, 1649), Descartes suggests that the mind or soul, though incorporeal and indivisible, exercises its functions in one particular part of the brain, the *conarion*, or pineal gland. But this manoeuvre seems not to solve but merely to reimport the problem of causal interaction: if there is a problem about how a nonphysical soul can cause my arm to go up, there will be no less a problem about how a nonphysical soul can cause movements in the brain by acting on the pineal gland.

Although in his psychological and physiological writings Descartes devoted great efforts to the problem of interaction between soul and body, it is worth remembering that in his system there are many areas where such interaction simply does not arise. First, in the case of animal physiology and a great deal of human physiology (e.g.

that concerned with digestion, muscular reflexes, etc.), Descartes maintained that the soul is not involved at all: what occurs can be explained purely on mechanical principles. Second, in the case of

human beings, though much of our activity (e.g. senseperception) involves complicated transactions between soul and body, there are other mental acts (e.g. purely intellectual thoughts) which, according to Descartes, can occur without any physiological correlates at all; such 'ideas of pure mind'

are, in Descartes's view, from start to finish noncorporeal. It must be said that advances in brain science have made this latter part of Descartes's theory increasingly difficult to defend.

Although substantive dualism, the doctrine that the mind is a separate, nonphysical entity, now has ever fewer supporters, many philosophers have become attracted by a weaker version of Descartes's theory, which has been termed 'attributive dualism'. This is the view that, even if the mind is not a separate entity, there are none the less two distinct sets of properties or attributes that can be ascribed to human beings: psychological properties (thoughts, feelings, volitions) and physical properties (e.g. electrical and chemical properties of the nervous system). Attributive dualists maintain that even if all human activities must depend on some kind of physical substrate, there is none the less an important sense in which psychological descriptions of those activities cannot be reduced to mere physiological descriptions. This position on the one hand preserves Descartes's insight that what he called 'modes of extension' (size, shape, volume) are fundamentally different from 'modes of thought' (thoughts, feelings, volitions), while on the other hand resisting his conclusion that two separate entities, a 'thinking thing' and an 'extended thing' are involved.

This is similar to the hardware and software of a computer.

DESENSITIZATION. See BEHAVIOUR THERAPY; FEAR AND COURAGE; PHOBIAS.

DESIGN, ARGUMENT FROM, FOR THE EXISTENCE OF GOD. The universe appears designed; a design requires a designer; and so the universe was designed (created) by a designing intelligence. This of course raises the question: How was the Designing Intelligence (God) created? Therefore, although the argument by analogy—as human artefacts have human designers, so the universe must have a superhuman designer—is appealing, it lacks philosophical cogency, because how the Designer was designed remains unanswered. The design of organisms by natural selection

shows that intentional mind is not required for designing. The most famous critique of the argument from design is in David*Hume's *Dialogues concerning Natural Religion*.

DESIGN IN NATURE. Design generally implies the action of intentional intelligence. The 'design' of organisms is, however, on the theory of Darwinian evolution, produced without prior purpose or intention. In this sense evolution is 'blind'. It may be said, though, that random variation and natural selection form a kind of intelligence, as they produce designs which we would certainly rate as requiring high intelligence—indeed superhuman intelligence, as they are beyond us to produce or even to understand. See EVOLUTION: NEODARWINIAN THEORY; PALEY.

DETECTION. In*perception, the term refers to the acceptance of selected patterns of energy by the sense organs—which are transducers producing neural signals.

The retinal receptors can detect illumination down to the theoretical limit of one quantum. The ears detect sound energies down to the random motion of air molecules (10¹⁶ watts, or 0.00003 dynes/sq cm).

Sensitivity is always limited by the fact that energies cannot be less than Planck's quantum of action, and because all detectors have residual random activity, or 'noise', against which signals must be discriminated.

DETERMINISM AND FREE WILL. Nobody can

Page 191

predict how something as complex as the human brain would behave under all circumstances. With more than ten thousand million nerve cells, each connected to thousands of its neighbours, the human nervous system would defy detailed prediction even if the matter of which it is made behaved according to classically determinate physical laws. To some people this may be a comforting thought. The idea is widespread that if any of our actions could be predicted from knowledge of the state of our brains, we would have to be denied (or excused) responsibility for them. Others might go further and argue that even if *in practice* nobody could make successful predictions of our actions, any suggestion that *in principle* they were physically determined would rule out the possibility that they could be determined by our conscious thinking and deciding. Our future actions in that case would be 'inevitable' (the argument runs), and we could take no more responsibility for them than for the future of the solar system. 'It ain't me fault, Judge, it's me glands', as the pretty girl is reputed to have said on an embarrassing occasion.

Plausible though it may seem, however, this conclusion does not follow. Consider first an analogy. To an electronics engineer, a computing machine set up to solve a mathematical equation is (for practical purposes) a physical system behaving according to determinate physical laws. In that sense, its

behaviour is completely

'determined' by physical causes. To the programmer or user of the machine, however, what matters is that its behaviour should be 'determined' by the problem it is solving. Is there a conflict here? Must the user either prove that the engineer's explanations are faulty or leave 'gaps' in the chainmesh of physical causes in order to justify his own claim? Of course not. The mathematical equation is not something outside the computing machinery that has to force its way in to exert an influence. It is something *embodied in* that machinery, in such a way that the computer's behaviour is determined *both* by physical forces *and* by the equation. The solving of the equation is the *significance* of the physical activity of the computer. So here the two different answers to the question 'What determines the behaviour?' are not rivals, but complementary. Each makes a point which is true and necessary in order to do justice to all the facts.

In the case of a human action, a similar argument applies. A complete physical explanation, showing how an action was determined by physical causes, would rule out determination by thought and decision only if these latter were some kind of external agencies that had to force their way into the chainmesh of physical causes in the brain. If, however, our conscious thinking and deciding were *embodied in the* workings of our brains, in the sense in which an equation is embodied in those of a computer, there would be no contradiction in saying that our behaviour was determined by our thinking and choosing, even if our brain mechanisms were as physically determinate as the solar system (which they probably are not).

What then of the suggestion that physical determinism would make our future 'inevitable'? Suppose for example that some superscientist *S* could examine every particle in the brain of Mr *A*, and all its environment. Suppose, on the basis of physical determinism, that he could work out (in principle, if not in practice) a completely detailed description (*D*) of the immediate future of *A*'s brain, and of the body controlled by it. By definition *D* is then what the observer *S* would be *correct to believe*, and *mistaken to deny*, about *A*'s future. In that sense, the future state described by *D* is *inevitable for S*.

So far, so good. But now what about Mr *A*? Is all of the future described by *D* in the same sense *inevitable for A*? Oddly enough it is not. The reason is simple.

Mechanistic brain science works on the assumption that everything Mr *A* sees, feels, thinks, or believes is represented in some way in some part of his brain, in the sense in which all the data for a calculation are represented in some way in some part of a computer. This means that according to mechanistic brain science itself, no change can take place in what *A* believes without some change taking place in the detailed state of his brain. It follows that *no completely detailed description of the immediate future of A's brain can be equally accurate, whether or not A believes it*. (If it were accurate beforehand, *A*'s believing it would necessarily bring about a change that would make it out of date. On the other hand, if it were 'corrected' so as to allow for the effects of *A*'s believing it, then it would become accurate if—and only if—*A* believed it. But then *A* would not be mistaken to disbelieve it, since his disbelieving it would prevent his brain from taking up the state it describes!) Thus, even on the mechanistic assumptions of brain science, there are some details of *A*'s (present and future) brainstate for which there does not exist a single determinate specification that *A* would be

both correct to believe, and mistaken to deny. In the sense used above, then, these details are *not* inevitable for *A*. They are for him to determine; and there is no complete specification of them, which unknown to *A*, has an unconditional claim to his assent (i.e. such that *A* would be correct to believe the specification, and mistaken to disbelieve it, if only he knew it). This situation clearly has an element of *relativity*. The view that a nonparticipant observer may be correct to take about someone's future is necessarily different in detail from the view that that person himself is correct to take. The two views are complementary, and do not contradict one another.

Notice that in this respect *A*'s brain is distinguished from all the rest of the physical world, even assuming that its matter is subject to the same deterministic physical laws. For future events in any other parts of the world (such as eclipses or sunrises) which are not causally connected with *A*'s Page 192

brain, there would exist just one detailed description with an unconditional claim to his assent. Whether he knew it or not, or liked it or not, there would be one and only one future scenario that he would be correct to believe and mistaken to disbelieve. No such inevitable scenario, however, exists for the detailed brainstates we have been considering—nor for any events in the rest of the world (such as *A*'s bodily actions) causally dependent upon them. On the contrary, for these brainstates there may exist several (or an infinite range of) alternative scenarios, each of which *A* would be equally correct to believe: for *his believing* would be one of the factors determining which scenario is correct. In that sense, these details of *A*'s future would not be inevitable for *A*, even on the strongest assumptions of physical determinism.

To guard against misunderstandings, two notes should be added. First, the above argument does not depend on assuming physical determinism to be true. It shows that even if determinism were true, it would be irrational to conclude from it that people's future actions were already inevitable for them, or to deny them responsibility for those actions on the grounds that they were predictable by others. But if, in line with present-day physics, the assumption of determinism is rejected, this would do nothing to weaken our argument. The point is that there is no *need* to invoke physical indeterminism in order to make room for human responsibility.

Secondly, our argument does not depend on whether *S* in fact *tells* Mr *A* his prediction *D*, nor on whether *A* is psychologically suggestible or countersuggestible. If nobody does tell *A*, then *D* will presumably be fulfilled to the letter. Our aim has been to show that this does not mean that *D* (unknown to *A*) had an unconditional *claim* to *A*'s assent. To prove this there is no need actually to offer *D* to *A*. It is enough to show that *D* could not have been embodied in *A*'s brain without causing changes that would render *D* itself false in detail. This proves that even if *A* does not hear of *D* until afterwards, *D* is not what *A* rationally 'ought' to have believed unconditionally if only he had known. *D*'s later fulfilment merely proves that *S* was correct in believing it. It does not prove that *A* would have been correct to believe the same; for the truth is that if *A* *had* believed it, both he and *S* would have been mistaken.

DEWEY, JOHN (18591952). American philosopher and educationalist, born at Burlington, Vermont. He went first to the University of Michigan (188494) and then to the University of Chicago (18941904), where he did much to promote a*functional point of view in psychology. This was well expressed in an influential paper on the reflex arc concept (1896) in which he laid stress on the function rather than the structure of*reflexes. In 1904, Dewey, whose interests had now shifted almost entirely to the philosophy of education, accepted the Chair at Teachers' College, Columbia, where he remained until 1930. His bestknown books are *Democracy and Education* (1916), *Human Nature and Conduct* (1922), *The Quest for Certainty* (1929) and *Art as Experience* (1934).

DIAGNOSIS. The use of characteristic signs of a generally established disease or abnormality. This is based on the notion that diseases and typical abnormalities have grouped 'syndromes' of characteristics, such that recognition of some enables us to predict the others, and may also suggest the underlying cause and appropriate treatment. Typical clinical signs or symptoms are, however, sometimes 'seen' when not present, especially when they are likely to accord with the prevailing or probable diagnosis. This can lead to spurious confirmation. The philosopher Sir Karl Popper has emphasized the importance of looking for *negative* or *disconfirming* evidence to check diagnoses and to stop the generation of spurious syndromes when exceptions are overlooked.

DICHROMATIC. Literally 'twocoloured'. Usually applied to the (rare cases) of people who have only two, rather than the normal three, retinal colour channels.

They can match any colour visible to them by adjusting the intensities of only two coloured lights, which are mixed. Thomas*Young showed in 1801 that normally *three* spectral colours (red, green, and blue) are needed to match all the spectral colours, and white, by adjusting the relative intensities of the three lights. Normal people are thus 'trichromats'. See COLOUR VISION: EYE MECHANISMS.

DIGITAL. From the Latin for 'finger'—hence 'digital' counting (on the fingers). 'Digital' essentially means representing states or carrying out mathematical or logical procedures in steps corresponding to the symbolic operations of a calculus.

A digital computer works in steps representing steps of logic or computing by means of a formal code. Because the symbols of logic or arithmetical calculation are discretely different from each other, digital computers require circuits having discrete states, which can be selected at great speed. Analogue computers, on the other hand, do not operate by coding into a symbolic system. Rather, they

manipulate continuous physical variables, following a change or representing a function by an equivalent change or function but of a different physical form (such as the line of a graph).

Page 193

Digital computers are far more versatile than analogue ones as, in principle, they can be programmed to perform any operation that can be stated. The same mechanism can readily be reprogrammed to perform very different operations; whereas, typically, analogue computers must be virtually rebuilt for different uses. Early analogue computers were relatively fast, because they did not go through many stepped operations, but modern digital computers can carry out up to 10⁹ operations per second.

It is an open question whether the brain is essentially analogue or digital. It is interesting that we are extremely weak at digital operations, such as complicated arithmetical problems, although these are easy to carry out mechanically, or electronically in pocket calculators, which far surpass human accuracy and speed. This may well suggest that the brain works analogically rather than digitally.

DIMINISHED RESPONSIBILITY. The McNaghten Rules. In English law until 1957 there was only one defence based on disease of the mind available to a defendant, that of insanity. In 1843 an authoritative pronouncement by all the judges answered questions put to them by the House of Lords in its legislative capacity.

McNaghten had been tried for the murder of Sir Robert Peel's private secretary, Edward Drummond, under the mistaken impression that he was shooting at Sir Robert himself. He was acquitted by the jury on the ground of insanity. The acquittal aroused widespread controversy, and was debated in the House of Lords, with the result that their Lordships put abstract questions to the judges. The judges gave their answer to the second question in the following terms: To establish a defence on the grounds of insanity, it must be clearly proved that, at the time of the committing of the act, the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong: (1843) 10 Cl. & F.200.

From the medical standpoint, this all-or-nothing approach to psychological functioning was already obsolete. It had also been shown that inability to distinguish between right and wrong was only one symptom of insanity, and that many mentally disturbed persons knew the difference between right and wrong. In 1838 Isaac Ray had published in the USA his work *A Treatise on Medical Jurisprudence of Insanity*, described in 1961 by a psychiatrist as the best book in the English language on forensic psychiatry: Diamond (1961) 14 Stan.L.R. 59, 63. Defence counsel had used this book at the trial of McNaghten, but to no effect.

Doe-Ray tests of insanity. In the United States the McNaghten Rules were adopted as the test of insanity in most states, but the state of New Hampshire was an exception. Judge Charles Doe, later chief justice of that state, began to correspond with Isaac Ray, an exchange of letters that continued from 1866 to 1872. One passage from Ray's work may be cited: 'Insanity is a disease, and, as is the

case with all other diseases, the fact of its existence is never established by a single diagnostic symptom, but by the whole body of symptoms, no particular one of which is present in every case.'

Convinced of the inadequacy of the McNaghten tests, Doe came to regard the question of insanity as one of fact to be left to the jury, and by 1869 had converted his brother judges in the state to that view (*State v. Pike* 49 N.H. 399). In a letter to Ray he wrote: 'Giving this matter to the jury leaves the way open for the reception of all progress in your science. One jury is not bound by the verdict of another.' Doe and Ray are thus left in harmonious juxtaposition.

Diminished responsibility in Scotland. The McNaghten Rules had never been accepted unreservedly in Scotland, and in the very decade in which Charles Doe had wrought a transformation in New Hampshire, Lord Deas initiated a new defence, proof of which led not to an acquittal, but to a verdict of culpable homicide instead of murder. This was in *HMA v. Dingwall* 1867 5 Irv. 466. The development did not arise from close contact with medical writing, and seemed out of character for the judge himself, for his general attitude tended towards rigidity and severity. It has even been suggested that his direction to the jury may have sprung from a respect for Hogmanay, as the defendant's fatal attack on his wife had followed bouts of excessive drinking at that season, a time apparently when many a reasonable Scot will consume inordinate quantities of whisky. Whatever the reasons for the new idea, Lord Deas persisted in it. Before his retirement in 1885, he had contributed six of the first nine reported cases embodying the new doctrine. In the third case he instructed the jury that a weak or diseased mind, not amounting to insanity, might competently form an element to be considered in the question between murder and culpable homicide (*HMA v. Granger* 1878 4 Coup. 86, 103). In the last of the six, he said that *Dingwall* was now the recognized law of the land (*HMA v. Gove* 1882 4 Coup. 598, 599). The new defence received the name of diminished responsibility in *HMA v. Edmonstone* 1909 2 SLT 223,224. In *HMA v. Savage* 1923 JC 49 a direction to the jury from Lord Justice Clerk (Alness) has come to be regarded as a *locus classicus*. He stressed that the doctrine must be applied with care, and that there must be aberration or weakness of the mind, some form of mental unsoundness, a state of mind bordering on insanity, rendering the defendant only partially responsible.

It has been argued by some distinguished writers on the law of Scotland that diminished responsibility operates merely in mitigation of sentence, and does not affect responsibility. Such a view is

Page 194

certainly not tenable in England, where Parliament created the defence in 1957.

Diminished responsibility in England. In England the Royal Commission on Capital Punishment, 194953, heard much evidence on the operation of the defence of diminished responsibility in Scotland, but made no recommendation for its adoption, regarding the matter as outside its terms of reference. In 1956, however, during a debate in the House of Commons on capital punishment, the Home Secretary undertook to consider the question further. This led to section 2(1) of the Homicide Act 1957, whereby:

Where a person kills or is a party to the killing of another, he shall not be convicted of murder if he was suffering from such abnormality of mind (whether arising from a condition of arrested or retarded development of mind or any inherent causes or induced by disease or injury) as substantially impaired his mental responsibility for his acts and omissions in doing or being a party to the killing.

The defence is called diminished responsibility in a marginal note to the section. The burden of proof is placed on the defence, as in Scotland and under the McNaghten Rules. In such cases, as in all instances where a legal burden of proof is placed on the defence, the defendant has to establish the defence on a balance of probability, or in more homely language that it is more likely than not that his responsibility is diminished. If so proved, murder is reduced to manslaughter, just as in Scotland it is reduced to culpable homicide. It applies only to murder, following the predominant Scottish view. A successful defence of insanity leads to a verdict of

'not guilty by reason of insanity'.

The introduction of this new defence, coupled with the abolition of capital punishment for murder by Parliament in 1965, has led to the virtual disappearance of the defence of insanity.

From the outset difficulties were found in directing the jury on the question of fact they had to determine under section 2(1). In *R. v. Spriggs* [1958] 1 QB 270, the trial judge read the section to the jury, reviewed in detail the evidence relevant to the defence, made no attempt to explain the various medical terms that had figured in the evidence, and gave the jury copies of the section as they retired. The Court of Criminal Appeal quoted the charge to the jury from a Scottish case, which consisted largely of a quotation from the charge to the jury in *Savage* mentioned above as a *locus classicus*. The court considered that the case had been put to the jury in the only way it could be put, and affirmed the conviction.

In *R. v. Walden* [1959] 43 Cr. App.R. 201, the trial judge construed the section as meaning: 'Poor fellow, he is not insane, but not far from it; his mental condition is one which is bordering on, but not amounting to insanity.' He gave the jury copies of the section. The Court of Criminal Appeal refused leave to appeal. Parliament had not defined 'abnormality of mind' or 'mental responsibility'. The reference to substantial impairment connoted a question of degree, and questions of degree are questions of fact in each case.

At this stage English juries were not receiving the necessary guidance: Charles Doe, while insisting that the question of mental disease was one of fact for the jury, had also stressed that the jury must be given some help. Help was forthcoming from the Court of Criminal Appeal in *R. v. Byrne* [1960] 2 QB 396. The court gave a definition of two important concepts in the section. 'Abnormality of mind' meant a state of mind so different from that of ordinary human beings that the reasonable man would term it abnormal. It covered the mind's activities in all its aspects—not only the perception of physical acts and matters and the ability to form a rational judgement whether an act is right or wrong, but also the ability to exercise willpower to control physical acts. 'Mental responsibility' pointed to a consideration of the extent to which the accused's mind is answerable for his physical acts; this must include a consideration of the extent of his ability to exercise willpower to control his physical acts.

Inability to exercise willpower to control such acts entitles the accused to the benefit of the section; difficulty in controlling such acts may do so, if great enough to amount to substantial impairment. The jury must decide, though there is no scientific certainty to guide them. Thus the court in *Byrne* clearly decided that an irresistible impulse falls within the concept of diminished responsibility, a status it never achieved under the McNaghten Rules.

The effect of *Byrne* was soon apparent. In *Rose v. Reginam* [1961] 45 Cr. App. R. 102, a summingup that had passed muster in *Walden* now led to a successful appeal. In *R. v. Terry* [1961] 2 QB 314, a summingup that failed to explain section 2(1) on the lines laid down in *Byrne* was held deficient. Further, the jury had been handed a transcript of volumes of medical evidence without explanation. It is of course the duty of the trial judge to take the jury through the evidence, trying to synthesize it and render it easier to digest. The conviction was in fact upheld as the crucial question was held to be whether the accused was shamming, and on this matter the summingup was adequate. In *R. v. Gomez* [1964] 48 Cr. App. R. 310, a summingup to the jury by Judge Paull on similar lines to that in *Walden* was again held inadequate: the proper course was to tell the jury what in law the section means, and what are the ingredients in the section, and then direct them on the evidence. The conviction was reduced to manslaughter. In *Walton v. R.* [1978] AC 788, the Privy Council put the clock back to *Walden* by indicating that the main question before the jury was whether the state of mind of the defendant was bordering on but not amounting to insanity, supporting this view by a quotation from *Byrne* itself. It is submitted that this is oversimplified, and regard should be had to the more thorough examination of the question demanded Page 195

by *Byrne* rather than to an isolated passage taken out of context.

Although the question is one that the jury must decide, if they ignore unchallenged medical evidence that all points to substantial impairment, an appellate court may reduce the conviction to manslaughter, on the ground that the verdict of murder is unsafe or unsatisfactory, as in *R. v. Matheson* [1958] 42 Cr. App. R. 145. The verdict may, however, be allowed to stand if the medical evidence was challenged in cross-examination, as in *R. v. Latham* [1965] Cr.L.R. 434, or the solitary expert witness in the case, who considers the impairment to have been substantial, is unsupported by objective evidence of any history of mental disorder, as in *Walton* (above).

An issue of considerable importance is the position of one diagnosed as *psychopathic personality as defined by the Mental Health Act 1959. In the case of *Fenton* (1975, 61 Cr. App. R. 261) it was concluded that psychopathic personality was no defence under the terms of the Homicide Act 1957, regardless of whether the accused was affected by alcohol at the time of his offence. Furthermore, as intoxication with drink or drugs cannot be regarded as an 'inherent cause' of mental abnormality, an attempt to reduce the verdict to manslaughter in place of murder on the ground that the accused was drunk at the time of the killing will not succeed.

Nevertheless, the introduction of the defence of diminished responsibility has undoubtedly had beneficial effects. This is because psychiatrists have adapted themselves to giving opinions in accordance with the legal formula, vague and unscientific as it undoubtedly is.

Proposals for reform. The Butler Committee on Mentally Abnormal Offenders, in their report of 1975, Cmnd. 6244, recognizing the difficulties under which experts were labouring, proposed an alteration in the wording of section 2(1), substituting after the word 'murder', 'if there is medical or other evidence that he was suffering from a form of mental disorder as defined in section 4 of the Mental Health Act 1959, and if, in the opinion of the jury, the mental disorder was such as to be an extenuating circumstance which ought to reduce the offence to manslaughter'. The Committee claims that this amendment would provide a firm base for testifying psychiatrists to diagnose mental state. The claim is justified. The Mental Health Act 1959 contains definitions of mental disorder, psychopathic disorder, subnormality, and severe subnormality, so that the expert is now operating in a familiar field; and the Mental Health Act 1983 does not materially alter this situation. Although mental disorder includes psychopathic disorder as one of the defined components, as already mentioned, it is unlikely that this diagnosis will be admissible as a defence of diminished responsibility under the Homicide Act 1957.

The Criminal Law Revision Committee in its Fourteenth Report of 1980 (Cmnd. 7844) recommends that the Butler wording should be changed so that instead of the need for the jury to seek 'an extenuating circumstance' their quest should be for 'a substantial enough reason'.

The Fourteenth Report recommends, as the Committee had recommended in its Eleventh Report of 1972, and the Butler Committee in 1975, that there should be no burden of proof on a defendant raising a plea of insanity or diminished responsibility: the burden of proof should be on the prosecution to disprove the defence beyond reasonable doubt.

See also CRIMINOLOGY.

R. N. G.

DIOPTER. Unit for the power of a lens or prism. For a 'positive' (convex) lens, 1 diopter brings parallel light to a focus at a distance of 1 metre from the centre of the lens; a 2diopter lens a focal length of 0.5 metre, and so on.

DIPLOPIA. Double vision, resulting from failure to combine or 'fuse' the images from the two eyes. This often, though not always, gives total loss of stereoscopic depth perception. It may be due to squint (strabismus), or, temporarily, to tiredness, or to temporary or permanent disturbance of the central neural processes.

See also EYE DEFECTS AND THEIR CORRECTION.

DISHABITUATION. See INVERTEBRATE LEARNING AND INTELLIGENCE.

DISPLACEMENT ACTIVITY. During courtship a male threespined stickleback (*Gasterosteus aculeatus*) is often observed to break off his display to the female. He swims to his empty nest on the substrate and fans water through it. He may also creep through the nest before returning to display to the female. These nestdirected activities are normally associated with the parental care of eggs (carried out by the male in this species) and as such are considered 'out of context' or

'irrelevant' to courtship. Behaviour of this kind is called a displacement activity.

Displacement activities often occur when an animal has a tendency for more than one incompatible behaviour, such as approach and avoidance (motivational conflict), or when it is prevented from reaching a goal such as an anticipated food reward (thwarting). In stickleback courtship it is thought that the female represents a stimulus for both aggression and for mating. Other examples are groundpecking (feeding) during fights by red junglefowl (*Gallus gallus*), billwiping during fights by great tits (*Parus major*), and preening during approachavoidance conflict by the common chaffinch (*Fringilla coelebs*). Many human actions, such as excessive drinking, nibbling food, or manipulation of the face in stressful social contexts, seem to be similar to the displacement activities seen in other animals. There is an extensive ethological literature on displacement activities

Page 196

because of the clues they are thought to provide about mechanisms of motivation, and because of their possible importance in communication displays (see also ETHOLOGY).

In many cases displacement activities have been found to have a function related to their context. For example, it has been shown that stickleback courtship does not proceed to a normal completion if displacement fanning is prevented. Similarly groundpecking by red jungle fowl has an important influence on the outcome of a fight.

In other cases the activity has a function even if not relevant to the context: for example, billwiping by great tits removes sloughed material from the beak, although this is not relevant to a territorial dispute. But our judgement of irrelevance may simply indicate ignorance of the true situation.

While the time of occurrence and duration of displacement activities is mainly dependent on causal factors relevant to the context (conflict or thwarting) in which they occur, their form and intensity is dictated largely by causal factors related to the displacement activities themselves. Thus displacement preening in chaffinches is more vigorous when the feathers are made dirty, but the timing of preening bouts is hardly affected. One explanation for this is that displacement activities are disinhibited, and it is based on the idea that during normal behaviour the current activity inhibits other incompatible activities for which the causal factors are also present. During a motivational conflict the incompatible tendencies suppress one another, leaving the displacement activity to occur by default, governed in performance by its usual causal factors but delimited in time by the context. An empirical test of this explanation involves showing that the amount of displacement activity seen, depends on the ratio of the conflicting tendencies rather than on their absolute value. This has been demonstrated in terns (*Sterna hirundo*), sticklebacks, chaffinches, and great tits;

but there are other attributes of displacement activities which are not accounted for by this explanation. In chaffinches the precise preening movements seen during approachavoidance conflict depend on the context as well as on causal factors relevant to preening. In great tits displacement activities during fights are affected by the absolute levels of competing tendencies as well as by the

ratio.

Displacement activities often appear hurried, stereotyped, or incomplete when compared with similar behaviour occurring in its normal context. They share some of the characteristics of a variety of other behavioural effects seen when animals are thwarted. With rats, the omission of an expected food reward may lead to increased motivated behaviour towards the absent goal (e.g. increased running speed to the goal box of a runway), excessive performance of an alternative activity such as drinking or woodgnawing, or a generalized increase in the rate of activities normally seen between deliveries of food. Such phenomena are sometimes attributed to a generalized state, frustration, caused by thwarting. The excessive behaviour induced by certain intermittent reward schedules (adjunctive behaviour) may also be a related phenomenon, though such schedule-induced activities differ in some respects from frustration effects: for example, they are not abolished by minor tranquillizing drugs. Displacement activities and frustration effects may represent a class of 'coping behaviour', enabling an animal to resolve a situation in which it is unable, due to inadequate or contradictory information, to decide what to do next.

Apart from intention movements and compromise postures, many of the displays seen in social behaviour, especially in the courtship or agonistic behaviour of vertebrates, appear to incorporate movements which are derived from activities not relevant to the context of the display. For example, in birds many threat displays are very similar to preening movements. This has given rise to the idea that displacement activities may have been important in the evolutionary origin of social communication. Because of what they can reveal about the motivational state of the performer, it has been thought probable that displacement activities are attended to by other individuals to whom such information might be useful, and that it is often advantageous to the performer to inform others of its motivational state. It has been argued that this 'telltale' of internal state has become established as a means of communication, with natural selection leading to emphasis of the original signal (ritualization) and probably to the emancipation of the activity from its original motivational mechanism. More recently it has been pointed out by those interested in the game-theoretical analysis of social transactions between animals, that the contestants often need to conceal their true motivational state (e.g. not show fear to an opponent) or to mislead others (e.g. threaten to attack while contemplating flight). The highly redundant nature of derived displays, which are usually stereotyped, rhythmic, and repetitive, is characteristic of persuasive rather than informative signals. Persuasive signals are to be expected where it is advantageous to the sender to manipulate recipients of the message, but advantageous to the recipients to avoid manipulation. Animals that cooperate in the exchange of reliable information to their mutual advantage might be expected to communicate in 'conspiratorial whispers', rather than by means of conspicuous announcements, since signals are likely to be intercepted by animals other than the intended recipient, to the disadvantage of the sender. For example, some predators make use of the courtship displays of their prey in order to locate them. This currently controversial area is discussed in detail by Krebs and Dawkins (1984). Whatever the explanation, any animal signals are, apparently, derived from other actions in the repertoire which have no connection with the motivational context of the display.

DISSOCIATION OF THE PERSONALITY. Two—or more—mental processes can be said to be dissociated if they coexist or alternate without becoming connected or influencing one another. Prior to Sigmund*Freud and to the discovery of the*Unconscious, dissociation was a term much used by psychiatrists to describe and, by implication, to explain many neurotic symptoms; the underlying assumption having been that neurotics suffered from some inherent or constitutional weakness of the integrative function, as a result of which they were liable to perform actions, think thoughts, dream day and night dreams, which were unconnected with and dissociated from their usual, real, or true personalities. However, since Freud and the general abandonment of the assumption that the neuroses are the result of a 'functional', constitutional defect, the concept of dissociation has, with one exception, fallen into disuse, terms like 'repression', 'isolation', 'splitting' being preferred to describe those defence mechanisms by which a person, for specific though usually unconscious reasons, keeps wishes, actions, images, memories, etc., outside his selfimage or*ego.

The exception consists of a group of phenomena which have it in common that the subject maintains for a considerable length of time some line or course of action in which he appears not to be actuated by his usual self—or, alternatively, his usual self seems not to have access to the recent memories that one would normally expect him to have. Contemporary psychiatry categorizes such phenomena as 'hysterical dissociations', the bestknown examples being sleepwalking (see SOMNAMBULISM), trances, posthypnotic suggestions, fugues (in which the subject wanders off, not knowing who or where he is), loss of memory (hysterical*amnesia), in which the subject has a gap in his memory for some finite, recent period of time, and split, dual, or multiple personality, in which the subject appears to change from one person to another.

The last of these, dissociation of the personality, is a puzzling and, indeed, disturbing phenomenon, since it calls into question a basic assumption we all make about human nature, namely that for every body there is but one person; that each of us, despite the passage of time and changes in mood and activity, remains the same person, with a single biography and store of memories. Given the fact that all social relations and contracts presume consistency and unity of personality, it is hardly surprising that the occasional person who claims or appears to change into someone else becomes an object of concern to the police, of curiosity to the psychiatric profession, and of fascination to the general public.

Dissociation of the personality is not only bizarre but also extremely rare—so rare, indeed, that one has to take seriously the possibility that it may be a social and psychiatric artefact: i.e. that it can only occur if (i) prevailing views on the nature of personality make it conceivable that two personalities can occupy the same bodily frame, and (ii) the potential case of split or multiple personality encounters a psychiatrist who believes in, or is already interested in, dissociation of the personality.

In fact, the great majority of reported cases of multiple personality date from between 1840 and 1910

—that is, from after demoniacal possession had ceased to be a plausible, scientifically respectable explanation of sudden, extraordinary changes in personality until the time at which psychoanalytical ideas began to have an impact.

During this period two conditions existed which, it seems likely, must have facilitated the diagnosis of multiple personality. First, the prevailing Victorian conventions of reticence must have made it unthinkable that patients should tell, or that their doctors should enquire into, those intimate physical details of their lives which would have established continuity of bodily feeling despite massive changes in mental feeling; if *cogito, ergo sum* were the basis of identity, then indeed personality and identity could change if thought changed, in a way that could not happen if patient and physician believed that the ground of being is located in the body.

Secondly, there was obliviousness to what is nowadays called*transference and countertransference, and in particular, to the fact that patients can and will produce symptoms to please their physicians. The great majority of the physicians reporting cases of multiple personality have been men, and the cases they have reported have been women younger than themselves. For instance, Dr Morton Prince of Boston, Massachusetts, was 44 when, in 1898, he was consulted by Sally Beauchamp, a young, single woman aged 23, who suffered from various nervous disorders. During the next seven years, three further personalities emerged in or from her, two of them while Dr Prince was hypnotizing her, and in 1908 he described his treatment of the foursome, whom he called collectively 'the family', in his classic *The Dissociation of a Personality*. In view of the fact that Dr Prince had already published papers on double personality and was widely known to be interested in the subject, and that Miss Beauchamp is on record as pleading to be hypnotized by him—'And I do want you, please, please, to hypnotize me again. You know it is the only thing that has ever helped me ...'—it is hard to resist the conclusion that Miss Beauchamp was obliging Dr Prince by formulating her experiences in terms that accorded with his known enthusiasms, and that both were erotically more attached to one another than the proprieties of New England at the turn of the century allowed either to realize. 'There was

Page 198

over her spine a "hypnogenetic point", pressure upon which always caused a thrill to run through her that weakened her will and induced hypnotic sleep.'

Rather similarly, most of the work done on multiple personality by the French neurologist Pierre*Janet was with women—notably Lucie, Léonie, and Rose—who regularly produced new or subpersonalities during hypnotic sessions. Janet, incidentally, distinguished clearly between 'roles' played by hypnotic subjects in order to please their hypnotist and new, unknown personalities which emerge spontaneously during hypnosis, particularly as a return to childhood. Presumably Janet was describing as dissociated personalities what contemporary psychiatrists and analysts would call revivals of repressed memories. Janet believed that the new personality emerging during hypnosis was more nearly the real person than the one which the patient originally presented, and that it was therapeutically helpful to name an emergent personality.

Both Prince and Janet believed that the self is not a pristine unity but an entity achieved by integration of 'simultaneous psychological existences', and that, therefore, multiple personalities and dissociated states generally were due to failures in integration. Contemporary psychoanalysis and psychiatry tends to take the opposite view: that the self is a pristine unity but uses defence mechanisms, notably repression, which make it unconscious of much of its total activity. As a result, many of the phenomena which Janet, Prince, and other nineteenth-century physicians described in terms of dissociation of the personality are nowadays described in terms of repression, splitting of the ego, etc.

This change seems to have occurred around 1910 and must presumably have been due to the impact of Freud's more dynamic, more biological, more sexual view of human nature. According to H. F. Ellenberger (1970), 'after 1910 there was a wave of reaction against the concept of multiple personality. It was alleged that the investigators, from Despine to Prince, had been duped by mythomaniac patients and that they had involuntarily shaped the manifestations they were observing.' And, although Ellenberger reports a slight revival of interest in the subject, contemporary textbooks of psychiatry are notably cautious and uncertain in their approach to dissociation of personality and to hysterical dissociation states generally. Henderson and Gillespie, in their *Textbook of Psychiatry* (9th edn., 1962), give only two paragraphs to multiple personality and the only two clinical examples they give date from the nineteenth century, while the emphasis in their paragraphs on hysterical dissociation states generally is on their rarity, on their purposiveness, which is usually transparent to observers but not to the subject himself, and on their dependence on gullibility. Explaining their rarity, Henderson and Gillespie remark, 'Both the public and their doctors have become more sophisticated.' Hysterical dissociation states, including dissociation of the personality, seem indeed to have more to do with the psychology of deception and self-deception than with any innate or acquired incapacity for integration. In the second half of the nineteenth century it seems to have been possible, in some circles at least, to evoke concern among friends and family and earn attention, if not effective treatment, from physicians by having trances, fugues, losing one's memory, or being taken over by another personality; but in the second half of the twentieth century less dramatic and more subtle signals of distress became the order of the day.

DISTORTION. Strictly, nothing can be distorted—it is what it is. A ruler or straight edge is, however, said to be distorted when it produces aberrant measures, or curved lines when straight lines are required. 'Distortion' thus has a connotation of error or discrepancy from what is needed or desired.

Perceptual distortions include the classical visual 'distortion illusions' (see ILLUSIONS). Distortions

of memory tend towards the familiar, and towards social norms (see BARTLETT, F. C., and his book *Remembering*, 1932). It is of course a deep question how far *all* perception and knowledge is a distortion, or discrepancy, from physical reality—as physics describes things very differently from how they appear.

DISTRACTION. See ATTENTION.

DIVER PERFORMANCE. The professional diver has probably the most hostile working environment on earth—or indeed off it, according to Scott Carpenter, who has been both an astronaut and an aquanaut and rates the underwater environment as the more hostile. Not only must the diver take along his own breathing mixture, but if he breathes air he is likely to suffer the dangerous intoxication of nitrogen narcosis at depths below 30 metres; if he breathes pure oxygen he is likely to suffer from convulsions at depths exceeding 912 metres; and even breathing oxyhelium he is liable to have problems in voice communication and to find his performance impaired if he goes much deeper than 300 metres. He must either carry his supply of breathing mixture with him on his back, and risk it running out, or must be attached by an umbilical cord to some more generous source, with all the attendant risks of snagging and tangling and the dangers resulting from having the umbilical cord cut.

He will be relatively weightless, which might seem to be an advantage when it comes to moving about, but this presents real problems. If he is Page 199

required to exert any great physical pressure to turn a wrench or wield a hammer, it is all too likely that he will turn, the wrench remaining where it is. Underwater vision is severely restricted by the tunnelling effect of refraction through his face mask, if indeed he is fortunate enough to be working under conditions that allow him to see anything. He is often required to work under conditions of zero visibility, operating by touch alone.

A commercial diver will expect to have to work under very cold conditions. While suits heated by a constant flow of warm water may be available, they are by no means the rule. Similarly, although a wide range of diving gloves exists, none appears to be really adequate under nearfreezing conditions. Communication presents a further problem. The diver's voice is likely to be distorted by pressure and even further distorted if he is breathing an oxyhelium mixture. Helium unscramblers help, but are very far from perfect.

Having successfully completed a job under water, the problems are far from over. As the diver breathes air or oxyhelium at pressure, the nitrogen from the air or the helium from the oxyhelium is absorbed by his blood and body tissue. If he surfaces too rapidly, the gas forms bubbles in his tissue and bloodstream, leading to decompression sickness, otherwise known as 'the bends'. These may range from relatively minor joint pains (the niggles) to symptoms associated with breathing (the chokes), and to impairment of the central nervous system, producing motor disability (the staggers), pain, and possibly death. The bends can be avoided provided the diver surfaces slowly enough, but if he has been working at a depth of several hundred metres, decompression is likely to take a matter of days. In order to cope with this problem it is common for divers having a major job to do at depth to live at pressure in a decompression chamber, being transported to and from the job every day by

means of a submersible decompression chamber that can be locked on to or detached from the main chamber on board the ship or rig. After a week of living at pressure the diver will spend the next week or so decompressing before taking some well-earned leave.

Socially, a diver's life is likely to be a rather curious one: unless he limits himself to inshore harbour work, periods out on an oil rig or pipelaying barge are likely to alternate with periods of leave. If he is working on a rig, he may have long periods of inactivity followed by an emergency and a requirement suddenly to dive to a considerable depth. If he is working on a barge, he may be required to operate under saturation for many days. Under these conditions it is essential to be able to maintain good relations with fellow divers.

Diving is a dangerous occupation even if the diver takes good care to breathe the right gas mixture and maintain the right working temperatures and the appropriate decompression schedule. He is working in an environment in which accidents are all too common, even out of the water. Under water, a minor accident can be fatal. Divers are very well paid—and so they should be.

DODGE, RAYMOND (1871-1942). American experimental psychologist, born in Woburn, Massachusetts, the son of a physician. He was educated at Williams College, where he obtained his degree, but failed to gain admission to Harvard. He then spent several years in Germany working with Benno Erdmann in Halle, where he obtained his doctorate and jointly with Erdmann published a book on the experimental psychology of reading (1898), which was a classic in its day. He returned to America in 1898 and became a professor at the Wesleyan University in Middletown, Connecticut, where he became well known among psychologists for his originality and skill in psychological instrumentation and research. (Erdmann told him that he should have become an engineer!) Dodge saw service in the First World War and invented an instrument for testing, selecting, and training gunpointers, which found wide application. He also worked on the psychological effects of alcohol. He later became chairman of the division of anthropology and psychology of the National Research Council in Washington.

After the war, Dodge became a professor at the Institute of Psychology at Yale and continued to pursue his early interests on the relation of eye movements to perception and on the conditions of human variability, about which he published several books, the best known of which is *Conditions and Consequences of Human Variability* (1931).

DOMINANCE, HAND. See HANDEDNESS.

DOPAMINE NEURONES IN THE BRAIN. Dopamine neurones are one type of a class of neurones all of which use biogenic amines as neurotransmitters.

These have been identified as adrenaline, noradrenaline, dopamine, and serotonin. A common feature of these groups is that a comparatively small number of neurones of each type in the brainstem give rise to a highly branched network of ascending and descending fibres of very fine calibre. These fibres carry action potentials (see NERVOUS SYSTEM) of low frequency and slow conduction velocity. The postsynaptic effects of their transmitters are slowly mediated by chemical reactions, in contrast to more 'classical' neurotransmitters such as acetylcholine, which act extremely rapidly by means of the opening of specific ionic channels to carry current.

Anatomically there appears to be a high degree of connections between some of these neurone groups, Page 200

allowing for mutual interaction of function. The noradrenaline and serotonin neurones innervate a vast area of tissue throughout the brain and spinal cord. The adrenaline and dopamine groups on the other hand are somewhat more restricted in their anatomical distribution and their functions are likely to be correspondingly more specific.

The entire dopamine projection system arises from only a few thousand neurones located in the midbrain (see NERVOUS SYSTEM for a description of brain structure). One subgroup, the substantia nigra, innervates chiefly the caudate nucleus and putamen which lie in the basal ganglia—a brain region which controls movement. The substantia nigra also contains a nondopamine neurone population by means of which it is brought into close relation to other sensory and motor brain regions. Degeneration of the dopamine neurones of substantia nigra has been found to occur in Parkinson's disease, a condition characterized by poverty of movement (hypokinesia), tremor, and rigidity. It seems likely, then, that these symptoms are related to disturbance in the coordination of neural activity in these circuits. Several observations strongly suggest that in Parkinson's disease both the basal ganglia and thalamus are concerned with the appearance of tremor and rigidity. It is probable that globus pallidus (a subregion of the basal ganglia) is more concerned with the production of rigidity, while the thalamus is concerned with tremor. Successful neurosurgical treatment of these symptoms can be achieved by destroying small areas of these parts of the brain. On the other hand, it seems that the hypokinesia of Parkinsonism is due to degeneration of dopaminergic neurones. Thus it seems that there is a distinction between those symptoms in the Parkinsonian syndrome which are due to dopamine, and those due to nondopamine neurones. Indeed, symptoms of hypokinesia can occur independently of rigidity and tremor. Hypokinesia can be successfully treated by giving the patient levodopa, an amino acid which is taken up in the brain and converted to the neurotransmitter dopamine in those dopamine neurones not affected by the disease.

The other main dopamine subgroup of neurones innervates various nuclei in the limbic system, including the amygdala. They are likely to be closely involved in the organism's emotional response to the environment. The same dopamine group also provides an innervation to important areas of the cerebral cortex—the frontal and temporal lobe cortex. Both these areas (particularly the latter) are

targets for convergence of association fibres from extremely wide expanses of neocortex. They therefore provide potential anatomical structures in which the highest of cortical functions can be carried out. In man they are likely to be involved in the functions of memory, intellect, and personality. Dopamine neurones innervating these cortical regions also receive inputs from hypothalamic areas and the basal forebrain. These regions appear to be closely involved in motivation, learning, and rewarding mechanisms.*Schizophrenia is a condition which appears to be sensitive to the action of drugs that act on brain areas innervated by dopamine neurones. Drugs which act more selectively on only the limbic and cortical dopamine systems are also antipsychotic. Thus it may be that disturbance of these neurones, particularly those related to the amygdala and the temporal lobe cortex, may play an important part in the development of this condition.

O. T. P.

DOPPELGÄ NGER, or autoscopy, is the term given to the experience of meeting one's own 'double'. The apparition takes the form of a*mirror image of the viewer, facing him and just beyond arm's reach. It is lifesized and may move. Indeed, it usually replicates the viewer's posture, facial expressions, and movements as though it were his reflection. But beyond these features, reported experiences show several differences from the stereotype of popular imagination. First, the image is usually transparent: it has been described as being 'like jelly', or like a film projected on glass. (But it is not blurred or misty—its details are quite clear.) Secondly, it is generally monochromatic; if colour is observed, it is described as dull or 'washed out'. And thirdly, although the apparition may be inferred to include the whole figure, only the face, or head and trunk, are commonly 'seen'.

As reported by normal people, *doppelgä nger* experiences occur most often late at night or at dawn. They are rare, occurring during periods of*stress or fatigue and in conjunction with disturbed consciousness. (However, the first recorded account, which is attributed to Aristotle, describes a man who could not go out for a walk without meeting his 'double'.) A *doppelgä nger* episode is usually of very short duration with normal people, lasting only a few seconds. The experience is more common among delirious patients, among those with brain lesions in the parietooccipital regions, or, most notably, among epileptics, where it may be part of a complex partial seizure. Autoscopy can occasionally be a feature of an attack of migraine, sometimes in association with a sense of distortion of a part of the body.

The *doppelgä nger* experience, when the subject sees himself standing behind his back or in another room, is referred to as an extracampine*hallucination.

The fact that an apparition is presumed in most cultures to be a visitor from the grave, a spirit of the dead, may well account for the morbid response accorded the *doppelgä nger* experience. After all, the subject is apparently being accosted by his own ghost, which not only raises some knotty questions about the nature of time, but bears the distinct implication that the subject's own time is up. Indeed, the German folkbelief was that the *doppelgä nger* was a harbinger of death. Like many old wives' tales, this superstitious belief may have had a factual basis; for in those cases where Page 201

doppelgänger is associated with severe brain injury or cerebral thrombosis, the illness is often fatal.

The idea of a phantom 'double' has existed throughout recorded history, and still flourishes in superstitions, fairytales, and folklore throughout the world. It is taken seriously by some parapsychologists as an example of an out-of-body experience. It figures in many primitive religions, where the 'double' is assumed to be the person's soul. Witches and shamans put their 'doubles' to good use, sending them on occult errands or as representatives or intermediaries. But the *doppelgänger* concept has also intrigued sophisticated people, and induced in them a dread of the unknown and a morbid assumption of doom akin to the responses of primitive groups. Autoscopic phenomena have frequently been described in the literature of the Western world, always in terms of sinister foreboding or impending tragedy.

Descriptions have figured in the works of Dostoevsky, Kafka, de Maupassant, Edgar Allan Poe, Steinbeck, and Oscar Wilde. It is of interest that several of these suffered from epilepsy or cerebral disorder.

Doppelgänger experiences have attracted little medical or psychological study, despite widespread interest. Traditionally, the phenomenon has been classified as a visual hallucination, and its form can be examined in the same terms as other hallucinations. But an added dimension is that the experience is not limited to the visual modality; many subjects have reported that they could 'hear' and 'feel' their doubles. This multimodality suggests the intriguing possibility that *doppelgänger* may in some way represent an externalization or displacement of Sir Henry Head's 'body schema'. However, why should the apparition appear as a mirror image?

G. F. R.

DOUBLE VISION. See DIPLOPIA.

DOUBTING. The questioning of accepted beliefs or opinions. In Greek philosophy such doubting was erected into a philosophical system by the sceptics, such as Pyrrho of Elis (*fl. c.* 300 BC), who argued that all truth is unknowable and that the only appropriate attitude for life is one of total suspension of belief. In the seventeenth century, Descartes's famous 'method of doubt' involved withholding assent from all matters which allow even the smallest possibility of doubt. Thus all information derived from the senses is potentially unreliable; further, we cannot know whether we are awake or asleep, so that even such a simple statement as 'I am holding this piece of paper' is open to doubt; and, finally, there may be a malicious all-powerful demon who is bent on deceiving us, and so 'the earth, sky and all external things' may be merely delusions. Cartesian doubt is not, however, an end in itself, but it is designed to clear the way for the establishing of a secure system of knowledge built on indubitable foundations.

The questioning of accepted beliefs and preconceived opinions can be a valuable exercise both in philosophy and in science generally (see COMMON SENSE). It seems, however, that to insist on indubitability as a criterion of the acceptability of beliefs is to insist on an impossibly high standard. Immunity to all conceivable doubt is something that belongs to only a handful of very simple and relatively unexciting propositions, such as (perhaps) 'two and two make four', or Descartes's famous

'*cogito*' ('I am thinking'); and it does not seem possible to construct any worthwhile system of knowledge on such meagre foundations.

The difficulty of seriously maintaining a position of philosophical scepticism has been highlighted by G. E.*Moore in the twentieth century, and earlier by David*Hume.

Hume observed that 'Nature is always too strong for principle, and though a Pyrrhonian may throw himself and others into a momentary ... confusion by his profound reasonings, the first and most trivial event in life will put to flight all his doubts' (*Enquiry Concerning Human Understanding*, 1748).

J. G. C.

DOWN'S SYNDROME. Mental retardation due to a genetic abnormality which is believed to occur during the early stages of cell division during embryological development, some cells having too few or too many chromosomes. Cells having too few chromosomes generally die; but those with too many may survive and produce an individual with extra chromosomes in all the cells of the body. There are, however, severe mental and physical problems.

The characteristics of Down's syndrome (or 'mongolism') are: a flattened face, a thick tongue which may be too large for the mouth, extra folds of the eyelids, uncoordinated movements, and intelligence limited to an IQ of between 20 and 60.

Raised activity of the enzyme URNAP, indicates an 80% chance of Down's syndrome. The triplmarker test for Down's syndrome, and anencephaly and spins bifida, counts the alpha fetoprotein level. Best results are obtained at 1618 weeks of pregnancy. The incidence of Down's syndrome is higher in children born of older parents, especially of an older mother.

See also MENTAL HANDICAP; PENROSE, LIONEL SHARPLES; SUBNORMALITY.

DREAMING. In our*sleep we all intermittently experience insanity. Some of our dreams differ so from normal awareness that they have often been attributed to the departure of the soul to another world, or to the visitation of alien beings, such as angels. Since earliest history, dreams have been interpreted in order to give guidance for the future, up to the dream books of the nineteenth century and punters' guides of the twentieth. In the 1950s Nathaniel Kleitman of Chicago, with E. Aserinsky and W. Dement, opened an era of laboratory techniques for studying dreams.

Dreams are often misleadingly defined as successions of visual images, but these are merely common accompaniments. A dream is an experi

Page 202

ence of living in a fantasy world in which things happen, emotions are felt, actions are carried out, people are present, with all the waking sensations coming and going.

The congenitally blind have dreams that are no less vivid even though they see nothing. Visual images

in dreams are as often in colour as in real life.

Dement and Kleitman introduced the technique of awakening and questioning volunteers about possible dreams at critically sensitive moments during sleep, and found that during periods of sleep accompanied by rapid eye movements (REMs) detailed dream reports could usually be elicited, whereas recall from other times during sleep was meagre. Dement wakened some further volunteers repeatedly as soon as their REMs began, and later found a compensatory increase of sleep with REMs.

He proposed that he had deprived them of dreams, that they needed to dream, and that if they did not they might become insane. This notion achieved wide circulation but has not since been supported. We may need to dream, but no one has yet devised an experiment to see whether we have such psychological needs at night.

There are two kinds of sleep; they came to be called nonrapid eye movement (NREM or orthodox) and rapid eye movement (REM or paradoxical) sleep. In 1962

David Foulkes of Chicago asked of his subjects not the leading question, 'Have you been dreaming?' but instead, 'What was passing through your mind?' He found that NREM sleep allowed recall almost as often as REM sleep, but its less colourful content was more often characterized as 'thinking' and, despite considerable overlap, it was possible to distinguish between the 'dream' reports from REM sleep and those from NREM sleep. Typical dreams can be elicited especially easily from NREM sleep at the end of the night and when first falling asleep. The brief dreamlets that come as we drowsily drift to sleep are known as *hypnagogic hallucinations* or images.

In subsequent research Molinari and Foulkes made awakenings from REM sleep both just after one of the intermittent bursts of REMs and when over thirty seconds of ocular quiescence had elapsed during REM sleep, and sought details of mental life just prior to waking. The first type of awakenings elicited many 'primary' visual and other experiences (for example, a little brother suddenly vomiting 'on my shoulder'), the second elicited 'secondary cognitive elaborations' resembling the thinking characteristic of NREM sleep. Jerky eye movements, limb twitches, face twitches, middle ear muscle twitches, and sudden respiratory changes are all *phasic* components of REM sleep, whereas muscle relaxation and penile erections are *tonic* features. It seems that the special 'dream' elements are injected intermittently in company with the phasic components of REM sleep.

As the night progresses, the REM periods contain a higher rate of phasic components, and dreams are more active and less passive in quality. Sleeping pills diminish the phasic elements and dreams become more passive. There has been a lot of controversy about such relations between bodily events and the contents of a dream.

While the majority of the REMs certainly cannot be ascribed to scanning the visual field of a dreamworld, there are occasional large eye movements that do seem to bear a relation to described dream content. Closer correspondence has been found for movements of the limbs: Jouvet made lesions in the lower brains of cats so that they were no longer paralysed during REM sleep, and they

rose up and appeared to the observer to be acting out their dreams. There is certainly a strong correlation between dream emotionality and heart rate fluctuations or skin potential fluctuations (see ELECRODERMAL ACTIVITY), while in anxiety-ridden dreams there is loss of the usual penile erections.

The intensified dreaming qualities to the mental life that accompanies each REM sleep period about every 90-100 minutes led to findings that, while awake and in unchanging environments, people engage in intensified oral activity and have more daydreaming qualities to their thoughts according to a daytime cycle of 90-100

minutes. Daydreaming and nightdreaming are both associated with a 90-100 minute rhythm.

The term 'nightmare' is today used for dreams that occur during REM sleep, usually in the later night, and in which a series of events is associated with anxiety. As the sleeper awakens from his nightmare, he is often aware of the inability to move that characterizes REM sleep. On the other hand, night terrors arise in the early night, from NREM sleep with large slow electrical brain waves. They involve brief and less elaborately detailed experiences of entrapment, of being choked or attacked, often with shrieking, sitting up, or sleepwalking (see SOMNAMBULISM), and tremendous acceleration of the heart. Both nightmares and night terrors occur unpredictably in even the most emotionally stable people, but become more frequent when there is greater daytime anxiety; they are frequent among wartime battle evacuees and night terrors are commonly experienced by children aged 10-14. Likewise, those who are depressed by day have dreams by night that contain themes of failure and loss.

Environmental circumstances influence dream content. Dreams reported after awakenings by investigators in the home have more aggressive, friendly, sexual, or success and failure elements than those reported in the laboratory; but in both cases most are duller than would be supposed. Anxiety-provoking films seen prior to sleep can lead to dreams containing related themes. Events occurring around the sleeper during dreams are often incorporated, so that, for example, the words

'Robert, Robert, Robert' spoken to a sleeper led to his reporting a dream about a 'distorted rabbit'. Dream reports from successive periods of REM

Page 203

sleep in a single night can be distinguished from those of other nights, and the dreams of one individual are different from those of another: dreams thus reflect both day-to-day psychological variations and enduring individual traits. Sigmund Freud (see FREUD ON DREAMS), C. G. Jung, and many others since, have sought hidden features of personality and understanding of an individual's emotional conflicts, through examination of, or free association from, dreams described by day.

Whatever the clinical value of such dream recollections, they hardly compare with the rich reports that can be elicited by awakenings at night. Despite the symbolism and fascinating condensation of ideas to be found in dreams, there is no evidence that a more useful understanding of personality can

be gained from them than can be divined from the realities of waking behaviour.

DREAMS IN ANCIENT GREECE. Belief in the dream as a revelation was widespread in the ancient Near East, and is present in our earliest Greek documents, the poems of Homer. Dreams may contain prophecy or binding instructions, because they come 'from Zeus'; but they are a mixed blessing, because they may be sent to deceive. Later authors distinguish between significant and nonsignificant dreams; a dream that simply reflects the anxieties or desires felt by the dreamer during the previous day is nonprophetic. This distinction does not imply a weakening of belief; anthropologists report that no society treats all dreams as significant, and evidence of the most diverse kinds shows that some dreams were widely regarded as godsent or otherwise revelatory up to and beyond the end of the pagan Greek world. Of classical authors, the dream is noticeably absent only from Thucydides. *Plato describes* Socrates as composing poetry in obedience to a dream while in prison awaiting execution; the practical Xenophon twice records significant dreams of his own in the *Anabasis*; and the politician Demosthenes could claim to have received messages from the gods in sleep. Incubation, the practice of seeking significant dreams by sleeping in a sacred area, was a widespread oracular technique, and the incubation healing cult of Asclepius at Epidaurus became a centre of pilgrimage from all Greece. Dream interpreters are already mentioned in Homer, and from the fifth century BC there grew up an extensive literature on dream interpretation; this is represented for us by Artemidorus (second century AD), whose approach is, given his promises, cautious and practical, and shows that specialists in this sphere were not necessarily wild, marginal figures. It should be noted that Greek dream interpretation, though it operated with symbols, was prophetic in aim, and thus has little in common with the system of Sigmund Freud (see FREUD ON DREAMS).

Any dream that could be explained by the experiences or desires of the dreamer was dismissed as insignificant; many dreams, however, that would now be seen as psychologically revealing were regarded as externally motivated and therefore prophetic. For instance, the frequently reported dreams of incest (many men have dreamt of sleeping with their mothers, says Sophocles) were generally interpreted symbolically as auspicious, and Plato (*Republic*, 5712) is unusual in censuring them as wishfulfilment. Only a few passing remarks by Artemidorus on symbolic wishfulfilment (*Onirocritica*, preface to Book 4) and the role of puns in dreaming suggest modern ideas.

Scientific theories of the dream were strongly influenced by these traditional beliefs in its veridical nature. For Democritus (fifth century BC), images emanating from distant persons and objects, somewhat distorted in transmission, impinge on the sleeper: images of people reflect their thought as well as their external shape. Aristotle in his early works spoke of the soul exercising special clairvoyant powers, in accord with its divine nature, when freed from the body's constraint in sleep. Later, much more sceptically, he denied the divine origin of dreams (the gods would not care to communicate with the animals, or lower classes) and suggested that veridical dreams, if they really occurred, should be explained by a modified version of Democritus's theory. Of later philosophical schools, the Epicureans went still further in scepticism, but others much less far. Traditional belief in dreams of good and evil omen reappears, under a rather thin scientific disguise, in an anonymous medical treatise, perhaps of the fourth century. This distinguishes from 'divine' and wishfulfilment dreams a third category, in which the soul, being 'master of its own house' in sleep, indicates symbolically the condition of the body, thus providing a valuable aid to medical diagnosis.

Though numerous Greek dreams, real and literary, are recorded, comparatively few strike the modern mind as very dreamlike, presumably because reported dreams tend to fall into stylized, culturally determined types. In one typical dream, familiar also from the Old Testament, a god, parent, or figure of authority stands over the dreamer's head and issues prophecy or instructions; when the god is Asclepius in an incubation dream, he performs an act of healing that on waking proves to have been effective. The fullest account of an individual's dreams is postclassical, the 'sacred discourses' in which the hypochondriac orator Aelius Aristides (second century AD) describes Asclepius's revelations to himself, and his own extraordinary obedience to the god's commands.

DRUG. The word 'drug', when used in ordinary conversation, often denotes a substance whose use is forbidden by law and which, if ingested, will cause the most serious consequences, both legal and medical, for the user. Alcohol and nicotine, which are as much drugs as are opiates, amphetamines,

and cannabis, are often overlooked in this context, largely because both are legally permitted and widely used (see ADDICTION).

In more general terms a drug is any chemical agent that affects living processes. Pharmacology is the branch of science that studies these effects, particularly in the field of medicine. The development of clinical pharmacology, as a special area within the field of pharmacology, indicates the strong interest which is and always has been taken by doctors in the drugs they use. Until relatively recent times very little was known about the pharmacological effects of drugs and even less about their detoxification and excretion and distribution within the body. Although pharmacopoeias contained long lists of substances, most of these were of unproven efficacy.

Many were presented in combination with other medicaments, usually in a liquid form—the 'bottle of medicine' without which a consultation with one's medical adviser was considered to be incomplete. Today most of the older drugs and mixtures have been superseded and replaced by powerful agents of known chemical composition designed to have specific effects on bodily organs and systems. Unfortunately, with the rise of modern pharmacology and pharmacy, has come a new science—the study of the so-called sideeffects, or unwanted effects, or even unexpected effects, of many drugs used today. These iatrogenic disorders vary from the mildly inconvenient to the positively dangerous, and in some cases fatal. The greater the number of compounds that are prescribed, the greater will be the risk of adverse consequences. This is especially the case with older patients who, because of age, are likely to be suffering from more than one disorder, each of which requires treatment. Furthermore, the aged are less efficient at detoxifying and eliminating drugs, so that doses which may seem appropriate for younger patients will be greatly in excess of those required for patients approaching the *senium*.

Some orthodox and legal drugs may cause drugdependence (addiction). In this respect one should mention painrelieving drugs, sedatives, and preparations given to treat insomnia. Interestingly, opiates given for the relief of postoperative pain and of chronic pain in cancer patients do not usually cause dependence, a condition which more often occurs in younger persons. The study of drug dependence and its causes has become a major branch of pharmacology and psychology; but so far, it must be admitted, the amount of time and effort devoted to the subject have not been notably effective in controlling this psychosocial problem.

DUALISM. The philosophical theory that supposes that mind is essentially independent of the brain, though mental events run parallel with physical brain events. This leads to several suggested (usually causal) relations: (i) Mental and brain events run in parallel without causal interaction (epiphenomenalism). (ii) The brain 'secretes'

mental events, rather as glands secrete substances. (iii) Brain and behaviour are controlled by an essentially autonomous mind. (iv) The mind is an emergent property of brain processes, rather as the properties of water emerge from the combined atoms of oxygen and hydrogen, which in isolation have very different properties. (v) Mind and brain are essentially separate but have some mutual interaction (interactive dualism). This last was the view of Descartes. (vi) Mind is like 'software' of the brain ('hardware').

An account of the mindbrain relation which is not dualistic is the identity theory, of which there are various versions. These suppose that what we take to be mind and brain are different aspects of the same thing. See also MIND AND BODY; MINDBODY PROBLEM: PHILOSOPHICAL THEORIES.

DU BOISREYMOND, EMIL HEINRICH (1818-96), German physiologist, the son of a Swiss father and Huguenot mother, was born and lived in Berlin. He was assistant to Johannes Müller, and succeeded to his chair as professor of physiology at the University of Berlin in 1858, becoming head of the new institute of physiology there in 1877.

His work was of fundamental importance. It began with the investigation of electrical discharge in certain fishes; his discoveries related especially to electrical activity and chemical changes in the nerves and muscles generally. In 1845 he discovered the existence of a resting current in nerve. The value of this work was recognized early, and in 1851 he was elected to the Berlin Academy of Sciences. Later, in 1877, he suggested that nerve impulses might be transmitted chemically. His major published work was *Untersuchungen über thierische Elektrizität* ('Researches on animal electricity', 2 vols., 1848 and 1860).

DUNCKER, KARL (1903-40). German psychologist with strong affiliations to the Gestalt school. He worked for several years in Berlin as an assistant to Wolfgang Köhler but spent a year at Clark University in 1928-9. He then went back to Berlin, but returned to America in 1938 after a short interlude in the department of experimental psychology at Cambridge. He committed suicide in America in 1940.

Duncker reported an important study on induced motion, in part translated by W. D. Ellis (*A Source Book of Gestalt Psychology*, 1938, pp. 161-73). But his best-known work was a monograph on the psychology of productive thinking (German, 1935; English translation: 1945).

O. L. Z.

DUNNE, JOHN WILLIAM (1875-1949). British inventor, and philosopher of time. He designed the first aerodynamically stable aeroplane (1906-7), but he is best known for his philosophical-psychological books *An Experiment with Time* (1927) and *The Serial Universe* (1934). These inspired many people to record their dreams, looking for dream-predictions, the notion being that time is an unfolding of preordained events. Dunne's views are not now taken seriously, and there

seems no substantive evidence for predictive dreaming.

DYSLEXIA. The term 'specific developmental dyslexia' is frequently used in neurological, psychological, and educational literature to describe a severe disability which reveals itself initially in difficulty in learning to read, and subsequently by erratic spelling and deficits which affect written as opposed to spoken language. The diagnosis of this condition in children has led to much controversy, and views range from neurologists who postulate a 'developmental dyslexia' said to be the consequence of a neurological delay in development which is of constitutional origin, to psychologists who doubt whether such a syndrome, with a specific underlying cause and specific symptoms, has been identified. Workers in the latter group acknowledge that it is possible to distinguish the minority of children with severe reading difficulty (and often spelling, writing, and number problems) who fulfil some of the criteria of dyslexia, but they prefer to place these pupils on a continuum spanning the whole range of reading skills from the most fluent to those with the most severe difficulties.

Let us, firstly, look at some general descriptions of this condition that would attract fairly wide agreement from medical and psychological specialists working with atypical children. It appears to be a cognitive disorder, possibly genetically determined, which concerns a linguistic coding disability. The condition is not due to intellectual inadequacy as such and is not open to explanation in terms of a lack of sociocultural opportunity or inadequate teaching techniques. Secondary (reactive) emotional problems are frequently identified but the condition is not thought to be an outcome of a primary emotional resistance to learning. It is not due to any known structural brain defect and is possibly a specific maturational delay which will, in many instances, show positive responses to remedial help, especially if this is provided at a relatively early stage.

The term 'alexia' (word blindness) was initially used (and is still employed) by neurologists to describe very severe reading difficulties after a localized injury to the brain of an adult who was previously a competent reader. Towards the end of the nineteenth century, cases of children who seemed to have a similar disorder, although not caused by injury, were reported by physicians, and a number of papers were published in the *Lancet* and the *British Medical Journal* (for a summary of these articles see Hinshelwood, 1917). It was postulated that such children had a congenital disorder associated with a defect in the speech area of the left cerebral hemisphere which made learning to read extremely difficult, if not impossible. This was said to be a *specific disability* and as such could be distinguished from *mental deficiency*. Since this early work there have been numerous studies of children with severe reading difficulties, and the term 'specific developmental dyslexia' has been applied by some neurologists and a few psychologists to children who show at least some of the following difficulties within either one or both of the broad types of dyslexia outlined below.

The first type concerns children with what seems to be a form of language disorder. These pupils have a history of delayed receptive and expressive oral language acquisition and some may still have speech disorders. Although most will have overcome speech difficulties, they may have poor auditory discrimination (in the absence of any hearing loss) and find it hard to blend phonemes to form words. Such children have been found to score as many as 20 points fewer on verbal as compared with nonverbal intelligence tests.

Pupils in the second broad group have problems of visual*perception and*memory. Usually they can perceive simple material correctly but are deficient when asked to differentiate the parts of complex figures. Typically they reverse letters ('b' and 'd') and words ('was' and 'saw') when reading and writing. Cases of complete mirror writing have been reported. There seems to be a problem of directional confusion. Children in this group sometimes show a lack of firm unilateral cerebral dominance and are neither strongly right nor strongly lefthanded. It is not easy to estimate cerebral dominance, but a battery of tests could show some children to display crossed laterality, for example to be lefthanded and leftfooted but righteyed.

In a number of cases pupils show problems associated with both types of specific developmental dyslexia, and although simple auditory and visual perception is only mildly affected, if at all, they do have clear difficulties when attempting to associate spatially ordered visual patterns (letters Page 206 which combine to form words which, in turn, form sentences, etc.) and temporally ordered auditory patterns (the sound pattern of phonemes and spoken words). It could be said that the association between printed and spoken words is never completely regular and uniform in the English language, but visual/auditory association difficulties in pupils said to be suffering from specific developmental dyslexia are reported in countries (such as Italy) where spelling and lettersounding *are* completely regular.

It may be asked how we are to distinguish dyslexia from other reading difficulties. It must be stressed that some eminent educationists refuse to accept that it is possible to differentiate this condition as an identifiable syndrome from other forms of reading backwardness (Morris, 1966). Other eminent workers recognize the condition but consider it difficult to draw any clear line of demarcation between constitutional dyslexia and reading difficulties due to environmental circumstances (Vernon, 1971). As the volume of research in this field has increased, the number of 'symptoms' has grown accordingly, and fourteen areas of deficit are indexed by Wheeler and Watkins (1979). Given this situation, it will be appreciated that no widely accepted estimate of the frequency of the condition has ever been achieved.

Estimates as high as 10 per cent have come from the USA. Estimates in Britain have varied from 3 to 10 per cent. A wide age range in the school population has been studied, and the symptoms said to indicate this condition have been shown to vary with age. One example will suffice to illustrate the problems encountered when an estimate of prevalence is attempted. Approximately 05 per cent of 11yearold ordinary school pupils in Britain are reported to be illiterate, but not all these pupils are dyslexic. Further, it will be appreciated that not all dyslexic children are illiterate by the time they reach 11 years of age.

However, there have been recent advances in methods of assessment, and these include a comprehensive screening procedure which uses tests open to the class teacher (see Thomson, 1979). These measures provide a framework for teacher observation and cover a wide range of visual and auditoryvocal skills. Implicit in the employment of this technique is the assumption that the teacher will refer children who appear to have specific difficulties for a full investigation by an educational psychologist. It will be appreciated that there is much to be gained from the use of such screening

measures by teachers, because their own knowledge and experience will be extended and they will be in a better position to advise parents of pupils with specific reading (and allied) difficulties.

It must be stressed that there is much that parents can do, particularly when they can obtain sound and sensitive advice. They must learn how to be patient and persevering, both in their pursuit of knowledge about the practical manifestations of the condition, and in their daytoday contribution to their child's attempts to overcome what is seen to be, in conventional terms, 'educational failure'. It is essential that parents do not add to their child's anxiety. Direct and more formal attempts to help the pupil overcome specific difficulties are almost certainly best left to the specialist teacher. On the other hand, there are many relatively unobtrusive ways in which parents can help—always in close consultation with school staff. For example, they can use a structured oral language approach in visual/auditoryvocal games which, as well as being 'fun', are carefully devised to help at a precise level. The parents should be prepared to read to their child when, in the normal way of things, he would be able to read for himself. At a later stage, set books for examinations could be put on tape.

Cooperation of parents and teachers with an educational psychologist can be valuable. Sometimes the psychologist can help when a pupil's difficulties are such that special examination conditions are justified. For example, some dyslectics can be shown to be of good innate intelligence but to have abnormally slow reading speed—

this being a specific difficulty arising from their reduced ability to synthesize polysyllabic words—thus losing freeflowing comprehension of passages. The present writer has intervened on behalf of several such students taking public examinations, and examining boards have allowed the candidates additional time for a paper.

Thus what was an unfairly punitive *speed* test for an otherwise able student with a dyslexic history became a realistic *power* test, with speed playing a much reduced role.

Finally, reference is due to the assessment and teaching facilities established in Britain by the Dyslexia Institute, because these are making a valuable contribution towards our further understanding of this complex condition. The Institute itself is a useful resource centre for readers who wish to pursue this topic.

E

EBBINGHAUS, HERMANN (1850-1909). German experimental psychologist, born at Barmen, near Bonn, and educated at the University of Bonn. He obtained his doctorate in 1873 but thereafter worked for a number of years on his own. After a brief sojourn in Berlin, he travelled in France and England for three years, in the course of which he unearthed in a secondhand bookstall a copy of G. T.*Fechner's *Elemente der Psychophysik*, which evidently impressed him deeply and gave him the idea of applying Fechner's quantitative methods to the study of the higher mental processes.

Ebbinghaus thereupon embarked on a prolonged series of experiments designed to formulate the fundamental laws of human memory. As his experimental material, he laid great store on nonsense syllables in the belief that only by ridding his stimuli of conventional meaning could he treat them as constant and interchangeable units.

Somewhat as Fechner had treated just noticeable differences in sensation as equivalent units of sensation, he carried out numerous, and—for the time—surprisingly well-controlled, experiments to establish learning curves under a variety of conditions. He hoped that this work would not only lead to advances in our understanding of the nature of learning and forgetting but also be of practical value in the field of education. His results were embodied in *Über das Gedächtniss* (1885), much of which was replicated and in certain respects amplified by, among others, G. E. Müller of Göttingen; and it was introduced to English psychologists by C. S.*Myers (1909). See REMEMBERING.

In more recent years, Ebbinghaus's methods have come under considerable criticism on the grounds that he was concerned with the acquisition of verbal repetition habits rather than with memory as it operates under the conditions of everyday life. In particular, the artificiality of nonsense syllables has been repeatedly stressed. F.

C.*Bartlett, for instance, pointed out long ago that it is impossible to rid stimuli of meaning so long as they remain capable of eliciting any human response. He further insisted that the Ebbinghaus methods totally ignore those important conditions of recall which relate to preexisting attitudes and response

tendencies. None the less, the work of Ebbinghaus did much to convince the sceptical that quantitative methods were applicable to the higher mental processes.

ECT (electroconvulsive therapy). Applying a voltage, with surface electrodes on the head, across the brain. This is done under anaesthesia or muscle relaxant, as it produces convulsions which can be dangerous. ECT is extensively used as a convenient and quick treatment for depression, though there is no theoretical basis to justify it. There is considerable criticism of its extensive use because it may produce permanent brain damage, especially losses of memory and intelligence, though the evidence is not entirely clear.

ECTOMORPHY. See BODY BUILD AND PERSONALITY.

EDUCATION: THEORY AND PRACTICE. The true nature of education, its goals, proper methods, and effects have long been a matter of argument; certainly since the time of Plato (fourth century BC, see *Republic, passim*) and probably before, education has been a matter of concern, not only to the individual child who is to be educated, and to his parents, but to the whole society responsible for its provision. Though people sometimes urge that politics should be kept out of education (and they are right to hope that the extremes of party dogma may be avoided), the fact is that education is necessarily a political issue. For one thing, education itself is an expression of values, moral and political as well as academic. Moreover, what subjects children are taught, how and where they are taught, how many of them are taught and for how long, whether all are equally provided with education—all these questions are of interest to the whole of society, and the answers to them will determine the character of that society. No wonder, then, that politicians interest themselves in education, and if they are wise they will try to formulate a coherent theory, to justify the provision they decide to make.

In the eighteenth century the philosopher Rousseau (1712-78) thought of education as child-centred. In *Emile* he propounded the theory that a child would flourish if allowed to grow freely in his own way and his own time, not forced or stunted by too much teaching. He was not concerned with who should be educated, but only with how a child, any child, should or should not be taught. He thought of education in the 'true' sense Page 208

as a natural process, and therefore believed that all children, regardless of class or status, could benefit from it. His back-to-nature philosophy has had a considerable effect on later theories, if in nothing else then in the proliferation of all kinds of horticultural metaphors, according to which children, like plants, will flourish in the right soil, but may wilt or wither if either forced or neglected. In the early twentieth century this Rousseauesque philosophy was taken up and adapted by

John*^{Dewey} (1859¹⁹⁵²), who held that to educate a child was to provide him with experiences, out of which his thoughts and interpretations would flow; experience, and especially shared experience, was infinitely more educative than books. This antiintellectual kind of educational theory had considerable effects in the development of British education in the 1960s.

However, at the time when Rousseau wrote, education was narrowly spread. It was a luxury to which by no means everyone could aspire. Though there had long existed charity schools and the provision for poor scholars, the beneficiaries were comparatively few. In the nineteenth century education came to seem more and more desirable, and therefore the question to be faced was not what education was, or what its best form was, but rather who should have it. The Utilitarians in particular valued education extremely highly, for they believed that people could, all of them, be taught to take pleasure in the right things, that is in things which would spread social advantages widely in society, and would in general raise the standards of life, both morally and materially. A man of education, John Stuart*^{Mill} (1806⁷³) thought, would never wish to return to the enjoyment of the pleasures of the uneducated. Once introduce a child to the infinite resources of reading and learning, and his taste, his sensibility, and his understanding of true political goals would all inevitably be elevated. He needs must pursue the higher. This being so, Mill thought that it did not so very much matter what was taught, provided that education of some kind was universally available. Therefore in *On Liberty* (1859) he argued that the state should require all children to be educated, at least so that they could read, write, and calculate, but should not itself provide that education. If it were illegal to allow a child to go uneducated, demand would produce schools which could be inspected for efficiency by government servants, and the pupils of which could be publicly examined. Government could also subsidize those too poor to pay the fees. In this way he thought universal literacy at least would be ensured, while freedom to conduct educational experiments would also be preserved.

Mill's arguments were not accepted. But the goal of universal education gained ground, along with the conviction that the state must make provision for those whom it insisted should be educated. And at last, in the Education Act of 1944, all children in the United Kingdom became entitled to primary education, and to secondary education on up to the age of 15: such education as was, in the words of the Act, suited to their aptitude and ability. Only those children deemed to be too severely mentally handicapped to be able to benefit from education were excluded. Education was thus conceived as a right for everyone, but it was acknowledged that some kinds of education were better than others, not only in duration but in actual content. Success in life, in salaries, and the exercise of power all followed upon *good* education. What democracy demanded was that all children should have, not the same education, but the same chance of the best. So, in an admittedly competitive field, competition at the age of 11 for entry to the best schools, from which a child could proceed to university, was thought to be just, and also to be the best way of distributing an amenity which, by a marvellous natural harmony, was seen to be in short supply but also something from which only some members of the population would benefit.

But two things went wrong. First, the elevenplus selection became suspect. It selected too many of the middle classes. Secondly, it became clear that the mere *chance* to enter the lists for selection was not sufficient. Those children who were not selected for the best education at 11 had virtually no further chances, and it began to be thought that one chance was not enough. And so gradually, during the

1950s and 1960s, it began to seem that what was wanted was not equality of opportunity to be educated, but something more like equality of education for all. Even the universities were not exempt from the demand that they should open their doors to literally everybody. (Financial considerations and a certain realism, however, prevailed.) But at school things were different. The comprehensive school, which had started as a convenient and often excellent way of educating a large number of children of very different abilities under one roof, began to be identified with a demand that all children should be given the very same education, so that neither their social nor their intellectual differences would distinguish one from another.

During the 1960s, educational theory was predominantly concerned with such issues as these. The comparative affluence of the country, which allowed the establishment of new universities, also made it seem feasible to take the competitiveness out of education. Especially in the primary schools, the voice of Rousseau spoke again. Children must not be taught; they must discover things for themselves at their own pace. So an innate love of learning would find expression, and the old authoritarian style of education, which insisted that children be marked, graded, put in order of merit so that the best could get to the top, would finally disappear off the face of the earth. This was the kind of ideal incorporated in the Plowden Report (*Children and their Primary Schools*, HMSO, 1967). But it spread into the sphere of secondary education as well. In particular, it was linked with a Marxist view of the role of

Page 209

teachers (that the very concept of 'teaching' entailed the domination of one class over another, the perpetuation of a bourgeois value system, embodied in an insistence, for example, on reading, when books were predominantly middleclass productions). The very word 'teach' became suspect in the 1960s and early 1970s, and educational theory itself was difficult to separate from Marxist-dominated sociology.

However, while these influences were certainly important, in that they had a considerable effect on young teachers, and therefore on the actual educational provision within the comprehensive system, there was another element in educational theory which persisted from the 1950s onwards, and this was what may be called the Anglo-Saxon philosophical school. The theories of education that may be called, loosely, Marxist naturally linked theory with practice; and equally naturally were quite overtly political in their aims. Education is and ought to be a part of the armoury of the classwar. The philosophers, on the other hand, believed (I think wrongly) that education could be treated as a 'pure' subject; that it need have no connection with politics, and that, in so far as educational theory led to a change in practice, this would be practice based on totally rational considerations, concerned with the nature of knowledge and thus with the process of passing on knowledge from one person to another.

P. H. Phenix in America, and P. H. Hirst and R. S. Peters in the United Kingdom, were the most influential philosophers of education in the 1960s. They believed that there is a finite number of forms or kinds of knowledge, separable from each other by a process of logical analysis, and that no human being could be a full 'person'

without some acquaintance with all these forms of knowledge. A school curriculum, therefore, must

be so constructed that all of the forms have their place. Sometimes the august name of Wittgenstein (1889-1951) was invoked in favour of this kind of theory, with the suggestion that each form of knowledge was naturally incorporated in its own 'language' or 'languagegame'; and this was sometimes taken to prove that if the forms of knowledge were confused with each other, the result would be nonsense (but it can never have been taken to show that everyone ought to be able to speak in each of the different languages). This stipulation was, and must always have been, an independent judgement of value. The list of the forms of knowledge was intended to provide a value-free schema, arrived at a priori, within which education could be organized. The difficulty was that there exists no Platonic world of forms of knowledge. The list of forms, mathematical, historical, moral, literary, artistic, and so on, looked suspiciously like something derived from the timetable of an old-fashioned grammar school. And some of the items on the list could only very dubiously be counted as knowledge at all. Is it really the case that the moral education of children, for example, consists in teaching them to know certain things? And how about religion? The difficulties were manifold; and the practical effect of such philosophical theories was not as great as the proponents hoped, for the very good reason that it is quite impossible, by the analysis of the concept of education, to derive any satisfactory or agreed guide to action.

Nevertheless the influence of this kind of exercise was not absolutely negligible. Especially in the contentious sphere of moral education, held, ever since the days of J.

S. Mill, to be one of the most important aspects of education, and even to constitute a justification for increasing the spread of education among people in general, the analytic approach has had some consequences, in the kind of curricular material thought appropriate for school. It has been widely argued that, particularly in a multicultural society, it is impossible, and in any case undesirable, to lay down any actual moral principles for children to adopt. What must be done is to teach children to conduct moral arguments, so that they will be able both to determine what is and what is not a moral matter, and to make their own decisions rationally. Thus the analytic value-free educational philosophy at this point coincided with the anti-authoritarian theory of the neo-Marxists, and the result has been a considerable increase in some relativism among teachers. Nothing must be declared right or wrong; children must construct their own values, and are entitled to value anything high or low, provided they can argue on a rational basis to defend their evaluation.

Roughly, then, these two types of theory, the one overtly political and at first concerned with the distribution of education, the other supposedly value-free and concerned with curriculum content, dominated the field of educational theory and consequential practice until the late 1970s. Then a change came about. The affluent 1960s had passed; the financial climate was threatening; unemployment was beginning to be alarming. The days of student revolt, of permissiveness, of the excesses of the youth cult seemed to be over. Employers in industry were beginning to complain that young people coming out of school were ill-prepared for employment.

Parents were becoming increasingly disenchanted with some of the educational theories of young teachers. In 1977, the Prime Minister, James Callaghan, instituted what was known as 'the Great Debate'. Everyone was encouraged to think about the proper goals and purposes of education, what should be taught, and in what state of preparedness for life children should leave school. A reform of

the school curriculum, as well as of the public examination system which dominated the curriculum in most schools, began to be universally expected.

It had been clear for a long time that, despite the greater spread of education since the beginning of the century, in many ways the structure of the school curriculum had remained remarkably unchanged. Some schools, it is true, had invented

Page 210

interdisciplinary subjects to replace the old subjects of 'geography' or 'history'. But as long as universities demanded competence in classical languages, or even the ability to translate modern foreign languages though not to speak them, the old standards, according to which knowing Latin and Greek brought the highest prizes, were not wholly overthrown. Even when the universities relaxed their demands, the old domination of the classics remained to bedevil the teaching of modern languages, taught traditionally as if they were a kind of dialect of Latin; and the notion that a child must choose between language learning and science, that if he was doing well with languages he could drop mathematics as early as possible ... all these factors remained unchanged, and were ossified in the examination system and hence in the school timetable. Moreover, the children who did not take, or did not succeed in passing, public examinations had very little that was structurally different in their curriculum. A school devoted to the egalitarian ideal of the 1960s could not discriminate too blatantly between the curricula of different children.

Meanwhile in the early 1970s another quiet reform had come about which had a significant effect. It was then that those very severely mentally retarded children, hitherto deemed ineducable, and therefore left as the responsibility of the health services, were brought under the educational umbrella. At last it became the duty of local authorities to provide education for all children without exception. It was inevitable that the notion of education itself should be reexamined now that it was supposed to be available for children of such totally different capabilities. The fact that these newly educable children had to have a curriculum, with curricular aims which could be achieved slowly and step by step, cast fresh light on the practical nature of teaching itself. Successful education depends on teachers who know what they are doing and what they are doing it *for*.

In the context, then, of economic recession and the widening scope of education, together with the general assumption of the 1970s and 1980s that government should be open, and provision or lack of it publicly justified, a new way of looking at education as a whole can gradually be seen to emerge. It is a mixture of pragmatism and idealism. All children are now legally entitled to education, not merely so that they may get better jobs (for some of them may get no jobs at all) but so that their lives may be of a decent quality. The old utilitarian belief in education is perhaps returning, but in a different form. Education is seen to have certain quite general goals, to increase the understanding, the independence, and the pleasure of the child who receives it; and if these aims are not to be frustrated, then as many obstacles to education as possible must be removed from the path of the child. The dominant question has become 'What does this child *need*, if he is to get from his education what he is entitled to?'

Of course, part of what a child needs is a sensible, useful, enjoyable curriculum. But the question of needs goes further. For a curriculum is futile, however well devised, if the particular child has no access to it, either because he cannot understand what he is being taught, or because the environment of the school where he is taught it is inimical to learning. Thus one of a child's essential educational needs is a good school, in the simple sense of a school where learning is possible. It has been increasingly recognized in the last few years that what has been called the 'hidden curriculum' is as important as the curriculum itself—the system of values, that is, which the school by its very existence as an institution hands on to its pupils.

Once the philosophy of educational needs is accepted, the criteria by which education is judged to be good or bad become immediately extremely wide and varied. It is no longer adequate either to raise the simple political question 'Is education justly distributed?' or the supposedly more philosophical question 'Is the curriculum appropriate to the common epistemological framework?' On the contrary, the first question must be 'Does this kind of education *work*? Is this child or that child actually learning anything?', and then the second question is the value-laden one: 'If he is learning something, what do we hope will come of it—exactly how will he benefit?' Increasingly, schools, and teachers themselves, are taking responsibility for answering these questions, with the more and more active cooperation of parents. There has never, perhaps, been any time when theory and practice have been so closely interrelated. The philosophy and the action can hardly any longer be separated.

EGO AND SUPEREGO. Sigmund*Freud supposed that three components make up the psychic structure: the id, the ego, and the superego. The id represents instincts and innate needs. The superego, manifest in conscience, shame, and guilt, is the agency by which the influence of parents and others is prolonged. Their judgements and prohibi

tions are internalized by the process of introjection in early childhood before the child is able to question them. The ego has been differentiated from the id through the influence of the external world, to whose demands it adapts. In so adapting it has to reconcile the forces of the id and superego in such a way as to maximize pleasure and minimize unpleasure. The development of egopsychology as a branch of psychoanalysis, which reflected a shift of interest from the earlier instinct theory to the adaptive functions of the ego, in relation to other persons especially, facilitated some rapprochement between psychoanalysis and psychology.

EGYPTIAN CONCEPTS OF MIND. Whereas the people of other ancient civilizations believed that they were created by gods from matter, the Ancient Egyptians saw themselves as created directly out of nothing by the god who created the universe. They saw themselves as a divine nation, and their king as a god, though with a mortal body. They were uniquely religious. They had far more gods than any other country or civilization, their many gods reflecting their extremely animistic way of looking at nature—the heavens and everything on earth being seen as under the control of a great variety of often hostile beings. The most hostile spirits were often represented by dangerous animals: wolves, crocodiles, and venomous snakes, which overran Egypt in predynastic times. The more powerful the threat, such as inundation of the Nile, the more powerful the responsible god; so the sun god was more powerful than the god of the moon. Many of the gods, however, were benevolent; or at least their goodwill might be sought by prayer or bought or bribed by gifts or offerings; or they might be made to help through the powers of magic and prayer. They might be persuaded to challenge the evil gods—so there were battles of good and evil in heaven, where the gods lived. Heaven was at first thought of as a rectangular ceiling, the earth (the land they knew) being this shape; later, it was thought of as the arched body of the goddess Nut, the stars being her jewels.

Many of the gods or spirits were occupied with carrying out the routine processes of nature, for everything in nature depended on the intentions of the gods; but as even these guardians, of what to us are natural laws, were open to suggestion or propitiation, magic was seen as immensely powerful. Perhaps this is why science was less developed in Egypt than in the contemporary Babylonia. Egyptian science lacked imagination and was essentially practical. From their experience of embalming the Ancient Egyptians had considerable knowledge of anatomy, and also of surgery and dentistry (their teeth were ground away by the sand in their food), but their knowledge of mathematics and physics was not sophisticated and their literature lacked incisive questioning or thoughtful discussion. Their knowledge and application of mechanical principles, for handling and carving stone and constructing vast buildings from blocks weighing several tons, is however uniquely impressive,

and they did achieve much in the measurement of time, if again for practical purposes. For arithmetic, multiplication was done with a twotimes table (much as with presentday*digital computers) and their geometry was simple and practical, without a system of proof. There were, nevertheless, a few enquiring minds: Imhotep, for example, wrote the mathematical treatise known now as the Rhind Papyrus (c.2600 BC); but even this lacks abstract notions or any concept of proof, which was the invention of the Greeks.

The gods of both Egypt and Babylonia were credited with speech, and with at least human intelligence, and human passions, and morality. The Egyptian judgement at death was not, however, entrusted either to gods or to men—but to a great mechanical balance on which the heart was weighed against the feather of truth. This balance in the hall of judgement was served by many gods, including the god of wisdom, learning, language, and number—the ibisheaded god Thoth (who was sometimes baboonheaded, baboons being seen as highly intelligent).

Egyptian hieroglyphic writing was fully developed by 3000 BC. It is a wonderful record of the use of pictures as formal symbols to represent meaning. Although pictures cannot at all directly convey opinions, beliefs, commands or requests, or logical or other relations, they were given such powers by referring to animal characteristics—such as the power and fecundity of the bull associated with the sun and controlling the Nile—and by representing human gestures. Thus 'not' was written as arms flung out, the hands later being left out, to become our negation sign ". It seems strange that, little or no attention has been paid by psycholinguists to ancient picture writings; for, surely, here lies invaluable 'fossil' evidence of the development of human communication and mind. (See, for example, CHINESE

EVIDENCE FOR THE EVOLUTION OF LANGUAGE.)

The flowering of Egyptian literature occurred in the eighteenth dynasty (1570-1293 BC). In the writings of this period, especially in its second half, are to be found in many references to complex though not always consistent notions of mind, soul, personality, and their relations to the body. Throughout, there is a consistent and indeed dominating belief in eternal life. Man was believed to consist of several entities, each separate but each necessary for his welfare. These were the natural body, the spiritual body, the heart, the double, the

Page 212

soul, the shadow, the intangible casing of the body, the form, and the name.

The body as whole, the *khat*, is associated with things that decay. In early times the bodies of the dead were buried in the dry sand, beyond the agricultural land watered by the Nile, and they were preserved for thousands of years. But when the dead were placed in stone coffins, the flesh disappeared—supposedly eaten by the stone. Hence the Greek 'sarcophagus', meaning 'flesheating', which reflects the prehistoric notion of the body and soul of the dead entering and being preserved in stone.

For the Egyptians, the brain (being bloodless in death) was not important and was generally ignored; the heart was the power of life, and the source of good and evil.

Thus, in their funerary literature, the *Book of the Dead*, the heart was weighed, against feathers, to determine the balance of good and ill at death. According to the Egyptologist Sir Wallace Budge (1895, in a most lucid account of this complicated psychology of gods and men, p. lxiii): In close connection with the natural and spiritual bodies stood the heart, or rather that part of it which was the power of life and the fountain of good and evil thoughts.

And in addition to the natural and spiritual bodies, man also had an abstract individuality or personality endowed with all his characteristic attributes. This abstract personality had an absolutely independent existence. It could move freely from place to place, separating itself from, or uniting itself to, the body at will, and also enjoying life with the gods in heaven. This was the *ka*, a word which conveys at times the meanings ... image, genius, double, character, disposition, and mental attributes. The funeral offerings of meat, cakes, ale, wine, ungruents, etc., were intended for the *ka*; the scent of the burnt incense was grateful to it. The *ka* dwelt in the man's statue just as the *ka* of a god inhabited the statue of the god. In this respect the *ka* seems to be identical with the *sekhem* or image. In the remotest times the tombs had special chambers wherein the *ka* was worshipped and received offerings ...

The *ka* ... could eat food, and it was necessary to provide food for it. In the twelfth dynasty and in later periods the gods are entreated to grant meat and drink to the *ka* of the deceased; and it seems as if the Egyptians thought that the future welfare of the spiritual body depended upon the maintenance of a constant supply of sepulchral offerings. When circumstances rendered it impossible to continue the material supply of food, the *ka* fed upon the offerings painted on the walls of the tomb, which were transformed into suitable nourishment by means of the prayers of the living. When there were neither material offerings nor painted similitudes to feed upon, it seems as if the *ka* must have perished; but the texts are not definite on this point.

The *sekhem* was also thought of as the power, or vitality, of a man; but evidently it is very difficult to establish just what *sekhem* meant.

The Egyptians also accepted a more refined 'soul' named the *ba*. Again according to Wallace Budge (1895, p. lxiv): To that part of man which beyond all doubt was believed to enjoy eternal existence in heaven in a state of glory, the Egyptians gave the name *ba*, a word which means something like 'sublime', 'noble', and which has always hitherto been translated by 'soul'. The *ba* is not incorporeal, for although it dwells in the *ka*, and is in some respects, like the heart, the principle of life in man, still it possesses both substance and form: in form it is depicted as a humanheaded hawk, and in nature it is stated to be exceedingly refined or ethereal. It revisited the body in the tomb and reanimated it, and conversed with it; it could take upon itself any shape it pleased; and it had the power of passing into heaven and of dwelling with the perfected soul there. It was eternal.

There is more: the shadow, or shade of a man— the *khaibit*—which may be compared with the *umbra* of the Romans. The *khaibit* is not so frequently mentioned as the *ka* and *ba*. Wallace Budge

(1895, p. lxvi):

It (the *khaibit*) was supposed to have an entirely independent existence and to be able to separate itself from the body; it was free to move wherever it pleased, and, like the *ka* and *ba*, it partook of the funeral offerings in the tomb, which it visited at will ... in later times at least the shadow was always associated with the soul and was believed to be always near it.

Little seems to be known, though, of the life of the shadow.

Now we come to human intelligence. The *khu* of a man could journey to heaven as soon as the prayers said over his dead body allowed it. Wallace Budge again (1895, p. lxvii):

Another and most important and apparently eternal part of man was the *khu*, which ... may be defined as a 'shining' or translucent, intangible casing or covering of the body, which is frequently depicted in the form of a mummy. For want of a better word *khu* has often been translated 'shining one', 'glorious', 'intelligence', and the like, but in certain cases it may be tolerably well rendered by 'spirit'.

Finally, there is the *ten* of a man—his name. This too had its own existence and could live in heaven among the gods.

The scholarship of Egyptologists tells us of past minds, and modes of thought and understanding. But clearly there are limits to modern understanding of what dead words such as '*ka*', '*ba*', and '*khaibit*' meant for there may be no analogies from our experience to read the past. Even now a word like 'soul'—or for that matter

'mind'—is exceedingly hard to define, and different writers may use it differently. Evidently the Egyptians saw *khaibit* as more than we see in the shadow of a man; for theirs could walk away and be its own self. Is it possible for scholarship to become so immersed in ancient ideas that such thoughts of longlost minds can, through their dead language, enter our present understanding? Even though this is doubtful, the journeys of such scholarship are wonderfully rewarding.

EHRENFELS, CHRISTIAN VON (1859-1933). Austrian philosopher and psychologist, who was a student of Franz*Breton in Vienna and is remembered as a precursor of*Gestalt psychology. His important paper *Über Gestalt Qualitäten* (On Gestalt Qualities) appeared in 1891. Although influenced to some extent by Mach's *Analysis of Sensations* (1896), this was an original and timely contribution to the psychology of*perception. Ehrenfels introduced the term 'Gestalt qualities' to denote the perception of form or melody which, though based on sensory stimulation, can in no sense be regarded as inherent in the pattern of stimulation. In his view, Gestalt qualities represent novel elements in the field of perception, and this is well brought out in the phenomena of transposition. For example, a form such as a square or circle is recognized as such even after changes in its size or colour. Similarly, a melody is recognized even when played in a different key. Indeed objectconstancy, whether spatial or temporal, is perhaps the most basic property of a Gestalt quality.

Ehrenfels, and after him Alexius Meinong (1853-1920), elaborated the system further, pointing out for instance that a particular direction of change might be a potent source of Gestalt qualities, as when one observes a slowly spreading blush. Gestalt qualities may also combine with one another to produce superordinate Gestalt qualities, as commonly found in music. Although no precise theory was put forward to explain Gestalt qualities, Ehrenfels came very close to formulating the principle of isomorphism, which is usually attributed to Max*Wertheimer and Wolfgang*Köhler, and which played so important a role in the Gestalt theory.

The idea of Gestalt qualities was then little known outside Austria, but it seems to have inspired the English philosopher and psychologist George Frederick Stout to write his two-volume *Analytic Psychology* (1896).

EIDETIC IMAGERY. See IMAGING.

ELECTRA COMPLEX. A son's hostility towards the parent of the same sex and sexual impulses towards the parent of the opposite sex make up the *Oedipus complex. Usually the same term is applied to the corresponding feelings of a girl; less often, but following C. G. *Jung, the term applied is the Electra complex. In the plays of ancient Greece, Electra, unmarried and still grieving for her father Agamemnon, who has been killed long before by her mother Clytemnestra and Clytemnestra's paramour, encourages her brother, Orestes, to kill them in retribution. Versions of Electra's story have been used by modern playwrights, notably T. S.

Eliot, Jean Giraudoux, Eugene O'Neill, and JeanPaul *Sartre.

ELECTROCONVULSIVE THERAPY. See ECT.

ELECTRODERMAL ACTIVITY. The preferred general term for the electrical activity of the skin, replacing 'psychogalvanic reflex' (PGR) and 'galvanic skin response' (GSR). These earlier terms were confusing because although they referred to the phasic response patterns of electrodermal activity they were often used by implication to refer to longerterm changes (tonic activity). Furthermore, they did not distinguish 'endosomatic' responses (changes in skin potential) from 'exosomatic'

responses (changes in the skin's resistance or conductance). The former are determined by measuring the potential difference between two electrodes, the one placed on the palm of the hand or sole of the foot and the other on an electrically indifferent site. In the case of exosomatic measurement, electrodes are normally placed on two active palmar sites, and the conductivity of the pathway between them is measured by passing a current through the pathway. If this current is less than 10 μ A per square cm then the tissue of the skin obeys Ohm's Law and linear calculations of conductance can be employed. As the eccrine sweatglands of the palms and the soles of the feet are the essential conducting pathways involved, and these can be viewed electrically as resistors in parallel, it is appropriate to use units of conductance rather than resistance in quantifying exosomatic tonic levels and phasic responses. (This is because resistances in parallel add as their reciprocal, and the reciprocal of resistance is conductance.)

The first work on electrodermal phenomena can be attributed to Vigouroux in 1879, but it is to Féré and to Tarchanoff that credit is usually given for really establishing work, respectively, in the fields of skin resistance (conductance) and skin potential activity. Féré's work, reported in 1888, states that 'irrigation of the tissues' caused a diminution in skin resistance and thus established the role of the sweatglands in exosomatic electrodermal activity. This position is accepted today, in spite of attempts to suggest vascular or even muscular involvement. The sweatglands are also responsible for a major part of skin potential activity, a fact that may be established by inactivating them by an anticholinergic drug such as atropine. Although the sweatglands are innervated by the sympathetic branch of the autonomic nervous system only, and the sympathetic system may in general be considered to be

adrenergic, the sweatglands are unique in having acetylcholine as their peripheral*neurotransmitter, as shown by their inactivation by anticholinergic drugs.

The central control of electrodermal activity is evident at several levels. Stimulation of the brainstem reticular formation (see NERVOUS SYSTEM) Page 214

provokes an electrodermal response, although inhibitory modification of the response may be seen by stimulating the brainstem area at a bulbar level (the brainstem area below the activating system at reticular level). At the level of the*limbic system, bilateral removal of the amygdalae abolishes the skin conductance response, while ablation of the hippocampus retards habituation to repeated stimulation. The eccrine sweatglands of the hands are only involved in temperature regulation when temperature reaches about 25°C and at that point activity of the anterior hypothalamus is involved.

Until the 1950s only the amplitude of the electrodermal response and the level from which it started were measures of interest. Since that time three temporal measures have been shown to be of importance. These are latency, the time from stimulation to the intexion of the recording at the point where the response first becomes evident; rise time, the time taken for the response to reach its peak; and half recovery time, the time taken for the response to decline to half its peak amplitude.

The main relevance of the electrodermal response is as a component of the response patterns known as the orienting and defensive responses. The former is seen, following Pavlov, when the organism responds to any change in its environment. The latter may be seen as having a protective role: one which prevents the organism from becoming overstimulated. While, for instance, pattern changes in heartrate and vasomotor activity may signal differences between orienting and defensive responding, there is usually little difference in the amplitude of the skin conductance response to stimuli which would produce orienting (OR) and defensive (DR) responses (e.g. 70 dB and 95 dB auditory stimuli respectively). However, while the amplitude of the response may not adequately differentiate ORs from DRs, the recovery time may be as much as three times as long in the case of the latter. Furthermore, the rate of habituation of the skin conductance response to weak stimuli which elicit ORs is very much quicker than to intense stimuli which elicit DRs.

The electrodermal response may be the subject of*conditioning procedures and, as one of the few readily measurable responses in man which reflect 'unconscious'

activity, there has been a proliferation of skin conductance conditioning work. However, in spite of the fact that the immediate control of electrodermal activity is via the sympathetic nervous system, the accessibility to control from higher cortical levels results in modification of electrodermal conditioning by instructions, and the conditioning process in man cannot be viewed simply as parallel to that in animals.

Perhaps the most useful aspect of work using electrodermal activity is on individual differences and in mental illness. Some of the earliest work in this area was done by*Jung in Zurich at the turn of the century, when he used it as an adjunct to his word association studies. Since that time it has proved important in studies of neurosis and psychosis. In*schizophrenia, for instance, it is a wellreplicated

finding that some 40 per cent of adult patients show no electrodermal responsivity while a large proportion of the remainder respond excessively to weak stimuli. Measurement of electrodermal activity in the premorbid state has shown that these patterns of response are able to predict later breakdown; possible use as a screening device is thus indicated.

It is unfortunate that to many members of the public the use of electrodermal measurement is associated with the use of the so-called liedetector. This 'technique', where electrodermal and other autonomic responses to 'critical' and 'noncritical' stimuli are recorded, has become an industry in the United States under the name of

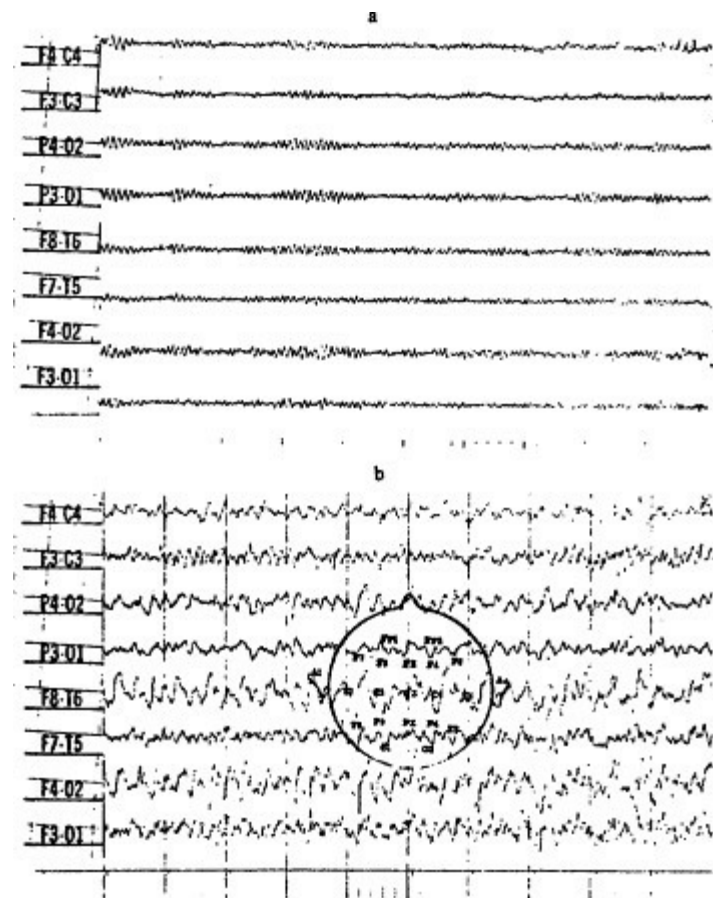

'polygraphy'; but it has little scientific support, and the detection of true from false responses is probably not more accurate than 65/70 per cent as an average figure. It becomes a matter of political decision whether this small increase over chance level in the possibility of detection makes the use of the technique acceptable for the detection of those who might be security risks, or as evidence for court conviction. Clearly in the latter case the extent of inaccuracy makes its use unacceptable.

The potential interest of electrodermal activity is now apparent, even though at the end of the 1950s it appeared that half a century of experimentation had produced nothing useful. The turningpoint came with improvements in technique that eliminated a large amount of the error introduced—for instance, by electrodes which polarized and produced random activity. The measurement of electrodermal activity is now a useful part of the experimenter's armamentarium.

P.H.V.

ELECTROENCEPHALOGRAPHY. A common aim of research of the normal brain and of clinical diagnosis of its disorders is to build a complete image of the living tissue and its activity. All practical techniques allow one to view only one aspect of it. The electroencephalogram (EEG) registers potential differences on the scalp which arise as a result of 'feeble currents' of the brain. Electrical activity of the brain was first reported in 1875 by Richard Caton, a British physiologist who studied it in monkeys, cats, and rabbits. Human EEG was first described by Hans*Berger, a German psychiatrist, in 1929, but not until E. D. Adrian (later Lord*Adrian) and Matthews in England published their work in 1934 did human EEG become a routine diagnostic test in neurology and psychiatry. It also became one of the widely used tools of brain research in humans.

For clinical purposes, most modern EEG machines register as many as sixteen*'channels' of brain activity. Many channels are used in order to be able to detect if there are different types of electrical activity in neighbouring brain areas.

Page 215

Fig. 1.

a. Eight simultaneously recorded channels of normal EEG. Letters to the left of each trace represent electrode locations referring to a schematized drawing of a head. Notice on the right side of the figure the spindling of normal alpha range activity in several channels.

b. Abnormal EEG of a patient with right cerebral lesion. Notice large amplitude slow wave activity in the evennumbered rightsided channels.

especially in the frontotemporal (F T) derivation. There was clinical

8

6

evidence of focal seizure manifested by jerking of the left leg of the patient.

However, as will be explained later, spatial resolution of abnormal brain activity is not one of the strong points of clinical electroencephalograms. A 'channel' refers simply to the amplified record of the potential difference between two points on the skull and its changes. Since brain potentials change in time and do not usually measure more than 100 microvolts, the tiny signals need to be amplified and registered, usually with the help of an ink pen recorder. In most clinical EEG studies, discs pasted on the skull, or fine needles inserted into the scalp, will pick up the electrical activity of the brain. They are called electrodes, and each is connected to a powerful amplifier. A number of amplifiers, each with its pen recorder, constitutes the essence of an electroencephalographic machine. When the brain is alive, the potential difference between two recording electrodes changes 'spontaneously' as time goes on. When written out by the pen recorder, this is seen on the EEG record as undulations. By inspecting these one gains the impression that the brain produces waves. In fact, 'brain wave test' is a term used in the United States for the EEG.

The wavy appearance provides a simple way of describing and classifying the EEG by sheer visual inspection. The Greek letters alpha, beta, delta, and theta are commonly used for the different periodicities or wave frequencies apparent in the EEG. Alpha stands for brain waves with a periodicity of about 9 to 11 per second.

Beta is a higher frequency 'component' of the EEG, while delta and theta are slowerchanging brain potentials, or lowfrequency waves.

Much interest has accompanied the nature of the alpha rhythm since it was shown by Berger that it appears when a human is resting quietly, but disappears when he opens his eyes. This disappearance is called 'alpha blocking'. Some people produce alpha waves even with eyes open, and in these people a flash of light is needed to block them. The presence of alpha is thought to be associated with a meditative, quiescent state, while its disappearance in the normal human is thought to be due to*attention and*arousal. Because of the relation of the alpha rhythm to vision, several investigators studied its presence or absence when patients suffer from abnormalities of their visual system. It has been reported that if a person has reduced vision due to some ocular abnormality but can see flashes
Page 216

of light, these are not enough to block his alpha rhythm. Apparently, not all visual activities block alpha. However, mental imagery, such as occurs when playing blindfold chess, can block alpha rhythm. Another pertinent observation has been that most patients who lose the ability to see as a result of a*stroke of the visual cortex on both sides of the brain do not have alpha rhythm. Stroke results from depriving a part of the brain of its blood supply, such as occurs when one of its supplying arteries is completely or partially occluded. Bilateral stroke of the visual cortex occurs when the so-called basilar artery or its branches receives diminished blood supply.

The slow waves of the EEG occur for short periods only in normal*sleep, but commonly when there is pathology of the brain—such as a stroke or a tumour. The electroencephalographer can sometimes diagnose the size and nature of brain pathology by comparing the simultaneous activity of many channels of the EEG. In some patients brain waves paroxysmally change their characteristics: they no longer appear as gentle waves of the sea, but become very sharp and spiky. (The appearance of such a

'brainstorm' unfortunately does not represent the occurrence of some sharp thought.) These abnormalities are seen in seizure disorders, called epilepsies. The EEG provides a major contribution to the diagnosis of epilepsy. Clinically different types of epilepsies have their individual EEG fingerprints, and these different types respond to different medications. Sometimes a medication which is good for one type of seizure disorder may be harmful in another. Thus for these patients EEG recording is indispensable.

The understanding of potential changes of the human brain has been helped by experimental recordings done in other animals. While their surface skull potential EEG is recorded, simultaneously an electrode is being advanced into the depth of the cortex and a third electrode may be held at a constant depth near to or within a single cortical cell. Thus surface EEG, intracellular potential changes, and extracellular spike activity can be recorded in the same animal at the same time. Studies by D. A.

Pollen showed that slow surface potential changes (one of the main components of the EEG) are not influenced by spike generation of individual neurones; rather waves represent changes of potential differences between the bodies and processes of single neurones.

Using the electroencephalogram to reveal abnormal or even normal cognitive processes of the brain has been very disappointing. The attempt has been likened to trying to diagnose the problems of a computer by holding a voltmeter up to it. The EEG reveals the pathology of the human brain, but little about abnormal thinking.

One reason may be that the EEG scalp electrode samples potential changes which arise in a large volume of the brain, and deficiencies of specific nerve cells which may not all be in the same volume of tissue cannot be detected. The situation is different when, under surgery, the electrical activity of the brain can be directly recorded. With some patients there are medical reasons for putting electrodes on the surface or in the depth of the cortex, and exploring connections between distant areas of the brain. Surprisingly, under this condition, even a relatively large surface electrode samples only the activity of a small volume of tissue. Two intracranial surface electrodes, when spaced only 1 millimetre apart, can show different EEGs.

Resolution of brain pathology by EEG methods is limited by the organization of the human cerebral cortex itself. Sensory stimuli such as light through the eyes, tones through the ears, temperature and pressures, and other sensations, are first transduced and then transmitted to the cortex as changes in electrical activity along nerve fibres as a series of pulses. Often, as the nerves enter the cortex they branch like a tree and connect to many different cells (neurones) of the brain. In addition there are connections between various neurones in the immediate vicinity of each other, as well as long fibres connecting different parts of the brain. Consequently distant cells may register identical changes.

Modern diagnosis in clinical neurology relies less and less on registering spontaneous activity of the brain. Rather, one attempts to induce changes in specific brain areas devoted to one or another sensory modality, such as vision and hearing. Induced activity is of much smaller amplitude than the

'spontaneously' arising potential change and, to detect it, the averaging and summation of a large number of tiny signals is required. The technique is called '*evoked' (as opposed to spontaneous) potentials.

The conventional EEG is obtained through an alternating current (AC) coupled recording. Usually only changes in potentials which occur in less than 1 second are registered. Recordings that show the slower changes of so-called 'standing' potentials of the brain were made as long ago as the nineteenth century. 'Slow' in this context means a DC shift noticeable only over many seconds. Beck, a Polish investigator, was remarkably successful using the then available technique to record DC

potentials. DC recording became clinically useful only with the development of transistorized amplifiers and better electrodes. DC potential changes of the brain may reveal more about cognitive processing than classical EEG does. For example, W. Grey*Walter, one of the pioneers of modern electroencephalography, has been able to show that DC potential shifts occur and may relate to · anticipation and decisionmaking by the human. A potential shift measured at the top of the head and called the contingent negative variation or CNV is the bestknown example of a 'slow' potential change.

EMBARRASSMENT. See BLUSHING.

' EMERGENCE' AND 'REDUCTION' IN EXPLANATIONS. A classical question of philosophy is the one/many problem: is everything in the universe ultimately one thing—or are there, as it certainly appears, many things? In another and more interesting form the question becomes: are there many *kinds* of things—or could there be a single unifying account of all the apparently various kinds of events and phenomena?

It is sometimes raised as an objection to science, especially to medicine, that reducing complex issues to simpler terms produces loss of significance of the whole, which like Humpty Dumpty cannot be put together again. This is the 'holistic' criticism of science's reduction of complex issues into simpler parts or concepts. The converse of reduction is that when parts are combined, surprising or mysterious 'emergent' properties may appear— mysterious because reductiondescriptions are inadequate. A familiar example is the creation of water by the combination of the gases oxygen and hydrogen.

Just as the properties of water are different from those of its constituent gases, so, it is sometimes

suggested, mind may be similarly emergent upon physical brain structure or activity. Douglas Hofstadter (1979) makes effective use of an analogy—originating from a paper (1911) by William Morton Wheeler—that though ants build their nests they cannot reconstitute them when they have been disturbed and the structure has been destroyed. To conceive that the functioning ants' nest is more than the sum of the ants is helpful when thinking about braincells (which, also, individually do not understand); and it is helpful to conceive of the cooperative functioning of braincells in the process of understanding the mind. Knowledge of individual ants cannot explain nest behaviour and knowledge of individual braincells cannot explain the mind, even though the nest is no more than ants and the mind depends entirely on braincells.

Vitalist biologists such as Hans Driesch (1867/1941) have held that the functioning of organisms can never be explained from knowledge, however complete, of their parts because of a vital principle which relates to the whole but not the isolated parts. This doctrine precludes 'reductive' explanations drawn from analyses of the whole into parts that may be separately investigated and described. It implies that the biological and medical sciences are essentially outside the kinds of explanation by reductive analyses that have proved so powerful in the natural sciences. If this is so, biology (and psychology even more so) would seem to be essentially different in kind from physics. Is this holistic view of biology and mind justified? To consider this it is useful to look at simple *machines* and ask: do we find emergence when parts of a construction set, such as Meccano, are combined to make a simple working model? Putting the parts together in various ways creates very different mechanisms: cars, cranes, clocks, and so on. It is indeed remarkable that the same differently arranged parts may move as a car, lift things as a crane, or keep time as a clock. This can look like emergence beyond explanation—much as for organisms—though here we clearly have simple mechanisms.

The Oxford philosopher Gilbert Ryle tried (1949) to exorcise common concepts of mind that, implicitly or explicitly, dubbed the mind 'the Ghost in the Machine'. But even the simplest of Meccano mechanisms can look quite ghostly! Is this because they have emergent properties? If so, do they still appear ghostly in this way when they are fully understood? Or could it be that we do not yet completely understand simple machines reductively—though we may come to understand machines and organisms so fully that appearance of emergence vanishes, as analysis of the functions of their parts becomes complete?

A machine is assembled from component parts, yet how it functions may be explained by more or less abstract general concepts rather than in terms of its parts. Thus, how a clock keeps time is explained less by describing the parts and their mechanical interactions than from general principles, such as those stating why pendulums swing at a constant rate. We have to look beyond the parts of a mechanism to explain what the parts do. Moreover, there is no simple relation between a machine's structure and its function. A single part, such as the anchor of the clock's escapement, may have several functions, or several parts may combine to provide a single function. Similarly there is no simple correspondence of parts to functions in an organism. (Insights to relations between structures and functions of machines are powerfully expressed by Robert M. Pirsig (1974)).

It is tempting to believe that the highlevel properties of organic systems must somehow be present in a rudimentary or dormant form in their parts. But such belief does little to explain how organisms

function, and can lead (as with inorganic mechanisms) to notions of molecules, atoms, or even fundamental particles such as electrons having*intention, or*consciousness. Such notions are without verification, however, and must surely be dismissed (see FALSIFICATION). We should prefer to say that mind emerges from brain function—if only because there is some hope of finding out what is so special about the brain. But it is hard enough to understand how organisms can be intelligent or conscious, even with all their interacting complexity; and to say that individual braincells (or, even more extreme, that the individual molecules, atoms, or electrons of which we are composed) have intelligence or consciousness merely pushes the question further beyond answer.

The Cambridge philosopher C. D.*Broad argued (1929) that the universe is inherently 'layered', to give emergences with increasing com

Page 218

plexities that can never be predicted or explained from any knowledge of lower (generally simpler) 'layers' of reality. On this account, mind may remain beyond understanding despite knowledge of brain or other function—even though mind is causally given by physical functions. Moreover, most neurophysiologists, at least until recently, have held that brain and mind are essentially different—irreducibly two kinds of things—the causal connection (denied by*Leibniz) notwithstanding. (See also MIND AND BODY; MINDBODY PROBLEM: PHILOSOPHICAL THEORIES.)

This duality may be criticized on the principle of Occam's razor, as postulating entities unnecessarily; though one might follow the physiologist Sir Charles*Sherrington's (1906, 1940) opinion: 'That our being should consist of two fundamental elements offers, I suppose, no greater inherent improbability than that it should rest on one only.' By contrast the neurologist Wilder*Penfield (1975) came to the view that the mind is the emergent characteristic of brain function and depends on physical processes of the brain. This is probably the prevailing view, though Broad's 'layers', limiting reductionist explanations, are largely ignored or denied.

Whether these dualist and emergent accounts of mind are so different, and just what each implies, depends on extremely difficult issues of what should be accepted as causal and what as emergent; and how emergence may be seen in causal terms. The answer seems to be that causal explanations require general concepts, or 'meta'

accounts, and that these can remove the mysteries of emergence, though not simply by 'reduction' to the parts. But so far an adequate meta account for linking brain function to mind is lacking.

These issues have significance not only in science but also for anyone who wishes or needs to understand or apply scientific concepts; for the language, ideas, and aims of scientists differ according to the level of reduction in which they think and work. Thus a fundamental particle physicist or a cell biologist may find the concepts and aims of the neurologist alien and hard to appreciate—while the cognitive psychologist might as well be living in a different universe. And yet such universes of discourse have to be bridged for adequate understanding, and in many cases for effective research and action. Art and science have been described as 'two cultures'; but science is

also divided within itself, with prestige accorded to the 'deeper', more 'fundamental' concepts—even though they may be inadequate to explain the way things are higher up the tree. And it is not clear even that this tree is rooted in the 'fundamental' sciences—for its 'levels' of explanation depend on the observations and intelligence of our minds, at the treetop.

EMMERT'S LAW. It was reported by E. Emmert in 1881 that a visual*afterimage appears to change in size, according to whether it is seen as lying near by or far away. This is easy to demonstrate by looking for a few seconds at a bright light, or a camera's flashlight, and then viewing the afterimage as seen on a nearby surface (say a book held in the hand) and then on a distant screen or wall. The afterimage is perceptually 'projected' on to the viewed surface, so that it appears near on the book and more distant on the wall. When near it looks small, and the more distant it is seen to be the larger it appears. Its apparent size—though it is actually a fixedsize 'photograph' on the retina of the eye—increases roughly linearly with its apparent distance. This linear increase of apparent size with increasing distance is Emmert's law.

Consider now a normal retinal image, of some object, rather than the local fatigue of a region of retina of an afterimage. As the object increases in distance its image in the eye will correspondingly shrink—just as for a camera. But (and this is easily checked for oneself) as the viewed object recedes it does not appear to shrink anything like as much as the optical halving of the retinal image with each doubling of its distance. It normally *looks* almost the same size over a wide range of distances. This is due to a perceptual compensation called 'size constancy scaling'.

Afterimages are odd because they do not change in size at the retina. What we see in the *apparent* changes of size noted by Emmert is a compensation at work. It is compensating for what would normally be changes of size of the retinal image; but as the afterimage remains unchanging, size

constancy gives illusory changes of size.

Constancy scaling is set by several 'distance cues': convergence of the eyes, geometrical perspective, and the graded texture and falling of sharpness ('aerial perspective'), which are all associated with increasing distance of a viewed object. Correspondingly, afterimages change their size with changes of convergence angles of the eyes, or with perspective—many*illusion figures having converging lines. Any cue to distance can set the compensatory size scaling mechanism, and when misset there is a corresponding size or shape distortion illusion.

Emmert himself thought that a visible screen, on which afterimages are 'projected', is necessary for the size changes he described. This is not so, however, for these changes occur in the dark, if the

Page 219

observer moves backwards or forwards from an imaginary screen. This observation is important for it shows that Emmert's law is not due merely to relative size changes of the fixed afterimage and the changing image of the screen, or its texture, but is indeed due to the brain's perceptual compensatory size constancy scaling, which, when inappropriate, produces illusions of size or shape.

EMOTION is a topic that, more than any other, has bedevilled students of mental life. The peculiar characteristics of emotional behaviour and experience have been repeated stumblingblocks in the attempt to see human nature as rational, intelligent, and even sublime. From the earliest philosophical speculations to the present day, emotion has been often seen as interfering with rationality, as a remnant of our presapient inheritance— emotions seem to represent unbridled human nature 'in the raw'.

In modern times the single most influential contribution to the study of the emotions is Charles*Darwin's work entitled *The Expression of the Emotions in Man and Animals* (1872). His general thrust represents a second major theme that has characterized the study of emotion—the notion

that there are specific, fundamental emotions that find their 'expression' in the overt behaviour of humans and lower animals.

The current flux of speculations about the emotions started with a very specific event, the publication in 1884 of an article by William*James in *Mind* entitled 'What is an emotion?' James turned conventional wisdom completely around. Instead of the outward signs of emotions, such as facial expressions and visceral reactions, being the *result* of some prior emotional, neural signal, he insisted that 'our feeling of the [bodily] changes as they occur IS the emotion'. Similar points were made at about the same time by various other writers, the most important being the Danish physician C. G.*Lange, whose contribution appeared in Danish in 1885 and became generally available with its German translation in 1887. Since then, the theoretical position has been known as the JamesLange theory of emotion.

The theory dominated psychological thinking well into the first half of the twentieth century. It postulated that some external event, perceived by the individual, produces bodily responses, particularly specific avoidance or approach reactions, together with responses of the*autonomic nervous system. The perception of *these* events in their totality then constitutes the emotion that is experienced. Lange restricted the bodily reactions to the visceral, autonomic domain, but James stressed the total response of the organism. The obvious implication is that each specific emotional experience is generated by a specific and unique set of bodily and visceral responses.

The JamesLange theory remained dominant at least until the late 1920s, when **W. B.*Cannon** published a detailed and trenchant critique of its position. Briefly, Cannon noted that emotional behaviour was still present when the viscera were surgically or accidentally isolated from the central nervous system; that different emotions did not seem to differ in important ways in their accompanying patterns of visceral response; that perception of visceral response tends to be diffuse and nonspecific; that autonomic responses are relatively slow and that emotional experience seems to occur faster than the visceral response; and that emotional states do not follow the artificial production of visceral response as a matter of course. Cannon's major contribution to the study of emotion was this critique; the theory he offered as an alternative to James never did achieve great popularity.

In the ensuing decades speculation about emotion abounded, much research being devoted to problems of special visceral patterning; but, until the middle of the century, few new advances were made. The question seemed to remain where James and Cannon had left it: do we experience an emotion because we perceive our bodies in a particular way, or are there specific emotional neural patterns which respond to environmental events and then release bodily and visceral expressions? Do we grieve because we cry, or do we cry because we grieve?

What did happen in the decades after Cannon was the (unfortunate) American interlude known as*behaviourism. With hindsight it appears that the main deleterious effect of behaviourism arose not from its insistence on dealing only with the objective and the observable as basic psychological data—in a sense all psychologists have become methodological behaviourists—but from the behaviourists' implicit dictum against complex theory, against the postulation of useful fictions to

serve the explanation of behaviour. Uninhibited and expansive theorizing has generally characterized the cognitive theories, which implicate the knowledge and thought of the organism as determinants of action and experience. With the resurgence of cognitive theories, particularly in social psychology, came a concern with cognitive aspects of emotion. The single most important contribution in the form of both directionchanging theory and innovative experiments was made by Stanley Schachter, a psychologist from Columbia

Page 220

University in New York. He postulated that only a general state of visceral arousal was necessary for the experience of emotion: i.e. that different emotional experiences arise out of the same visceral background. Next he assumed that, given a state of visceral arousal, an individual will describe his feelings in terms of the cognitions (thoughts, past experiences, environmental signals) available at the time. Schachter's contribution cut the Gordian knot in which James's theory and the Jamesian critics had been entwined. Visceral arousal was seen as a necessary condition for emotional experience, but the quality of the emotion depended on cognitive, perceptual evaluations of the external world and the internal state.

With the new insights into the possible nature of emotional experience, it was possible to raise new questions about the nature and function of emotions. If the emotional experience is a concatenation of visceral arousal and cognitive evaluation, what is the role of emotions in adaptive behaviour; what is the function of visceral, autonomic*arousal?

Rather than emotion appearing as an interfering, irrelevant, and chaotic state of affairs, it seems that different kinds of situations (and cognitions) become especially marked if they occur in the 'emotional' visceral context. This notion corresponds with the common experience that emotionally tinged events occupy a special place in our memories. The visceral component of the emotion may well serve as an additional cue for the retrieval from memory of specific events, and sets them apart from the runofthemill catalogue of everyday events. The 'emotional' memory of a visit to a theatre is selected from among all the plays we have seen; it h 'special'. The memory of a friend with whom one interacted in the 'visceral' mode is different from the memories of people with whom one has interacted in nonarousing contexts.

But if the visceral component of emotion has this special role of selecting important events, what are the conditions that give rise to the visceral reaction?

The best candidate for the psychological conditions for visceral arousal seems to be the occurrence of some cognitive or perceptual discrepancy. The notion that emotions, both positive and negative, have as their antecedents some discrepancy or conflict between the state of the world and the expectations which the individual brings to the situation has been bruited about for at least a century. The most eminent ancestors of the suggestion are the French psychologist F. Paulhah and the American philosopher John*Dewey. They implied that specific discrepancies and conflicts produce specific emotions. Current wisdom would suggest that any discrepancy, any interruption of expectations or of intended actions, produces undifferentiated visceral (autonomic) arousal. The* *quale* of the

subsequent emotion will then depend on the ongoing cognitive evaluation (meaning analysis, appraisal) of the current state of affairs. Thus, riding on a rollercoaster produces serious disturbances and discrepancies between our expectations and current feelings of balance and bodily support. Whether the ride is seen as joyful or dreadful depends on what we expect about the ride, who accompanies us, what we are told to expect, and whether we feel in control of the situation. Some love it, others hate it.

The notion that discrepancy or interruption produces a special visceral event suggests that in addition to the homeostatic function of the autonomic nervous system there are other adaptive characteristics ascribable to it. In fact there is good evidence that, with the initiation of autonomic arousal, attentional and scanning mechanisms are directed towards important aspects of the environment. In other words, in addition to the autonomic nervous system caring for the internal balance of the energyspending and energyconserving functions of the body, it also serves as an alerting and marking mechanism for events that are 'important'. The concept of discrepancy or interruption provides an independent criterion for what is 'important' for the organism. When the usual, habitual actions and experiences of the individual are interrupted, when expectations of the world fail, then attention is focused on the environment, and the event itself is subsequently stored in memory as special and easily retrievable.

The modern view answers the ancient concern about emotions. They are not necessarily remnants of our presapient past, but rather they are important characteristics of an active, searching, and thinking human being. Novelty, discrepancy, and interruption generate visceral responses, while our cognitive system interprets the world as threatening, elating, frightening, or joyful. The human world is full of emotions not because we are animals at heart, but rather because it is still full of signals that elate or threaten, and replete with events and people that produce discrepancies and interruptions.

EMPATHY. The feeling of 'belonging to', associating ourselves with, or 'being carried along' with something. Thus a golfer may feel that he is almost soaring into the air with the ball when he hits a good drive. It has been suggested that when we look at the columns of buildings, such as Greek temples, we identify ourselves with the columns: if they are very thin, we feel uncomfortable as

they support; and if they are very fat, we feel uncomfortable as some people do when large and clumsy. This application of the notion of empathy is a theory of aesthetics due to the German philosopher and psychologist Theodore Lipps (1851-1914), professor at Bonn, Breslau, and Munich. 'Empathy' in this sense is a rough translation from the German *Einfühlung*. The theory has been stated as: 'Aesthetic pleasure is an enjoyment of *our own* activity *in* an object.' This idea was developed by Vernon Lee (penname Violet Paget, 1856-1935), who applied it especially to studies of Renaissance architecture.

ENCOUNTER GROUP. During the Second World War and immediately after it, there were several initiatives intended to help individuals to become, through participation in groups, more sensitive to their own and other people's attitudes and emotions and more spontaneous in expressing feelings. The focus of 'Tgroups' (training groups) was on issues of leadership and authority and the dynamics of change in organizations. 'Sensitivity' groups aimed at producing change by promoting 'interpersonal awareness'. Encounter groups, which became popular in the 1960s and 1970s, first in California and later in Britain, developed from Carl Rogers's 'clientcentred' therapy, which emphasizes personal growth and communication. Encounter groups provide the conditions in which participants can be freed from a sense of isolation and alienation through selfdiscovery in a supportive, permissive, nonauthoritarian group setting. The qualities to be induced are openness, authenticity, honesty in the physical, nonverbal expression of feeling, and 'actualization' as a person. Those who advocate them have resisted any attempt at scientific formulation and investigation of the processes involved, and claim that they are 'theoryfree'. Nevertheless, several assumptions seem to be made—for example, that the physical expression of feeling in an unstructured setting is cathartic and beneficial. Participants probably do acquire certain social skills, which are transferable outside the groups. Whether the persona revealed in the group, although more congenial to the other participants, is more real or true than the one it replaces is open to question. A few participants are more confused than liberated, and there is a small risk of more serious illeffects, especially if, despite the claim that groups are

'threatfree', a participant is confronted aggressively.

ENDOMORPHY. See BODY BUILD AND PERSONALITY.

ENDORPHINS are one of the major classes of peptides that occur in the brain. They appear to take part in the transmission of chemical messages between nerve cells by acting on receptors which have the characteristic property of binding opiate compounds such as morphine.

It has been known for a very long time that certain plant extracts contain opiates and that these compounds have powerful effects on behaviour, mood, and pain (see OPIUM). Only recently, however, was the question asked whether the presence of opiate receptor sites indicated the existence of naturally occurring opiatelike compounds in the nervous system itself. In 1975 the first successful extraction of such endogenous compounds was achieved. They were called enkephalins (literally: in the brain). Originally two distinct forms were found. Both were peptides with five amino acid constituents in the sequence, differing from each other only at one site and named methionine-enkephalin and leucine-enkephalin.

Following this breakthrough, many more active endogenous compounds were found. They all contain the same opioid core of five amino acids found in enkephalin. It is now clear that they can be grouped into three genetically different peptide families with different distributions in the nervous system. The situation appears to be similar to that found for another family of neurotransmitter substances—the monoamines, where modification in the basic chemical structure is associated with their distribution in several anatomically distinct groups of neurones.

Three opioid peptide families. It has been known for some time that hormones secreted into the gut are synthesized initially as high molecular weight precursors, and that the active hormones are produced by cleavage of a fragment or several fragments from the precursor before they act at receptor sites. This same principle appears to hold true for hormones secreted from the pituitary gland and for the opioids in the brain and pituitary. The three precursors for the opioids are called proopiomelanocortin (POMC), proenkephalin and prodynorphin. The POMC molecule, in addition to containing the enkephalin sequence, contains another opioid peptide of very high potency, and two other hormone sequences, one for adrenocorticotrophic hormone (which stimulates the adrenal cortex) and one for melanocyte-stimulating hormone (which regulates skin pigmentation). Proenkephalin contains several peptides all of which have opioid activity; while prodynorphin is a simpler precursor than the other two and produces three main opioids.

As is the case for many other neurotransmitters, there appear to be several types of receptor for the opioids. This may reflect differing mechanisms for translating opioid effects into different responses or the presence of several types of opioid compound within a given synaptic terminal, or the different anatomical distribution of the three main

opioid families (see below) or all these possibilities together. For example, slight variations in the structure of the peptide sequence may result in subtly differing effects at the opiate receptor, particularly when these variations occur in the amino acids adjacent to the central enkephalin

sequence. It is possible to imagine a wide range of activity at receptors resulting from such modifications, which, when they act at different receptor subtypes, confer an enormous dynamic range of responsiveness. In addition, receptor super or subsensitivity resulting from longterm functional adaptation may add further to the complexity of effects. The picture becomes even more complicated by the discovery that transmitters may coexist in the same synaptic terminal. It was thought that neurones used only one transmitter to exert their effects at chemical synapses, but this assumption collapsed. Many examples are now described where a low molecular weight transmitter such as acetylcholine or noradrenaline coexist with a peptide. One example is the copresence of enkephalin and noradrenaline in the adrenal medulla, an endocrine gland. The significance of the phenomenon of coexistence is unknown, but it may be related to the slow timecourse of action of many neuropeptides. Thus the peptide may modulate the responsiveness of a neurone to its partner transmitter in some way perhaps to sharpen or broaden the time resolution of the synaptic message. These properties may confer further subtlety to neuronal events, which may allow us to transcend the simple idea that excitation or inhibition in a neural network is the only information subject to coding, translation and transformation.

Anatomy of the opioid systems. In the brain the main POMC cell group lies in the arcuate nucleus of the hypothalamus and it sends*axons to innervate many limbic and brainstem regions. Another small group of neurones lies in the brainstem centres that regulate autonomic functions (such as cardiovascular control). In the pituitary gland POMC is synthesized mainly in the intermediate lobe and in a few anterior lobe cells.

The most abundant type are neurones which synthesize proenkephalin. They are distributed widely in the brain from the highest cortical to the lowest spinal levels, as both long axon and short axon pathways. In the peripheral neuroendocrine system, proenkephalinderived peptides are also found in the adrenal medulla, the gut, and many other structures.

Prodynorphin is found in the gut, posterior pituitary, and brain, where it is located chiefly in the hypothalamus, basal ganglia, and brainstem.

Functions. The distribution of opioids indicates that they participate in many different brain functions and (in a broad sense) probably in every brain function. For technical reasons, however, some areas have received more attention than others. These are mechanisms of*pain sensation, cardiovascular regulation, hypotensive*shock, and endocrine activity. More complex systems controlling feeding, drinking, movement, motivation, reinforcement, memory, mood, and affect are also influenced by opioids but little is known of their effects in these difficult areas.

Pain and stress. The experimental finding that brain stimulation of specific sites produces a reduction in pain responses, which can be reversed by the specific opiate antagonist naloxone, suggests that endogenous opiates are involved in analgesic mechanisms (see ANAESTHESIA). Furthermore, pain relief is accompanied by increased opioid levels in the cerebrospinal fluid which circulates around the brain.

Analgesia may also be produced by repeated stressful stimuli. This is accompanied by a reduction in

hypothalamic opioids, perhaps because the material is released by the stimulus. Stress-induced analgesia may also be counteracted by opiate receptor-blocking drugs. The site of action and neural circuits involved are far from clear, however, and they must involve nonopiate as well as opiate pathways. In addition, stress-induced analgesia may depend partly on opioids released from the pituitary gland or peripheral organs such as the adrenal glands. Thus the adrenal medulla stores and releases both the catecholamines and enkephalin together in responses to stress.

An interesting finding has been obtained in relation to the phenomenon of placebo analgesia. Here subjects may report relief of pain even when given a dummy tablet.

Those reporting analgesia following an inactive placebo show raised opioid concentrations in the circulation. No matter where the opioid is generated, the result suggests that physiological processes may be influenced by the belief of the subject that an analgesic substance has been given. The implications of this finding would appear to be quite far reaching.

Circulation and endocrine control. The anatomical distribution of the three opioid families suggests that they all play a role in the central regulation of cardiovascular functions. Thus, all three are present in neurones of the brainstem cardiovascular regulatory centres. The POMC family is present in the anterior pituitary which influences the adrenal cortex and hence blood pressure, and the prodynorphin group act on posterior pituitary hormones to control blood volume. Furthermore, the enkephalins of the sympathetic nervous system, via their control of the vascular bed, are well placed to regulate regional bloodflow and hence blood pressure.

These fundamental discoveries feed through to applications of importance to medical treatment. For example, the state of shock resulting from loss of blood is a dangerous condition which is difficult to treat. Since naloxone, by blocking opiate receptors probably located in the brain, can reverse shock-induced reduction in blood volume,

Page 223

it is possible that more effective management of this condition will soon be available.

ENGRAM. A physical brain change, supposed to take place as a result of experience, and to represent memories. The physical basis of memory is not, however, known. The problems of the concept are beautifully described by Karl Lashley, In search of the engram, *Symposia of the Society of Experimental Biology*, 4, 45-82.

ENTAILMENT is the relation that holds between one or more propositions $P \dots P$ and each

proposition C which follows logically from them. Thus 1

n

$P \dots P$ entail C (frequently symbolized $P \dots P \supset C$) if, and only if, the inference from $P \dots P$ to C is logically valid. The further analysis of this relation has been 1

n

1

n

1

n

extensively discussed and disputed both by logicians and by philosophers. It is generally agreed that whenever A entails B it must be impossible for A to be true without B also being true, in which case, according to the definition introduced by C. I. Lewis, A strictly implies B (see IMPLICATION). The further analysis of entailment has thus come to be linked to the account given of the logic of the modal notions of*possibility and necessity which is supplied in works on modal logic.

Lewis, who produced the first axiomatized modal logic, proposed that the relation of strict implication should be regarded as the correct formal counterpart of the informal notion of entailment. Others, however, for example Anderson and Belnap, have argued that for A to entail B it is not sufficient merely that it be impossible for A to be true without B being true. On their view there must also be some connection between the meanings of A and B, and the truth of A must be relevant to the truth of B (giving rise to the idea of developing what has been called a relevance logic). This would mean, for example, insisting that although a contradiction strictly implies any proposition whatsoever ('Grass is green and grass is not green' strictly implies 'The earth is flat') it only entails those propositions to which it is relevant ('Grass is green and grass is not green' entails 'Grass is not red').

ENTELECHY. The term *entelecheia* is first used in Greek philosophy to mean the actualization of something as opposed to its mere potentiality. Thus Aristotle in the *De Anima (Concerning the Soul)* defines* *psyche* (soul) as the 'entelechy of an organic body', viz. that which makes a body actually alive and functioning. Aristotle did not, however, regard the *psyche* as a separate nonmaterial entity,

but merely as the 'form' or organizing principle of the body.

In the philosophy of*Leibniz, 'entelechy' is used to refer to the active principle present in all created substances, which makes them complete, selfsufficient and changing only as a result of internal action. Later the term was used by*vitalists to refer to the (alleged) active principle responsible for organic life.

J. G. C.

EPICURUS (341270 BC) was born in Samos, and died in Athens. He founded a school in Athens whose members secluded themselves from the city and lived austere, and included (most surprisingly) slaves and women. The second head of the school was a slave called Mys.

Of Epicurus's enormous literary output (about 300 rolls) most is lost, including his thirtyseven books *On Nature*. Although he lived frugally, his moral precept was:

'We say that pleasure is the beginning and end of living happily.' He argued that the pleasures of the soul—contemplation, and the expectation of bodily pleasures—are more valuable than bodily pleasures alone. The ideal is freedom from distraction; and the study of philosophy is the best way to achieve this ideal. Natural (physical) explanations of mind and soul free us from being distracted by the fear of the supernatural.

Epicurus maintained the notion of unchanging and indestructible atoms, from Leucippus and Democritus. He was unusual in holding an atomistic philosophy, which was revived only in the early nineteenth century, by John*Dalton, though in a rather different form. Most Greek philosophers thought that it could be made to explain anything, and therefore explained nothing. Epicurus also denied the power of gods, holding that natural motions explain all phenomena. He held a view of evolution that anticipates in some respects Charles*Darwin's theory of natural selection by survival of the fittest.

EPILEPSY. A person is said to suffer from epilepsy if he is prone to recurrent epileptic seizures. The epileptic seizure is a transient episode of altered consciousness and/or perception, and/or loss of control of the muscles, which arises because of abnormal electrical discharges generated by groups of brain cells. Many varieties of seizures are recognized. They differ according to the nature of their symptom content. Most last for no more than a few minutes, but occasionally they are prolonged beyond 30 minutes or else recur so rapidly that full recovery is not achieved between successive attacks—these conditions are labelled status epilepticus.

It has been estimated that 67 per cent of the population suffer at least one epileptic seizure at some time in their lives and that 4 per cent have a

Page 224
phase when they are prone to recurrent seizures (i.e. can be said to suffer from epilepsy). Between 0.05 and 0.1% of the population suffer from 'active epilepsy'—that is, they have had a recurrent seizure within the previous five years or are taking regular medication to prevent the occurrence of seizures. Seizures are particularly liable to occur in early childhood, during adolescence, and in old age.

The history of epilepsy is probably as long as that of the human race. The definition of the condition as a clinical entity is generally attributed to *Hippocrates. He recognized that it arises from physical disease of the brain. He also took the first step towards unravelling the intricacies of cerebral *localization of function with his realization that damage on one side of the brain can cause convulsions which commence on the opposite side of the body. Further significant advances in this direction, based on observations of seizures, were delayed more than 2,000 years until the nineteenth century, and in particular until the observations and deductions of Hughlings *Jackson.

William Gowers, writing towards the end of the nineteenth century in the same era as Hughlings Jackson, proposed a dichotomy with his suggestion that some people have epileptic seizures because of overt cerebral pathology whereas others have them because of some factor in their brains innate constitution unaccompanied by any detectable abnormality of structure. To some extent this is reflected in the current classification which divides epileptic seizures into the two main categories: 'primary generalized' and 'focal' (or 'partial' in the current terminology). However, further advance lay beyond simple clinical observation and was delayed until the technique for recording the electrical activity of the human brain (the electroencephalogram, EEG—see ENCEPHALOGRAPHY) was developed, first in the 1920s by the German psychiatrist Hans *Berger and then in the 1930s by the Cambridge physiologists E. D. *Adrian and B. H. C. Matthews. The technique was rapidly applied to the analysis of epilepsy especially by E. L. and F. A. Gibbs, W. G. Lennox, H. Jasper, and H. Gastaut. Their findings, and the findings of those who followed them, have supported the view that seizures can be broadly divided into the two main categories mentioned above. Primary generalized seizures are those in which the symptoms of the seizure, and the EEG if it is being recorded at the onset, indicate that the whole of the brain becomes electrically abnormal synchronously at the moment when the seizure commences. In contrast, focal (partial) seizures are those in which the symptoms, and the EEG if it is being recorded at the onset, suggest that the electrical abnormality commences in a restricted area, usually a part of the cerebral cortex, even though the electrical abnormality may then spread more or less widely.

The commonest forms of primary generalized seizure are the tonicclonic convulsion without aura (the *grandmal* convulsion), the *petitmal* absence, and the myoclonic jerk. The convulsion commences with the tonic phase in which the muscles stiffen symmetrically on both sides of the body and this is followed by the clonic phase of muscle jerking. Consciousness is lost from the outset and the person falls to the ground if he was standing. There may be an epileptic cry at the outset, a blue coloration may develop around the lips (cyanosis) and the facial skin especially in the tonic phase when breathing is interrupted, the bladder and/or the bowels may be emptied and the tongue may be bitten. When consciousness is regained the person may be confused and may act in an automatic fashion (see AUTOMATISM); a period of sleep may follow. The *petitmal* absence lasts only a few seconds. There is loss of awareness but the person does not fall to the ground; he stares blankly and any movement is confined to flickering of the eyelids and/or very slight twitching of the facial and/or arm muscles. There are a number of varieties of absence seizure, but the true *petit mal* absence is characterized by an EEG pattern consisting of spikewave activity occurring at the rate of 3 cycles per second. The myoclonic jerk consists of a very rapid symmetrical upward jerk of the arms accompanied by a nod of the head and a forward bend of the trunk.

The true *petitmal* seizure occurs very predominantly in childhood and adolescence. It is almost invariably a manifestation of constitutional epilepsy rather than due to cerebral pathology, and it is strongly associated with a hereditary factor. Children who are prone to *petitmal* seizures may also have myoclonic jerks and tonicclonic convulsions. *Petitmal* absence seizures and myoclonic jerks tend to become much less frequent after adolescence but convulsions may continue. Primary generalized convulsions and myoclonic jerks are most often seen in childhood and adolescence when the epilepsy is usually due to a constitutional predisposition—idiopathic epilepsy—but they can be due to diffuse cerebral pathology.

Focal (partial) seizures commence with electrical discharges in a restricted area of the brain. The initial symptom of the attack depends upon the location of the focal discharges. Thus, when the focus is in the motor cortex the seizure usually begins with jerking in a restricted group of muscles on the opposite side of the body, especially those of the face, hand or foot, since these are represented by the largest areas within the motor cortex. As the electrical discharges spread to other parts of the motor cortex, so more and more muscles on the opposite side of the body are incorporated into the convulsion. This spread in a pattern corresponding to the homunculus mapped on the motor cortex is known as the Jacksonian seizure and indeed enabled Hughlings Jackson to predict such a map. When the electrical discharges extend beyond the motor cortex, and especially when they pass through the corpus callosum to the opposite cerebral hemisphere, consciousness is lost and the

Page 225

convulsion may become generalized involving both sides of the body.

A particularly common variety of focal seizure originates from discharges in the structures of one or other temporal lobe temporal lobe epilepsy. The demonstration, particularly by the Montreal school under the leadership of Wilder*Penfield, that some cases of temporal lobe epilepsy can be cured by surgery has been an enormous stimulus to detailed study of many of its facets. The seizures often commence with a visceral sensation or an alteration of thought processes and perception which can be remembered afterwards. This is the aura. Those who experience an aura often find the content very difficult to describe, partly because their awareness and memory systems are distorted by the seizure and partly because the appropriate words to convey the quality of these abnormal sensations do not exist. Common visceral sensations include a feeling of nausea in the stomach or chest which may rise to the throat or head, nausea felt elsewhere in the body, hallucinations of smell or taste, giddiness, and palpitations. The alterations of thought process and perception often have an emotional content and frequently involve a distortion of memory.

Brief feelings of extreme fear, anxiety, or depression are common. Feelings of elation are much less so. The aura may contain a feeling of familiarity as if everything has happened before (* *déjà vu*), there may be a feeling of intense unreality, sensations of perceptual illusion such as macropsia or micropsia may occur, and occasionally a complex visual or auditory hallucination is experienced. The aura may be followed by an automatism (referred to as a complex partial seizure in the current terminology). That is a period of altered behaviour for which the person is subsequently amnesic and

during which he appears to have only limited awareness of his environment, if any at all. The behaviour in an automatism is usually primitive and stereotyped consisting of, for instance, lip smacking, chewing, grimacing, and gesturing, but sometimes much more complex behavioural acts are performed. Very occasionally an automatism continues for a prolonged period a state known as an epileptic fugue (see DISSOCIATION OF THE PERSONALITY).

Whereas primary generalized seizures are characteristic of epilepsy due to a constitutional predisposition (idiopathic epilepsy) focal seizures are attributed to a focus of pathology. It is usually impossible to define the precise nature of this pathology, but occasionally it is a tumour or an area of brain damage due to head injury. Some cases of the most severe temporal lobe epilepsy are due to loss of neurones in the hippocampus (a structure situated in the medial part of the temporal lobe) caused by a prolonged convulsion occurring in early childhood, and when this abnormality is restricted to one side of the brain there is a good chance that surgery will effect a cure. Regular medication can suppress the seizures of many people prone to epilepsy but unfortunately by no means all.

Lastly, mention must be made of the concept of an epileptic personality. It has been claimed that a particular personality type is associated with epilepsy. The matter is complicated because epilepsy is associated with many factors which themselves may affect not only personality but many other aspects of mental function. These include cerebral pathology, antiepileptic medication, the depression to which many people with epilepsy are prone, and the restrictions which society imposes on them. It is difficult to find any evidence that a particular personality is associated with epilepsy *per se* after due allowance has been made for these factors.

EPIPHENOMENA. Phenomena that occur in association with, or are supervenient upon, a given set of events, yet supposedly are not caused by those events. The term is applied particularly to the mind-brain problem. An epiphenomenal account of mind is that mental events, and especially*consciousness, occur during physical brain activity but are not caused by physical activity. They are supposed, rather, to run in parallel but to be autonomous. This, of course, leaves mind totally inexplicable and mysterious from the point of view of physiology and everything we know of the physical world.

René*Descartes narrowly avoided epiphenomenalism, holding that the bodies and brains of organisms are 'mere' machines and supposing that mind is causally linked to the brain at the pineal

gland. Mind and brain were, for Descartes, largely independent, and this is also so for many more modern psychologists, philosophers, and neurophysiologists—such as William*James and Sir John Eccles (Popper and Eccles, 1977)—who hold forms of interactive parallelism. These are almost statements of epiphenomenalism, except for limited causal interaction between mind and brain. It is indeed often thought that mind (especially awareness of pain, colours, emotions, etc.) is more affected by physical brain states than it, considered as a largely separate entity, itself affects the brain. The commonsense view is that most behaviour is automatic (in physiological terms, controlled by*reflexes) without corresponding mental events, and that only when there is deliberate or conscious volition does mind affect behaviour.

EPIPHENOMENALISM. See MINDBODY PROBLEM: PHILOSOPHICAL THEORIES.

EPISTEMOLOGY. The branch of philosophy con

Page 226

cerned with the theory of*knowledge. One of the oldest of philosophical debates concerns the origin of human knowledge. Empiricists traditionally maintain that all knowledge is ultimately derived from sensory experience. According to John*Locke the mind at birth is a blank sheet, or *tabula rasa*: 'how then comes it to be furnished with that vast store which the busy and boundless fancy of man has painted on it? To this I answer in one word, from *experience*' (*Essay Concerning Human Understanding*, 1690). Rationalist philosophers such as Descartes, by contrast, insist on the doctrine of innate ideas—that the mind is furnished from birth with certain fundamental concepts which enable it to arrive at knowledge a priori, independently of the senses (see INNATE IDEA). The question of whether human knowledge can transcend the senses, and of whether, and in what sense, a priori knowledge is possible, is one of the major themes of the philosophy of Kant (see KANT'S PHILOSOPHY OF MIND).

A central epistemological issue that goes right back to*Plato is the question of what is the difference between knowledge and mere belief. In what sense does the person who has knowledge differ from one who has a belief that may happen to be true? Much recent work in epistemology has been concerned with answering this question by analysing the concept of knowledge, and attempting to formulate a precise set of necessary and sufficient conditions for the truth of statements such as 'S

knows that P'. (See further, ENTAILMENT; ESSENCE; KNOWLEDGE; NATURALISTIC ANALYSES.)

J. G. C.

ERGONOMICS, the study of efficiency of persons in their working environment, sometimes called 'human engineering', received its first impetus during the First World War, when the problem was to increase the productivity of semiskilled munitions workers. This led to work by the British Medical Research Council's Industrial Health Research Board in the 1920s and 1930s on the effect of fatigue

and boredom in repetitive tasks, and on the effect of the environment at work: lighting, heat and humidity, and noise. The main thrust came during the Second World War, when men in the fighting services had to handle equipment which was a lot more complex than they were used to. The obvious alternative to long and difficult training was to make the work easier.

Design of displays. Late in 1945, as soon as the war was over, Paul Fitts of the US Aero Medical Laboratory at Dayton, Ohio, started a comprehensive investigation of the problems facing people using the new complex equipment. He and his colleagues asked wartime pilots to describe actual experiences in which errors were made in reading and interpreting aircraft instruments. Of the 270 critical incidents reported, 40 involved a misreading of a threehanded altimeter by 1,000 feet (300 metres) or more.

An altimeter tells the pilot how high he is flying. Its three hands are covered with luminous paint. One hand is for the 10,000s, one for the 1,000s, and the third for the 100s. A bedside clock has only two luminous hands; even so, when waking up at night it is possible to confuse the minutehand for the hourhand, when the minutehand is pointing to a likely hour like 2 or 4 a.m. With three hands to confuse, the altimeter provides still greater opportunities for error. On a clear day, an error in reading the height will be realized because the pilot can see the ground below; but on a dark night, and when flying in or above cloud, the pilot has no external means of telling that he has misread his height. An investigation in the laboratory compared reading the threehanded altimeter with reading the same heights from a digital counter, like the counter showing mileage in a car. The threehanded altimeter took longer to read, an average of seven seconds, compared with about one second for the counter. It caused more errors of 1,000 feet or more, which could be fatal in an aircraft—10 per cent compared with less than 1 per cent for the counter. Threehanded altimeters were used by the commercial airlines for another twenty years and continued to result in accidents. But they are not used now.

Design of controls. Fitts and his colleagues also asked the wartime pilots about errors in .operating the controls of aircraft. Practically all the pilots of the US Army Air Force who were questioned reported that they sometimes made errors. Of the 460 errors reported, 89 involved confusing the three engine controls which alter the throttle, the propeller speed, and the fuel mixture. This was because the three controls were located in three different orders in three of the standard aircraft in use at the time. A pilot who was used to flying one type of aircraft was particularly likely to make an error when he changed to flying one of the other two types. As Fitts remarked: 'Imagine the difficulty most car drivers would experience in learning to brake with the left foot and to use the clutch pedal with the right.' In aircraft the error can be serious if just after takeoff the pilot inadvertently reduces the throttle or mixture, when he intends to reduce the propeller speed. Yet pilots are trained not to look at the controls they are operating: they have to look at their instruments, and at the world outside the aircraft. They should not need to look to see if they are operating the correct control.

These and other reports of confusion between the controls of aircraft also led to laboratory investigations. One question investigated was the distance between controls needed to prevent a person from operating the wrong control. Another was the shape of controlknobs needed, so that each could easily be identified and distinguished by touch. Following this work, the controls in aircraft are

position in each new type of aircraft. (See also TRANSFER.)

Control-display compatibility. Of the 460 pilot errors reported in operating controls, 27 involved moving the control in the direction opposite to that required to produce the desired result. Some of these moves would have been in the correct direction if the pilot had been in his accustomed type of aircraft, and they are avoided by standardizing controls between aircraft. But other errors involved moving the control in the 'natural' or 'expected' direction, which happened to be wrong.

This finding led Fitts to his principle of 'control-display compatibility'. The most compatible control is the display-marker itself. In setting the minute-hand of a clock, the minute-hand is clasped directly with the fingers and rotated to the desired time. The nearer the control-display relationship can approximate to this, the easier it will be for the person operating the control. If the clock-hand is controlled by a knob or key, the control should rotate in the same direction as the clock-hand, not in the reverse direction. Where a number of instrument displays and their controls are located on a single panel, each control should be next to its display. The controls should not be mounted on a separate panel far away from their displays, or the person may operate the wrong control in error.

Layout of equipment. The investigations of displays and controls led naturally to investigations of the optimal layout for a set of displays and their related controls.

People have to be able to see the displays and to reach the controls. Yet people come in different sizes: from anthropometry, the systematic measurement of body heights and lengths of limb segments, it became clear that seats must be adjustable, both in height and in the distance from the working surfaces. With adjustable seats, most displays and controls are now located in positions suited to the people who use them. The strength of the limbs operating controls in various positions has also been measured, to ensure that a control in a particular position is not too stiff to operate.

The layout of individual workplaces is now often part of the overall layout of a control room or factory department. Since equipment has to be maintained as well as operated, it is necessary to leave space behind the consoles for the maintenance engineers. The time spent maintaining equipment may be small compared with that during which it is operated but, when equipment breaks down, it is inconvenient, expensive, or in the case of military equipment unacceptable if repairs cannot be carried out quickly. Thus maintenance needs have to be considered in design, as well as the needs of operatives.

In planning a factory department, the ergonomist now usually considers the organization of the work to be done. Some functions can be performed automatically, while others require people. The layout of the machines and work stations is made to follow the sequence of operations to be carried out.

The environment at work. Equipment sometimes needs to be designed especially for the environment in which it is to be used. Driving farm tractors and harvesters over rough fields subjects

both the driver and the equipment to vertical vibration and jolting. The vibration blurs the numbers on the instrument scales, and so they have to be larger than usual if they are to be read easily. The jolting may make the driver move a control accidentally: the chances of this happening may be reduced if the controls move horizontally—that is, at right angles to the vertical jolting.

It is particularly important for the equipment which a person is using in a noisy environment to be designed ergonomically. In quiet surroundings a person can usually hear when he is operating equipment correctly: switches may produce audible clicks when they are pressed, and the tap of a hammer has a higher pitch when it hits a nail or rivet than when it misses and hits wood or canvas. In noisy surroundings such cues may not be audible, or may be difficult to distinguish one from another. If in operating equipment a person has to use his eyes, or sense of touch, instead of his ears, and if these senses are already heavily engaged, he may fail to notice mistakes.

The medical problems of the environment at work are now giving ergonomics a new impetus. Loud noise causes industrial deafness, as well as masking sounds, and calls for noise control and hearing protection. Vehicles and aircraft crashing at speed cause injuries that call for better designs of safetyharness and seatbelts. Work under water, say on oil and gas installations, is carried out at pressures several times greater than atmospheric pressure, and requires foolproof equipment (see also DIVER PERFORMANCE). Industrial processes produce dusts, vapours, and gases which may cause cancer or other illnesses. Ionizing radiation, and electromagnetic radiation of short wavelength, like gamma rays, Xrays, ultraviolet light, and the microwaves used in cooking, can also damage human organism.

Dosimeters have to be designed and worn. The more generally harmful effects of atmospheric pollution need to be reduced by changes in industrial activity.

Ergonomists today require knowledge of chemistry and physics in addition to their traditional knowledge of displays and controls.

Interface between user and computer. Research has now expanded to study the interface between people and computers. At first a computer system was considered acceptable as long as it worked. To use the system, the operator had to learn to think like the computer engineers who designed the system. The few fulltime computer operators learnt to do this, but it was too difficult for many of the nonspecialists who wanted to use a computer to help them with their job. Research is now

Page 228

directed towards designing 'user friendly' interfaces, which are easy for the parttime and casual user to learn and use (Card, Moran, and Newell, 1983).

EROTIC. Evocative of sexual passion, from the name of the god of love in Greek mythology. Eros is not personified in Homer, although the word is used to describe the sexual desire that drives Paris to Helen, and Zeus to Hera. Hesiod describes Eros as the god who 'loosens the limbs and damages the mind', and makes him (together with Earth and Tartarus) the oldest of the gods and allpowerful.

The Greek philosopher Parmenides makes Eros (the power of love) that which joins contrasting things together. In fact, it is no exaggeration to say that love for the Greeks was a binding force in their physics. Magnets (loadstones) were described as male and female; according to Pliny (*Natural History*, xxxvi, 12630) strong magnets are male and weak magnets female.*Plato discourses upon Eros in the *Symposium* and *Phaedrus*.

ESSENCE. The essence of something is what it is to be that thing as opposed to something else. Thus the essence of a triangle is threesidedness. In*Aristotelian philosophy, a thing's essence is given by specifying its defining characteristics—its 'essential' as opposed to 'accidental' features. Thus, being a malleable metal would be an essential characteristic of gold, but being mined in South Africa would be an accidental characteristic (since if gold ceased to be mined in South Africa it would still be gold).

There is a celebrated philosophical debate about whether statements about essence reflect the real nature of things or merely human linguistic conventions. The former view is known as 'essentialism' or 'realism', the latter as 'nominalism'. Recently the American philosopher Saul Kripke has revived a version of essentialism according to which natural kinds (gold, water) possess real essences: that is, certain characteristics are necessarily true of these substances, and this is not a matter of linguistic convention but is a matter of the real structure which these substances necessarily possess.

Questions about essence ('what is X?', 'what is it to be x?') have traditionally been distinguished from questions about existence ('does X exist?'), and questions of the former sort have been supposed to be prior to the latter (thus we can raise questions about the essential characteristics of triangles without having to concern ourselves about whether triangles really exist). Existentialists such as*Sartre, however, maintain that, in the case of human beings, 'existence precedes essence'. On this view, the

first truth of which a human is aware is simply that he exists; his freedom to choose how to live is not constrained by any predetermined 'nature' or essence.

ETHICS OF BRAIN MANIPULATION. See BRAIN MANIPULATION, ETHICS OF.

ETHOLOGY. Modern ethology abuts on so many different disciplines that it defies simple definition in terms of a common problem or a shared literature. The subject started out as the biological study of behaviour. However, as Robert Hinde (1982) noted, those who *call* themselves ethologists are now to be found working with neurobiologists, social and developmental psychologists, anthropologists, and psychiatrists, among many others. Even classical ethology gave itself a wide remit. Niko Tinbergen (1963) pointed to four broad but separate problems raised by the biological study of behaviour, namely: evolutionary history, individual development, shortterm control, and current function. Moreover, it was plain that he and the other grandmasters of the subject, such as Konrad Lorenz, were not only aware of these different problems, but were actively interested in all of them.

Inasmuch as ethology still has a distinctive flavour, much of it derives from this breadth of interest. For that reason it is worthwhile taking a closer look at the four central problems identified by Tinbergen. (i) *Evolution*. What is the ancestral history? What can be deduced about the ways in which the behaviour evolved and the pressures that gave rise to it? (ii) *Development*. How is the behaviour assembled? What internal and external factors influence the way it develops in the lifetime of the individual, and how does the developmental process work? (iii) *Control*. How is the behaviour controlled? What internal and external factors regulate its occurrence, and how does the control process work? (iv) *Function*. What is the current use of the behaviour? In what way does the behaviour help to keep the animal alive or propagate its genes into the next generation?

Many ethologists had strong childhood interests in natural history and subsequently received a training in zoology. This aspect of their personal

Page 229
histories explains their interests in the evolution and survival value of behaviour. Impregnated as their thinking has been with the Darwinian theory of evolution, they repeatedly speculate on the adaptive significance of the differences between species. Indeed, many ethologists are primarily interested in biological function. Others are wary of proceeding far in laboratory studies without first relating their findings to the context in which the behaviour naturally occurs. The functional approach has certainly helped those who are interested in the study of mechanism.

Understanding what behaviour patterns are for provides the scientist with an important way of distinguishing between different types of behaviour. Equally valuable, the background knowledge obtained in functional studies has been fruitful in guiding investigators to the principal variables controlling a behaviour pattern. Being able to distinguish the important causal factors is extremely useful when designing experiments—in which, inevitably, only a small number of independent

variables are actually manipulated while the others are held constant or are randomized. While looking at animals in an unrestricted environment, the observer becomes aware of the context in which each pattern of behaviour occurs. This suggests some of the conditions necessary for its occurrence and the events that bring it to an end.

The preoccupation of many ethologists with function has led to many excellent studies of animals in natural conditions. The justification for fieldwork is that an animal's behaviour is usually adapted to the environment in which it normally lives, in the same way that its anatomical or physiological characteristics are adapted. A captive animal is usually too constrained by its artificial environment to provide a complete understanding of the functions of the great variety of activities which most animals are capable of performing. To observe the full richness of its repertoire and understand the conditions to which its behaviour is adapted, the animal must usually be studied in the field. The patient observer notices the circumstances in which an activity is performed and those in which it never occurs, thereby obtaining clues as to what the behaviour pattern might be for (that is, its function). Field studies also relate behaviour patterns to the social and ecological conditions in which they normally occur. This led to the development of an area of research known as behavioural ecology. Another subdiscipline, sociobiology, brought to the study of behaviour important concepts and methods from population biology and stimulated further interest in field studies of animal behaviour. As commonly happens, the announcements that a new discipline had been founded were accompanied by strenuous efforts to distance the newcomer from its roots (see Wilson, 1975).

However, the eclectic wisdom of the classical ethologists seems to have prevailed, and the various subdisciplines are showing signs of merging into a unified approach to the study of the biology of behaviour.

Studies in unconstrained conditions of animals, and increasingly of humans, have been an important feature of ethology and have played a major role in developing the distinctive and powerful methods for observing and measuring behaviour. Even so, it would be a mistake to represent ethologists as nonexperimental and merely concerned with description. The point of doing an experiment is to distinguish between alternative explanations of hypotheses. Field observation can also achieve this goal if, for example, naturally occurring events demonstrate associations between variables that previously seemed unrelated, or break associations between variables that previously seemed bound together. Moreover, many simple, well-designed experiments have been performed outside the laboratory.

For example, Tinbergen wanted to explain why the groundnesting blackbeaded gull removes the eggshell from its nest site after a chick has hatched. A number of different functional explanations initially seemed possible—the chick might injure itself on the sharp edges of the shell; the shell might be a source of disease by harbouring microorganisms; the chick might get trapped under a shell and suffocate; the white inner surfaces of the shell fragments might attract predators visually; or the smell might attract predators by olfactory means. Tinbergen and colleagues were able to exclude a number of these candidates at the outset, using comparative evidence. Another gull, the kittiwake, nests on cliffs where it is not vulnerable to predators and does not remove the eggshell from its nest. This suggested that the first three possibilities were unlikely to be of major importance. A simple test,

which involved placing shells at different distances from the nest, was then used to show that the broken eggshell does indeed attract predators to the blackheaded gull's nest. The egg is cryptically coloured on the outside, but the inside is white and therefore easy for an airborne predator, such as a crow, to spot. The study confirmed that nests with open shells lying near them were more likely to be raided.

Field experiments have also been used to understand how an animal's behaviour is controlled. For example, taperecordings of predators or conspecifics (such as offspring or potential mates) have been played to freelifving animals in order to discover how they respond (see DANGER RECOGNITION). Dummies of different designs have similarly been used to gauge responsiveness to a particular shape or colour, such as the pecking of gull chicks at different objects more or less resembling the bills of their parents. These and many other examples make the point that even core ethology involves a great deal more than passive observation. Moreover, a great many people who call themselves ethologists have devoted much of their professional lives to laboratory studies of the control and development of behaviour.

Page 230

At a certain stage in the history of ethology, certain key concepts and theories were associated with it. They no longer form a central part of ethological thought, although they were important in its development. Two basic concepts were the 'sign stimulus' and the 'fixed action pattern'. The notion of the sign stimulus, such as the red breast of a robin releasing an attack from an opponent, was productive in leading to the analysis of stimulus characters that selectively elicit particular bits of behaviour. Fixed action patterns (or modal action patterns as they are sometimes more appropriately called) provided useful units for description and comparison between species. Behavioural characters were used in taxonomy, and the zoological concern with evolution led to attempts to formulate principles for the derivation and ritualization of signal movements.

Both the concept of sign stimulus, or releaser, and that of the fixed action pattern played important roles in the early ethological attempts to develop systems models of behaviour. Lorenz's lavatory cistern model was a flow diagram in more than one sense and provided a generation of ethologists with a way of integrating their thinking about the multiple causation of behaviour, from both within and without. Needless to say, the model was seriously misleading; and in some systems of behaviour, notably*aggression, performance of behaviour makes repetition *more* likely, not less as the model predicts. Another systems model has stood the test of time rather better. It was developed by Tinbergen and was concerned with the hierarchical organization of behaviour. Here again, though, its major role lay not so much in its predictive power but in helping ethologists to bring together evidence that would otherwise have seemed unrelated.

Another classic ethological concern was with the inborn character of much behaviour (see INSTINCT). Indeed, Lorenz saw adult behaviour as involving the intercalation of separate and recognizable 'learned' and 'instinctive' elements. Very few people share this view any longer, and the work by the developmentallyminded ethologists on such phenomena as songlearning and imprinting in birds has been important in illustrating how the processes of development involve an interplay

between internal and external factors (see IMPRINTING). After the early abortive attempts to classify behaviour in terms of instincts, attention has increasingly focused on faculties or properties of behaviour that bridge the conventional functional categories, such as feeding, courtship, caring for young, and so forth.

Consequently, more and more emphasis is being placed on shared mechanisms of perception, storage of information and control of output. As this happens the interests of many ethologists are coinciding to a greater and greater extent with the traditional concerns of psychology.

The modern work has also eroded another belief of the classical ethologists: that all members of the same species of the same age and sex will behave in the same way. The days are over when a fieldworker could confidently suppose that a good description of a species obtained from one habitat could be generalized to the same species in another set of environmental conditions. The variations in behaviour within a species may, of course, reflect the pervasiveness of learning processes (see CONDITIONING). However, as in a jukebox, some alternative modes of behaviour may be *selected* rather than informed by prevailing environmental conditions. For instance, many adult male gelada baboons are very much bigger than the females and, once they have taken over a group of females, defend them from the attentions of other males. Other males are the same size as a female and sneak copulations when a big male is not looking. The offsetting benefit for the small males is that they have much longer reproductive lives than the big ones. It seems likely that any young male can grow either way, and the particular way in which it develops depends on conditions. Examples such as this are leading to a growing interest in alternative tactics, their functional significance, and the nature of the developmental principles involved.

In describing and analysing behaviour, it makes good sense to start by obeying the canon of Conwy Lloyd*Morgan and treat animals in the simplest possible way until there is good reason to think otherwise. Nevertheless, as in other fields, many ethologists have come to feel that slavish obedience to a methodological maxim tends to sterilize imagination. A person who studies behaviour and *never* treats the animal as though it were human is liable to miss some of the richness and complexity of what it does. Many experienced ethologists have found how much they are helped if they put themselves in the animal's place and consider how they would deal with the situation. They notice important influences on the animal's behaviour which they would otherwise have overlooked, and are led to perform experiments which they would not otherwise have done. For these reasons, terms such as 'intention', 'awareness' and 'reasoning' are being used with increasing frequency in studies of animal behaviour, despite the wellknown pitfalls of excessive anthropomorphism and teleological argument. It seems likely that cognitive ethology will expand and, as it does so, start contributing to the study of mind.

EUCLID (*c.* 300 BC). Famous for his work on geometry, known as *Euclid's Elements* (modern English translation by T. L. Heath, 1956), Euclid was a Greek whose birthplace is not known. (In the Middle Ages he was known as Euclid of Megara, but this was the result of a confusion between him and a philosopher who lived around 400 BC.) It is

Page 231

thought probable that he received his mathematical training in Athens from pupils of*Plato. What is known is that he taught in Alexandria and founded a school there.

From the writings of Greek commentators we learn that he wrote about a dozen works other than the *Elements*. Only five of these, the *Data*, the *Division of Figures*, the *Phaenomena*, and the *Optics*, have survived.

Aristotle described as elements of*geometry those propositions whose proofs are contained in proofs of most other geometrical propositions. In a similar vein Proclus (*c.* AD 41285) likened the relation the elements of geometry bear to the rest of geometry to the relation the letters of an alphabet bear to a language. Euclid's was not the first exposition of the elements of geometry; we know of at least three earlier versions, including one by Hippocrates of Chios. But Euclid's seems to have so outclassed these that it alone has survived. His achievement was to have imposed a thorough systematic organization on geometry, one in which, starting from*axioms, definitions, and postulates, each proposition is proved either directly from these or from these together with propositions already proved. It thus provides an early example of a deductively organized body of knowledge, and it has functioned as a paradigm for all other sciences for at least 2,000 years.

The *Elements* is divided into thirteen books of which the first four concern basic plane geometry. Books V and VI develop a theory of proportions, generally credited to Eudoxus of Cnidos (*c.* 390340 BC), which overcomes the problem of incommensurable magnitudes, which are explicitly tackled in Book X. Books VIIIX deal with numbers and ratios between numbers, and Books XIXIII are chiefly devoted to solid geometry.

EUGENICS. See GALTON, SIR FRANCIS.

EVOKED POTENTIAL. The study of evoked brain potentials arose as an extension of the interest in the spontaneous electrical activity of the brain, recorded in*electroencephalography. It was recognized even by Richard Caton, who first recorded the electrical activity of the brains of animals

in 1875, that the voltages recorded from the brain's surface could be influenced by external events impinging on the senses.

Hans*Berger, who discovered the resting alpha rhythm of the electroencephalogram (EEG) in man some fifty years later, noted the disappearance of this oscillation, which had a characteristic frequency between 8 and 12 hertz, when the subject was stimulated by stroking the back of the hand (Fig. 1) or alerted by an auditory stimulus. He noted that the alpha rhythm could also be blocked by voluntary movement or mental arithmetic. This alphablocking reaction could be said to be the first of the evoked responses of the human brain to become the subject of scientific study.

Lord*Adrian in Cambridge demonstrated that the alpha rhythm arose particularly from the occipital areas of the brain and that its appearance was associated especially with visual inattention. Visual stimuli were much more effective in blocking the alpha rhythm than those of other modalities (Fig. 2). He also showed that a train of evoked potentials could be recorded from electrodes situated over the occipital lobe in response to a series of bright flash stimuli presented to the eyes. These photically evoked potentials were the first of the 'specific' sensory evoked potentials to be recorded in man.

The two decades following Berger's discovery of the alpha rhythm were marked by an increasing pace of advance in knowledge of the electrical activity of the brain.

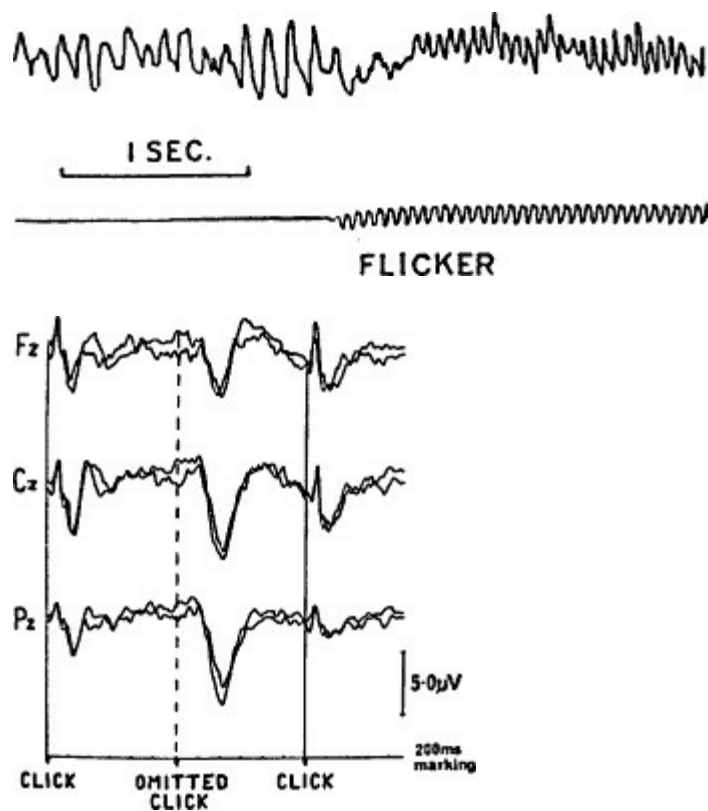

The potentials evoked by sensory stimulation in the specific visual, auditory, and somatosensory receiving areas in the cortex were studied in the exposed brains of animals and became accessible to study in man when methods of separating out the small potentials from the larger oscillations of the spontaneous background EEG

were developed in the 1940s by George D. Dawson. Recorded from electrodes on the intact scalp, he was able to show that consistent responses of around 10 μ V in amplitude could be recorded following electrical stimulation of peripheral nerve trunks through the skin in the conscious, intact human subject. The technique used depended on giving a large number of similar stimuli and adding the responses together, either by photographic superimposition or (in a later development) with an electronic averager. In this way, the consistent features of the response are reinforced, while the random variation in the background (noise) is minimized.

Dr. V., 30 year old physician. Doublecoil galvanometer. Condenser inserted. Recording from forehead and occiput with chlorided silver needle electrodes. Electrocardiogram with silver foil electrodes from the left arm and the left leg. At the top: the electroencephalogram; in the middle: the electrocardiogram; at the bottom: time in 1/10ths sec. *B*: time at which the dorsum of the right hand was touched and stroking with a glass rod along the latter began.

Fig. 1.

 RATE OF FLICKER (17 A SECOND) IS SHOWN BY THE PHOTO
 ELECTRIC CELL RECORD BELOW.

Fig. 2.

An early recording of the visual evoked potential to flicker stimulation, from a paper by Adrian, published in 1944.

Small laboratory averagers became commercially available in the 1960s, enabling many centres to begin work on the clinical and scientific applications of evoked potential recording. As well as much further work with the types of stimulation used in the earlier studies, such as electrical stimulation of the limb nerves and stroboscopic flash stimuli, the responses to more 'natural' forms of stimulation were investigated, including tactile stimulation of the fingers and the visual responses evoked by sudden reversal of a black and white chequerboard pattern, which the subject viewed on an

illuminated screen. The latter type of stimulus proved particularly successful in clinical work, as it transpired that marked abnormalities of the response were found in association with demyelinating lesions of the visual pathways in multiple sclerosis and in other disorders of vision associated with ocular or neurological disorders.

At about the same time, the scope of evoked potential research was greatly widened by an awakening interest in other event-related brain potentials associated, for instance, with preparing to make a response (readiness potential, *Bereitschaftspotential*, and motor potential) or expecting a stimulus to which one is to respond (contingent negative variation, CNV, or expectancy wave, Ewave).

The motor potential studies required the development of a new technique of opisthochronic averaging, 'averaging backwards in time', since interest was here focused on the events preceding an event, the response, whose exact time could not be predicted in advance. The latter is an example of a so-called endogenous potential as distinct from the exogenous sensory evoked potentials, whose occurrence and timing depended upon an external event, the sensory stimulus.

The Bereitschaftspotential, or readiness potential, which consisted of a slow buildup in negativity over the central regions of the cortex during the 12 seconds preceding a response, depended for its occurrence on the probability and predictability of the motor act, whether this was self-paced or made in response to an expected stimulus.

An even more interesting family of event-related potentials (ERP) can be recorded when a stimulus is sufficiently improbable and yet significant. These are the so-called P300 waves, which depend for their incidence on the unexpectedness of the relevant event. They were first described in two papers by Sutton and colleagues in 1965 and 1967 and have been extensively studied since that time. Even the unlooked-for absence of an expected event (Fig. 3) can elicit a P300, as in the case of a single missing stimulus in a long train of repeated tones.

Evoked potentials to omitted stimuli. Clicks were presented regularly every 1.1 sec and occasionally a click was omitted: the subject was asked to count the number of omissions.

The averaging computer was triggered by the click immediately preceding the omission. Evoked potentials are shown for three different scalp positions.

Each tracing represents the average of 64 responses. Subject T.P.

Fig. 3.

P300 evoked by a nonevent, viz. the unexpected

omission of one of a regular train of clicks. Note the large

P300 wave, occurring with each scalp position.

Page 233

Semantic improbability is associated with an N400 wave, a negativity occurring about 0.4 seconds following the unexpected word (e.g. when the sentence 'He spread the warm bread with socks' is presented, one word at a time, on a visual display, a large N400 wave occurs only in respect to the unexpected word 'socks'). No such response occurs to the sentences: 'It was his first day at work' or 'She put on her highheeled shoes'. These languagerelated ERPs were first described by Kutas and Hillyard from San Diego in 1980. Work on linguistically related ERPs has also been carried out by Goto in Japan, who has studied the brain responses associated with the resolution of linguistic ambiguities.

A. M. H.

EVOLUTION: HAS IT A PURPOSE? If we agree that all organisms show something that may reasonably be called*choice, it implies that their actions are at least partly directed towards an end. Of course, if one reserves the words 'aim' and 'end' for something that is sought 'consciously' then they cannot be used for the

'teleonomic' actions of all living things. The biologist's plea should surely be that we seek for enlightenment from the similarities between species, as well as from their differences, and not allow terminology to interfere. It is amazing that many biologists should have so strongly maintained that they did not wish to consider aims, in the face of the obvious fact that organisms act so as to stay alive. Equally surprising is the unwillingness to admit that it is possible to see any sign of progress in evolution.

Of course there are difficulties, but we can now put measures on the degree of complexity of organisms and can give a precise meaning to such statements as that man is the summit of an increasing process of collection of information. It is still conventional to say that questions of value cannot be decided by facts, and indeed everyone will agree that the meaning of 'good' is difficult to determine. Following G. E.*Moore, we are usually asked to hold that the only things that possess intrinsic value are human states of mind. The biologist can hardly accept that this is the last word. Surely our decisions about value are not wholly 'intuitive'. Whether we like it or not they are guided by the influences that have imposed themselves upon us, many of them biological, others social. Of course, to insist that it is nonsense to claim that judgements are wholly intuitive does not actually provide us with criteria for the meanings of 'good' and 'bad', still less for making ethical judgements and recommendations. Yet the general biologist can contribute marginally even to the characteristically human discussion of ultimates.

We do not know yet for certain how, when, or why life began or whether and when it will end. On such things indeed biologists are gaining some knowledge but can still only speculate. The anthropomorphic guesses of theologians have led people to hope for a certainty that we now realize to be unobtainable. But this does not mean that there are no signs of direction in human life. We can see that we have a long and wonderful history, involving an increasing collection of information and its use to allow life to invade regions not habitable before (Young, 1938).

Life probably began over 3,000 million years ago, perhaps in a probiotic soup of organic molecules (Bernal, 1967). We are uncertain what originally determined the ordering of specific nucleotides and proteins, but the subsequent course of evolution has certainly involved an increase of order. For perhaps the first 2,000 million years, life remained very simple. The few fossil remains that we have are of bacteria or algae. The evidence of the sedimentary rocks shows that by 500 million years ago there were already many complex invertebrates. Then came the first fishes and after them the amphibians, reptiles, birds, and mammals. The point of this now familiar story is that the whole sequence indubitably involves an increase of complexity of organization and of the information transmitted to ensure it. Under the pressure of natural selection, organisms have invaded ever new niches, made habitable by the development of special mechanisms. The examples are endless—to colonize fresh water an organism needs to pump out the excess that flows in. To colonize the land involves preventing loss of water and developing mechanisms for finding it. The skin, which in fishes is a relatively homogeneous tissue, becomes differentiated in mammals into perhaps 100 different sorts, all coded for in the DNA.

And so on, through all the adaptations that pervade organisms. Of course the progressive increase of order is notoriously irregular. But the numbers of pairs of nucleotides give us a means of quantifying it. In a virus there are about 2×10^5 pairs, equivalent to 100 pages of 2,000 letters to the page. In a bacterium there are $5 \times$

10^6 pairs (2,500 pages) and in man 3.5×10^9 (1,700 books of 1,000 pages each). There are many difficulties—for instance we cannot yet properly qualify the differences in complexity among mammals. But we do know that man has developed entirely novel methods of gathering information and storing and transmitting it outside the body.

These facts show that life has had a direction in the past and that man in the last million years has speeded it along its course. We cannot see direction or purpose when we look at the heavens, but we can see them in the progress of life on earth. Perhaps one day we shall be wise enough to see them in the stars too.

Meanwhile we can see that our wants and needs and ambitions are not in vain. They are there to guide us and we should not deny them. They tell us truly what is worth while to do for ourselves and for our species. If we look wider still we can see the implications of our very special place in nature. This shows the biological ethic, the imperative to increase variety and to collect further information with which to conserve life and even to create new ways in which it can continue.

Young, J. Z. (1938). The evolution of the nervous system and of the relationship of organism and environment. In de Beer, G. R. (ed.), *Evolution*. Oxford.

EVOLUTION: NEODARWINIAN THEORY.

History. Charles*Darwin was by no means the first evolutionist. Ideas of transformation of species can be found in the classics ('It's all in Lucretius' was Matthew Arnold's comment on Darwin) and in the writings of eighteenthcentury thinkers such as Buffon, Diderot, Goethe, and Charles's grandfather Erasmus*Darwin. But all those ideas are vague or covert. The French biologist (he coined that word)*Lamarck was the first to present an articulate and explicit theory of biological evolution in his *Philosophie zoologique* (1809). Other notable precursors of Darwin were the Scottish publisher Robert Chambers (180271) with his anonymous *Vestiges of the Natural History of Creation* (1844), and Alfred Russel*Wallace, whose independent discovery of the mechanism of natural selection prompted Darwin to abridge a vast, unfinished manuscript as *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (1859). Natural selection, a materialistic explanation for adaptation and the diversity of life, was Darwin's main contribution. Coupled with a candid and persuasive argument, it was enough to convince most scientists of the truth of evolution, and to capture the imagination of most late nineteenthcentury thinkers.

The latter part of the nineteenth century was a period of exploration of evolutionary theory. Its biological ramifications formed the mainspring of much late Victorian science, and Darwin's theory soon became influential in many other fields, notably anthropology, sociology, politics, philosophy, and psychology. As this list implies, Darwinism was seen by many as a coherent world view.

In 1900, Gregor Mendel's work on inheritance, originally published in 1866, was rediscovered, and the science of genetics was born. Mutation theory soon replaced natural selection as the most promising field of research into mechanisms of change, and for a while Darwinism was at a low ebb. But towards the end of the 1920s, mathematicians and geneticists—chiefly R. A.*Fisher, J. B. S. Haldane, and Sewall Wright—showed that genetic theory and natural selection were fully compatible, so founding population genetics, which became the central area of evolutionary research. The integration of population genetics with more traditional fields of evolutionary interest such as anatomy, palaeontology, and systematics (classification) was pushed forward in the late 1930s and early 1940s in books by T. Dobzhansky (a geneticist), E. Mayr (a systematist), and G. G. Simpson (a palaeontologist). Julian Huxley's *Evolution: the modern synthesis* (1942) gave an alternative name—the synthetic theory—for neoDarwinism.

In 1953 Francis Crick and James Watson transferred interest to the molecular level with their model of the structure of deoxyribonucleic acid (DNA), the material basis of heredity. Exploration of the implications of the WatsonCrick model soon resulted in the breaking of the genetic code, unravelling

of the mode of translation of the genetic message, and development of other branches of molecular biology. Ideas from molecular biology, though broadly consistent with neoDarwinism, are one of many sources of a new ferment in evolutionary thought. Darwinism and its modern descendant are by no means fossilized theories, embedded as true foundations by scientific progress. Where the current ferment will lead, or end, is impossible to guess. But the ingredients of the brew can be matched with some of the main headings of Darwin's argument as presented in *The Origin*: variation, natural selection, instinct (behaviour), fossils, classification, embryology—and the origin of species, the title of his book, but a topic that he hardly tackled.

Classification. The basic unit in biological classification is the species. Attempts to define species have been made for centuries and no definition has yet been found to cover every case. Virtually all definitions emphasize reproduction—species are those aggregations of organisms within which mating and reproduction are normal and successful. The modern abstraction covering this concept is 'genepool': a species is a set of organisms sharing a set of genes, and the sharing is manifested in the mixing of the genes of two parents in the fertilized egg. Genes of one species are not mixed with those of another, because mating is not attempted, or is unsuccessful through the sperm failing to fertilize the egg, or through failure in development of the embryo, or through sterility of the hybrid offspring. The molecular basis for success or failure in reproduction is the exact matching of maternal and paternal chromosomes which is necessary in the cell division producing egg or sperm cells.

These criteria are broadly applicable in all sexual plants and animals. In asexual organisms, reproducing by simple fission, for example, it is difficult to form a rational concept of species, since the only link between organisms is a historical one of more or less remote common parentage (see Fig. 1). We recognize this by resemblance between the descendants.

The basic tenet of a theory of evolution is that the relation between species is also historical and due to past common ancestry, manifested in resemblances between species. To evolutionists, the distinct genepools of today's species are selected and modified fractions of the genepools of more or less distant common ancestral species. One central task of a theory of evolution is to explain how discontinuities in gene exchange may arise—how a species may split (see section headed 'Origin of species' below).

Above the species level, it is common experience that there are groups of species which seem to go

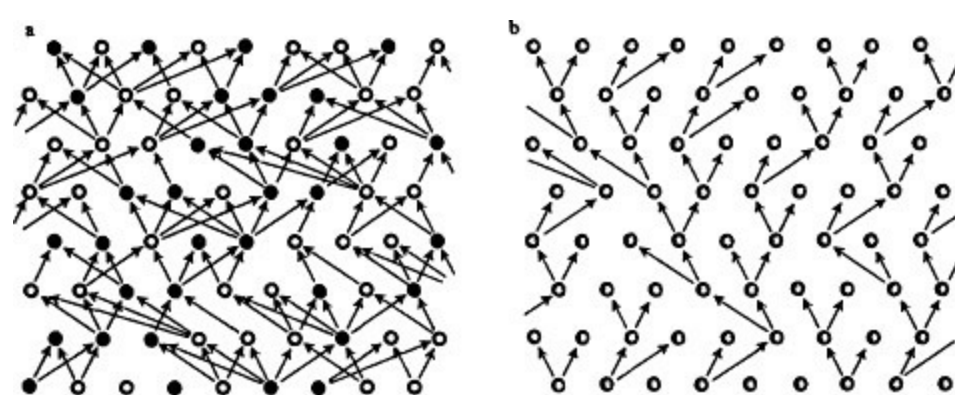

Fig. 1.

Population structure in sexual and asexual species. a. A sexual species, like our own, in which each individual has two parents of different sexes (dark or light blobs). b. An asexual species in which the parent reproduces by dividing into two, as in simple plants and animals like amoeba; each individual has only one parent. According to the theory of evolution, the history of life is a pattern like this, in which blobs are species, not individuals. If the population is to remain constant from generation to generation, only half the individuals in b may reproduce. In a, a parent produces more than two offspring only at the expense of others.

together: birds, for example, or beetles or cats. Biological classification formalizes this fact of life by giving these groups Latin or Latinized proper names (birds are Aves, beetles are Coleoptera, cats are Felidae), and by ranking those names in a hierarchy of more or less inclusive categories (Aves is a class—category—within the phylum Vertebrata; Coleoptera is an order in the class Insecta; Felidae is a family in the order Carnivora and class Mammalia). These names and ranks are conventions, but from Aristotle to Linnaeus (eighteenth century) to today, those who propose classifications usually believe that they express something real, an order in nature. Before Darwin, that order was commonly rationalized as 'the plan of the Creator' or the imperfect reflection of unchanging and ideal essence. According to Darwin and his followers, the relation between birds, or between beetles, or between birds and cats is not abstract but historical or genealogical, due to common descent (see CLADISTICS).

The central concept of classification is *homology*. When a child learns to recognize birds, the criteria used are, at root, the same as those used by the scientist: the feathers, beak, wings, and so on are 'the same' in a sparrow and a swan, whereas the wings of a beetle or the beak of a turtle do not make those creatures birds—the

'sameness' is different or inessential; technically, it is analogy rather than homology. The task of biological classification is thus to distinguish homology (informative sameness) from analogy (misleading sameness). And the interest of classification to the evolutionist is that homologies, the characters of groups, are seen as evidence of common ancestry, so that the hierarchy reflects real historical relations. A research programme is implicit here, to reconstruct the history of life through the common ancestry inferred from homologies. Since Darwin first proposed that 'Our classifications will come to be, as far as they can be so made, genealogies', this programme has been followed with enthusiasm. The programme concerns the main outlines of life's history; it integrates classification with morphology, palaeontology, and embryology. This work is an extrapolation from evolutionary theory, and the fact that the work can be carried out does not materially affect the theory itself. The theory depends on more basic matters, an explanation of how species originate. Darwin approached that problem first through his study of variation.

Variation. Lacking a sound theory of inheritance, Darwin studied it through the experience of those with a practical interest in it, animal and plant breeders. Of the manuscript, from which *The Origin* was abridged, the only part that Darwin actually published was the two-volume *Variation of Animals and Plants under Domestication* (1868). In *The Origin* Darwin argued by analogy. Under

domestication, breeders observed variations and were often able to perpetuate them by selective mating. Over many generations, the breeds or varieties of dogs, cabbages, pigeons (Darwin's pets), and so on are the result. Darwin's opinions on the causes and inheritance of variation are chiefly of historical interest now. He wrestled with the problem of whether variation is spontaneous, or is provoked by the 'conditions of life' (i.e. the environment), and favoured the environment. And he tried to analyse the mode of inheritance, whether or not it is 'blending', offspring being intermediate between the parents. Blending seemed empirically true for many characteristics, and it has the consequence that a new variation would be swamped or diluted over the generations. These problems, of the origin of variation and its inheritance, were not solved until the twentieth

Table 1. The genetic code.

The letters A, G, T, and C stand for adenine, guanine, thymine, and cytosine, the four bases in DNA. The 64 possible triplet combinations of these letters are shown, together with their meaning—the named amino acid, or 'stop'. Most of the redundancy of the code is in the third letters of the triplets: AG, GA, GG, GC, TG, CA, CG, and CC each has the same meaning, regardless of the third letter.

century, with the development of genetics and, later, molecular genetics.

There is no space here to go into genetic theory, and its outlines must be baldly stated. The material basis of heredity is DNA, a ladderlike molecule which carries a message in the form of a 'fourletter' code, the letters being four chemical bases, each of which may occupy any rung in the ladder. The message is read in triplets, or

'threeletter words', and the words are of two kinds, 'stop' or 'amino acid X'. Twenty different amino acids are encoded by triplets, some by a single triplet, others by up to six different ones (see Table 1). Thus the genetic message specifies sequences of amino acids terminated by stop signs, and, when translated and acted upon, the result is proteins, which are chains of amino acids. Genes are sections of DNA which specify a discrete amino acid chain.

DNA is carried in chromosomes, in the nucleus of every cell. When sex cells (eggs or sperm) are produced, the chromosomes pair off very precisely, each pair containing one chromosome from each of the two parents, and within each pair parts are exchanged at random (crossingover). The newly mixed chromosomes then separate in a cell division which produces sex cells containing one member of each pair, so that the number of chromosomes is halved. The number characteristic of the species is restored when the egg and sperm nuclei, each carrying a half set, unite in the fertilized egg. Inheritance is not blending: genes are passed on unchanged from generation to generation.

With that background, the sources of heritable variation can be specified. First, the genes of each new individual are a new assortment, because they combine two half sets (from egg and sperm) each shuffled in the crossingover between chromosome pairs in the parental cell divisions that produced them. This is a form of variation generated by shuffling existing material, as each deal of a shuffled pack of several thousand cards would be unique. Second, new variation may be introduced by mutations: accidents or mistakes in replication and repair of DNA or mishaps in cell division. Mistakes in DNA can alter one or more bases in the molecule (letters in the code), and may alter one or more amino acids in the protein specified. Mishaps in cell division may alter parts of chromosomes—lengths of DNA—which may be inverted, deleted, duplicated, or transferred to another chromosome. The effect of mutations on individual organisms ranges from negligible or undetectable to lethal.

The effect of mutations on the reproductive capacity of an individual (i.e. the formation of viable eggs or sperm) also varies from undetectable to sterility. Known mutations in DNA turn up with frequencies from about 1 in 10^4 to 1 in 10^8 : they are rare, but frequent enough for every human individual to carry several mutations which have arisen during his or her life. Most of these will be in somatic (body) cells, not in eggs or sperm, and so cannot be passed on to the next generation.

That statement recalls the other question that bothered Darwin—whether variations acquired during life can be inherited. The question refers to what is now called Lamarckian inheritance, for Lamarck proposed that the effects of use and disuse and other changes during life are heritable, and are a cause of evolutionary change. In fact, Darwin held much the same belief. The orthodox answer to the question is no—acquired characters

→

are not inherited. One reason for this is that offspring inherit only an egg or sperm from each parent, and at least in animals those cells are sequestered very early in embryonic life, before the environment takes its effect. A second reason is that translation of DNA into protein—construction of the organism—is held to be a oneway process, with no feedback from the organism to the DNA. This notion is the 'central dogma' of molecular genetics. The one known exception to that dogma is reverse transcriptase, an enzyme which transcribes RNA, the messenger nucleic acid, into DNA, the message store. But to get environmentally induced information into DNA requires more, a way of getting such information into RNA (reverse translation rather than transcription). No such mechanism is yet known. But there has been support for a neoLamarckian model of evolution, and various ways in which the environment might direct or influence the genes have been suggested.

Ideas on variation have gained impetus from techniques for separating variant protein molecules, and so estimating the proportion of variant genes in individuals and species. The result is surprising: there is much more hidden variation than was expected. Hidden genetic variation in one individual is due to different forms of homologous genes in the half set of chromosomes inherited from each parent. In humans, if the few that have been tested are a fair sample of the whole, the proportion of variant genes in each individual is at least 6 per cent, about normal for vertebrate species; in plants and invertebrates variation is often higher, 15 per cent or more.

With the discovery that the genes of species are less uniform than expected, the problem has shifted from Darwin's—where does variation come from?—to a new one—why is there so much variation? Orthodox ricolarwinism demands that it be due to natural selection.

Natural selection. Darwin's main contribution was natural selection, the survival of the fittest, a materialist explanation for evolutionary change. There have been several presentations of natural selection theory as a deductive argument. Here are three: (i) All organisms produce far more offspring than are necessary to replace them, yet numbers of each species remain roughly constant. Therefore, there is differential mortality, a struggle for existence. (ii) All organisms manifest hereditary variations. Therefore, those organisms inheriting variations useful in the struggle for existence will be more likely to survive to pass on those variations. (iii) The environment is not constant. Therefore, those hereditary variations advantageous in a changing environment will be selected, and species will change to remain in harmony with the environment. This is adapted from an 1870 formalization by A. R. Wallace. It emphasizes the effect of changing environments, and the observed constancy in numbers of individuals.

A briefer form, due to the philosopher A. G. N. Flew, is: (i) Geometrical rate of increase + limited resources Biological improvement. This emphasizes the theoretical limits on environmental resources rather than constant populations and changing environments, and introduces the notion of 'improvement'. What is improved is not specified.

Another brief form: (i) All organisms must reproduce. (ii) All organisms exhibit genetic variation. (iii) Genetic variations differ in their effect on reproduction. (iv) Therefore, variant genes with

favourable effects on reproduction will succeed, those with unfavourable effects will fail, and gene proportions will change. This emphasizes variant genes, and reproductive success rather than environmental factors.

If natural selection can be presented as a deductive argument in which the conclusion follows logically from the premisses, then it must be true if the premisses are true.

If the premisses in one, or all three, of these formulations are empirically true, natural selection must occur.

But we have to be clear about what is selected. Natural selection concerns differential survival or, the other side of the coin, differential extinction. What are the units that survive or become extinct: are they genes, or fragments of genes (e.g. triplets or single nucleotides), or chromosomes, or genotypes (genetic constitutions of individuals), or phenotypes (individual organisms, each expressing its own genotype), or groups of organisms, or species? Wallace's formulation of selection refers to species, Flew's perhaps to individuals, and the third form to genes: are they all correct? All descriptions of natural selection invoke interactions, of individual organisms with the inorganic environment, with other individuals in reproduction, with individuals of other species in predator-prey interactions, and so on. Descriptions of natural selection also invoke replication or multiplication, of genes, or of individuals carrying favourable mutations. DNA and chromosomes mutate and replicate, but since they do not interact with the environment, selection cannot act on them directly. It is individual organisms or phenotypes—life histories—that interact with the environment, but the genotype of every successful organism, the set of chromosomes, is broken up and reshuffled by crossingover when it produces eggs or sperm, so that individuals (genotype + phenotype) do not reproduce themselves exactly.

In the network of ancestordescendent relations over the generations (Fig. 1), the units that survive differentially, or are selected, are bits of DNA of unspecifiable length. If there is selective change over a number of generations, some bits of DNA in the original population will be represented by many copies in the final population, and others will not be represented at all, because they became extinct when the organisms carrying them failed to reproduce. In order to summarize the change, we

Page 238

have to use the abstraction 'genepool'. Over the generations, there is a change in the genepool of the population or species. Of course, no one has ever seen a genepool or dipped a finger in one, and the tangible effect of the change will be a change in the phenotypes in the population.

One definition of 'gene' is 'a portion of chromosome which survives enough generations to act as a unit of natural selection'. That definition may sound vacuously circular, as if we have to understand natural selection before we can understand genes, yet understanding natural selection depends on understanding genes. But it at least emphasizes the point that because chromosomes are randomly broken up in each generation by crossingover, there is no particular unit that survives intact over many generations. Indeed, there is a theory of 'hitchhiking' natural selection; a neutral or

disadvantageous mutation may spread because it happens to be adjacent to an advantageous one, so that the two survive as a unit without being separated by the chances of crossingover.

Because some organisms exhibit parental care, or social organization in which more or less extensive kinship groups take part, the family or kingroup may have sufficient cohesion to act as a unit of natural selection, kin selection as it is called. Beyond kingroups, the next steps up the genealogical hierarchy are populations and species. Like kingroups, they are linked by descent, by a shared genepool, and might act as units of selection, or of differential survival. It is doubtful whether populations of the same species ever interact so that one genepool becomes extinct: mixing of the genepools through interbreeding is the likely outcome (though some interactions between human populations may have resulted in extinction, by genocide without interbreeding). But different species do seem to interact in this way.

One thinks of the extermination of native species in the Galápagos and other closed habitats after the introduction of animals like pigs and goats. In such cases, one speaks of species selection (see section headed 'Origin of species' below). This, on its own, can only decrease diversity, not generate it.

The observation explained by natural selection is adaptation, the apparent design of organisms for the environments in which they live. The 'argument from design' was one of the chief preDarwinian props for natural theology—evidence for a wise and benign Creator. Darwin's theory of natural selection cut the ground from that argument (see also HUME). In essence, neoDarwinian selection theory is that mutations arise at random, with no feedback from the environment to direct or influence the type of mutation that is 'needed', and interaction between the environment and organisms bearing the mutation determines success or failure. Wallace's formalization of natural selection emphasizes changing environments as the driving force; but an alternative view is possible, of a static inorganic world which is explored by life through natural selection, so that the environment is in a sense created by organisms. For instance, it is difficult to conceive environmental change which would lead originally aquatic plants first to colonize the land, or terrestrial animals to take to the air: the land and air were there, but not part of the habitable environment until organisms made them so. Of course, once there are plants on land, or insects in the air, we can easily conceive the advantage of becoming a cow or a swallow.

But talk of cows and swallows introduces the problem with natural selection. Two entirely distinct aspects of the theory must be distinguished. One is concerned with things like cows, swallows, and giraffes' necks. The other is concerned with selection in populations, the bread and butter of population genetics. As for this latter sort, there is no doubt that it works. The deductive form of the argument for it proves that it ought to work, and there is experimental and observational evidence that it does. Classic instances of natural selection in populations include bird predation of light and dark forms of the peppered moth in industrial and rural Britain; the development of resistance to antibiotics in bacteria, to insecticides in insects, and to rat poison in rats; and the relation between human sicklecell trait and malaria in Africa. These instances cover two sorts of selection. In antibiotic or insecticide resistance, the genepool of the population is altered: genotypes to which the agent is lethal are eliminated, and those which can survive it increase. This is *directional* selection, where there is a shift from one state to another. Melanism in moths and sicklecell trait are instances of

stabilizing or *normalizing* selection, which results not in a shift, but in maintenance of the norm by elimination of variants. In both instances it happens that the norm maintained is a polymorphic population, and this is sometimes called *balancing* selection. Another type of selection is so obvious that it almost escapes attention; instances are the poor reproductive success of people suffering genetic defects which place them far outside the norm. Those defects are eliminated by *purifying* selection. The terminology seems varied and complex, but in general we can think of selection as either eliminating variation (purifying, directional) or maintaining it (balancing, stabilizing); and also as either promoting change (directional) or maintaining the status quo (purifying, stabilizing).

To neoDarwinians, the important types of natural selection are directional selection (an explanation of inferred change) and balancing selection as an explanation of observed variation. The basis of change is the replacement of one form of a gene, or portion of chromosome, by a new (mutant) form. This will take place when the mutant form confers a relative advantage, and spreads through the population. The rate of spread depends on the degree of advantage or selection pressure (roughly the proportion of selective deaths per generation), and on whether the mutation is recessive (expressed only in those

Page 239

inheriting it from both parents—homozygous for it), dominant (expressed if inherited from only one parent—heterozygous), or intermediate (expressed more strongly if inherited from both parents rather than one). Change is irreversible only when the original form of the gene has disappeared; that is, the mutant becomes fixed, or universal in the population. Fixation is achieved most rapidly when the mutation is neither dominant nor recessive but intermediate, which is probably true for most mutations considered at the molecular or proteinproducing level.

Balancing selection will occur when heterozygotes, inheriting different forms of a gene from each parent, are more successful than homozygotes. Here, selection will eliminate homozygotes in each generation, but will not alter the equilibrium proportions of the two (or more) forms of the gene. Balancing selection is the neo

Darwinian explanation for the high incidence (averaging 615 per cent of sampled proteins—see above) of heterozygosity observed in natural populations. The assumption is that heterozygotes are fitter than homozygotes because they have a wider array of resources to meet variations in the environment. An alternative explanation is the 'nonDarwinian' proposal that the observed protein variants are selectively neutral; they confer no real advantage or disadvantage and are maintained purely by chance, by random genetic drift. On this neutralist theory, harmless or even slightly deleterious mutations may spread and become fixed (or eliminated) purely by chance. As with natural selection, experiments show that genetic drift occurs, especially in small populations where biased samples are more likely, and there is a highly developed mathematical theory of how quasineutral mutations may behave in populations.

So far, it has proved impossible to discriminate between these two mechanisms, neoDarwinian selection and neutralist drift, as general explanations, though neutralism has had remarkable recent successes. In essence, the neoDarwinian expects that a given variation is correlated with some environmental variable, and the neutralist expects that it is not. When one such environmental

variable is identified with one genetic variant, as malaria has been with sicklecell trait (abnormal red blood cello in humans, this may seem a triumph for neoDarwinism, but a myriad protein polymorphisms remain to comfort the neutralist. The generality of balancing selection as an explanation for genetic variation took a sharp knock when it was found that bacteria, which lack sex and so cannot be heterozygous, are just as polymorphic as sexual organisms. At least the neoDarwinist seems to have a task, or a research programme: to dissect the environment into factors correlated with variations in organisms.

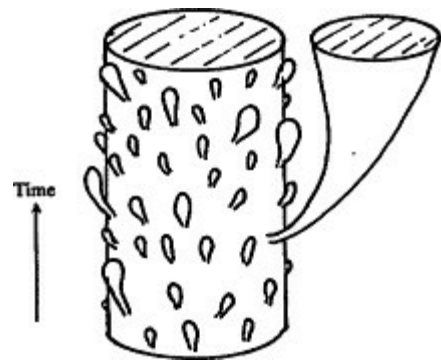

Neutralists have no such programme, and instead neutralism comes into its own in explaining evolution which is invisible to selection by the environment, changes in stretches of DNA which are not translated into the phenotype (see section headed 'Origin of species' below).

Natural selection, the idea that organisms are moulded or 'designed' by the environment, is also used as an explanation in quite a different sense, when applied to cows, or swallows, or giraffes' necks. Here, explanations are under virtually no empirical control, because the environmental factors invoked are necessarily in the past. In this mode, explanations take the form of conjectures or narratives, in which organisms are analysed in terms of function, and demonstration that one design is more efficient than another is sufficient to explain its origin by natural selection, or environmental conditions under which particular features could be advantageous are postulated or imagined. Critics argue that such exercises of the imagination demonstrate the emptiness of selection theory. In explaining everything, it explains too much; as an explanation of design in nature it seems hard to distinguish from the allseeing Creator of*Paley and other natural theologians. On this view, natural selection is equated with a vacuous Panglossian optimism—'all is for the best in this best of all possible worlds'—or with the explanation of the action of opium by its content of 'dormitive principle'. One response to these critics is that they do not touch the status of natural selection: it could still be as effective in the global sense as it is in the experiments of population geneticists. Nevertheless, no one has yet reported the origin of a new species by means of natural selection.

Origin of species. Although this was the title of his book, Darwin scarcely addressed the problem of how new species arise. His mechanism, natural selection, concerns change or transformation of species through time, but this alone will not produce new species; it will merely modify and preserve old ones. New species appear only if the number of species increases, if a species splits into two or more. Darwin proposed what he called the principle of divergence: by analogy with artificial selection, and by appealing to 'many and widely different places in the economy of nature', he argued that the most divergent members of a species tend to be preserved, and gradually diverge into varieties, subspecies, and eventually into distinct species. The kernel of his explanation was gradual adaptive divergence.

The neoDarwinian theory of the origin of species—of *speciation*—differs from Darwin's chiefly in the emphasis placed on geographic isolation as a necessary precursor of species formation, and in emphasis on genetic isolating mechanisms. NeoDarwinian speciation theory is by no means monolithic, and there are arguments for speciation without geographic isolation, and without Darwinian gradualism.

That species can arise at one stroke there is no doubt. Doubling of chromosome number in a cell is a fairly common accident: it happens if the chromo

Page 240

somes divide, as before normal cell division, but the cell then fails to divide. Such cells are unable to give rise to normal eggs or sperm, because the chromosomes will associate in fours, not in pairs as is necessary in production of sex cells. But in a hybrid between two species, itself sterile because of incompatibility between the two sets of chromosomes, chromosome doubling will restore fertility (each chromosome now has a partner to pair with), and self-fertilization can then initiate a new species intermediate between the two parents of the hybrid. Many species of plants and a few of animals have evidently appeared in this way, and some have been created or recreated in the laboratory.

Speciation by multiplication of chromosome number (*polyploidy*) is instantaneous; the new species is descended from a single self-fertilizing individual; accident—

macromutation—is the cause; and geographic isolation is unnecessary. In all these four ways, it differs from the classic neoDarwinian model of speciation, which demands geographic isolation, gradual selective change over long periods of time, and involves populations, not individuals. Between these two extremes, there is a third model of speciation which has received much recent support and interest. This model is inelegantly called 'punctuated equilibrium'—'quantum speciation' is an alternative. One group with evidence bearing on this model includes geneticists who have found that similar or closely related species usually differ in chromosome arrangement, implying fixation of chromosome mutations during their history. For instance, human chromosomes differ from those of chimpanzees by inversions of parts of nine chromosomes, and fusion of two. Whereas identical point mutations in DNA recur at measurable rates, each chromosome mutation is virtually unique, for each depends on the coincidence of at least two accidental breaks in a chromosome, followed by rearrangement and fusion. Organisms heterozygous for a chromosome mutation (inheriting it only from one parent) usually show reduced fertility, but those inheriting it from both parents (homozygous) are potentially fully fertile. Chromosome mutations can therefore act as genetic isolating mechanisms, favouring mating amongst carriers of the mutation (hence homozygous offspring) and so initiating speciation. But since chromosome mutations are each virtually unique, the only way homozygotes can be produced is by inbreeding among the offspring of the individual in which the mutation originally occurred. This model—'chromosomal speciation'—resembles the chromosome doubling mode of speciation in several ways: no geographic isolation is necessary, accident rather than natural

selection is the cause, inbreeding amongst the descendants of a single individual is necessary, and a new species may arise in a few generations, with the establishment of a population homozygous for the mutation.

A second set of arguments in favour of quantum speciation comes from palaeontologists, who generally fail to find evidence of gradual transformation in the fossil record. Instead, fossil species appear suddenly, persist unchanged over more or less long periods, and disappear as abruptly as they came. Data of the same sort were available to Darwin and his geological mentor, Charles Lyell (1797-1875). Lyell built a theory on them, of piecemeal creation of species by 'a power above nature'. Darwin, who believed natural selection was the power in question, appealed instead to imperfections in the fossil record, and hoped that future discoveries would show the gradual transitions he expected. Today, some palaeontologists have at last given up that hope and taken the fossils at face value, as a true record of the mode of evolution. They infer that speciation occurs rapidly, in small populations, so that transitions between species are evanescent. For if change does not occur during the recorded history of species, it must occur elsewhere, in the unrecorded history of small founder populations. From these ideas comes a theory of species continually and randomly throwing off small offshoots, of which most perish but a few succeed as new species (see Fig. 2). As in the chromosomal theory of speciation, natural selection is not responsible for the appearance of these offshoots, but operates at a higher level in selecting amongst them. In populations, random mutations throw up material on which selection acts; in just the same way, it is argued that random speciation throws up material—species—on which selection acts.

Major evolutionary changes are not due to the action of selection on mutations of genes or chromosomes, but of species selection on a mass of species, thrown up by a random process.

A third group of scientists whose ideas fit in here are molecular biologists. Techniques recently developed make it possible to work out the Fig. 2.

Diagrammatic model of part of the history of a species, as envisaged by advocates of quantum speciation.

The parent species is more or less stable through time, and is continually budding off potential new species in the form of small, inbreeding populations, which may be isolated by geography or by genetic accidents such as chromosome mutations. Most of these incipient species soon become extinct, but a few (one in this example) may succeed.

sequence of nucleotides in DNA and in the messenger nucleic acid, RNA. The letters of the genetic code may then be compared with the amino acid sequence in the protein synthesized on the message in the messenger RNA. The genetic code has a lot of redundancy. In eight of the sixteen boxes in Table 1 the third letter of the triplet makes no difference; the amino acid is specified by the first two letters alone. This means that mutations in the third position of many triplets will be 'silent' and will not alter the amino acid. Amino acids specified by triplets with different first (arginine, leucine) or first and second (serine) letters may also sustain silent mutations in the first and second positions. When the RNA and amino acid sequences are compared for human and rabbit beta haemoglobin genes, for instance, two-thirds of the differences between the RNAs are silent, not reflected in the protein; the same comparison between mouse and rabbit alpha haemoglobins gives virtually the same proportion of silent and nonsilent changes. If all these differences represent mutations fixed during the history of the species compared, two conclusions can be drawn.

First, the rate of 'silent evolution' must be greater than the rate of phenotypic change (we come back to this point later); second, the silent mutations must have been fixed by random drift, not by selection, since a change in DNA which is not reflected in the organism cannot be selected. If the majority of inferred change in DNA is due to mutations drifting randomly to fixation, then small populations should be frequent in the history of species, since drift is more effective in small populations, and most effective in inbreeding.

Thus three independent lines of enquiry— chromosomes, fossils, and molecular sequences— converge in a view of speciation which differs profoundly from neo

Darwinian orthodoxy. The nature of this difference or disagreement is interesting. It concerns three main things: time, or number of generations; number of individuals;

and natural selection. But these three things, the first two in quantity, are the staples of population genetics. NeoDarwinism depends on the synthesis of natural selection with experimental and mathematical population genetics, which themselves depend on avoiding random effects by considering many generations and many individuals. Population genetics can explain stability, or variety, or gradual change within species. The thrust of the above ideas on speciation is that those factors may all be irrelevant to the origin of species. In other words, the principles of population genetics are directed at the wrong level in the hierarchy: they explain the behaviour of genes in populations, but are inappropriate when extrapolated as an explanation of the history of life. It is, after all, a fairly fundamental criticism of neoDarwinism to propose that natural selection is not relevant to the origin of species.

Embryology. Before Darwin, the word 'evolution' had a different meaning in biology. It referred to the unfolding of form in the development of the embryo, and in particular to the notion of preformation—that the adult organism is preformed in the fertilized egg. One complaint among Darwin's critics was that he and his followers misused and misappropriated the word 'evolution'. But in the neoDarwinian theory, something approaching the doctrine of preformation seems to have reappeared.

The theory is concerned almost exclusively with genes, but what interests most biologists is

organisms and the form of organisms. NeoDarwinism has, as yet, little to say on how form is generated; it is assumed simply to be programmed in the genes, as if the adult and its development are preformed in the DNA, or the four dimensions of a life history are mapped in the two dimensions of the linear information store.

Darwinism and neoDarwinism are concerned with historical transformation of organisms. Despite more than a century of work in evolutionary biology, it remains true that the only transformations of which we have empirical knowledge are those observed in the life histories of organisms—the acorn into the oak tree, or the egg into the caterpillar, pupa, and then butterfly. It is remarkable that these transformations remain almost as mysterious today as they were in Darwin's time. The orthodox, genetic explanation of the genesis of form invokes control genes, which are thought of as switching on and off one or more structural (protein-specifying) genes. A hierarchy of control genes is envisaged, with 'master genes' which switch on batteries of lower-level control genes. Mutations in such control genes could obviously produce relatively large changes in the adult organism. But these control genes remain theoretical, and theoretical entities can, in theory, accomplish anything. Indeed, an immediate inference from the reductionist viewpoint of randomly mutating genes is that anything is possible, and it is natural selection which sorts out the actual from the possible.

Yet the regularity and uniformity of embryonic development in animals and plants seems to demonstrate that anything is not possible. One symptom of a reaction against the reductionist programme of neoDarwinism and molecular biology is the insistence of some biologists that the transformations of embryology demand

'something more' than proteins and interactions between proteins: the miracle that demands explanation is not necessarily how the eye (for example) evolved in the ancestors of vertebrates, but how it evolves from nothing in every vertebrate today. The embryologists and others who take this stand have produced no fully coherent alternative to neoDarwinism, but appeal to nongenetic inheritance (through the cytoplasm of the egg, inherited from the mother), to possible neoLamarckian modes of change, or to the self-organizing and self-regulating powers of the developing organism. This revolt against the tyranny of the genes may be summed up

as an interest in epigenetics (the sequence of events that happens in the embryo after fertilization).

A neoDarwinian response is that these complaints are nothing new, smack of vitalism, and demonstrate a confusion between proximate causes, the embryologist's proper domain, and ultimate causes, the domain of evolutionary theory. Epigenesists might reply that neoDarwinian theory offers no better explanation of the self-organizing capacity of the organism than contingency, a lucky chapter of irretrievable historical accidents. Like so much else in neoDarwinism, the argument degenerates here into incommensurables, the conflict between chance and apparent necessity.

Behaviour. One of the modern growth areas within neoDarwinism is sociobiology. It is concerned with evolutionary interpretation of behaviour, especially in social interactions within species. Darwin initiated work on these lines with explanations, in terms of natural selection, of insect societies (ants, bees) which entail selfsacrifice or altruistic behaviour by individuals or castes. Modern sociobiology is a fusion of population genetics,*ethology (study of behaviour), and game theory (see VON

NEUMANN), interpreting behaviour in terms of strategies which will have selective advantage if they increase the chance of survival of individuals or their kin, who share their genes. Though relatively uncontroversial when applied to birds or butterflies, these ideas have raised a storm when, as was inevitable, they are extrapolated to human societies. The controversy, which has marked political overtones, centres over the extent to which behaviour is genetically determined, a topic on which agreement seems no more likely than in the argument over the relative contributions of heredity and environment to intelligence.

In order to be subject to natural selection, traits—whether behavioural or structural—must be heritable, or under genetic control. To bring some behavioural trait within neoDarwinism, all that is necessary is to argue that it is adaptive under certain circumstances (few traits resist ingenuity), and to postulate a gene for it. There is little harm in theoretical genes for altruism or homosexuality, but critics of sociobiology see such exercises as examples of the reductionist tyranny of the genes, or of the emptiness of a theory which can explain anything.

Current status of neoDarwinism. In the preceding sections, various new directions in, and criticisms of, neoDarwinism were outlined. The basics of neo

Darwinism, as of Darwinism, are heritable variation and natural selection. Molecular and population genetics have supplied much insight into the source of variation and the mechanism of selection. There is no doubt that generation of genetic variation is an intrinsic property of sexually reproducing organisms as we know them. Nor can one doubt that natural selection censors variation, and maintains organisms in harmony with their environments. That might seem to be the end of the matter.

Nevertheless, there have been persistent arguments over the status of neoDarwinism, both as legitimate science and as a comprehensive explanation of life.

In considering these arguments, it is essential to distinguish the two disparate aspects of neoDarwinian theory. The first is that evolution has occurred: relations between species are material, not immaterial, and historical, due to common ancestry. This aspect is more general than Darwinism or neoDarwinism. The particular contribution of those systems is a mechanism—natural selection—to account for evolution.

The general aspect of the theory, that evolution has occurred, has a curious philosophical corollary: acceptance of it entails a revolutionary change in the ontological status of its subjectmatter. Concepts such as 'ravens' and 'swans' are traditionally considered classes or universals ('all swans are white' and 'all ravens are black' are classic statements about universals in logic). Evolution changes that.

Biological species, and groups of species related in a closed system of descent, become individuals, and names like *Homo sapiens* or Mammalia become proper names, the names of individuals, or 'chunks of the genealogical nexus', a nexus which is necessarily unique. If evolution has occurred, it follows that there can be no real laws of evolution, for laws concern classes or universals, and evolution implies that all of life is one individual system, like the solar system. In other words, one consequence of evolutionary theory is that comparative biology becomes historical science, and there can no more be evolutionary laws than there are historical laws.

The general scientific method is to propose hypotheses about nature, and to test them by deducing what each hypothesis forbids, turning to nature to see if the forbidden consequence actually occurs. Then the question is what forbidden consequences, or potential tests, may be deduced from the proposition that evolution has occurred. Various possible observations have been suggested, such as the discovery of human fossils in Cambrian rocks, which could falsify evolution and so demonstrate its testability. But none of the potential tests that have been proposed appears to be directed exclusively at evolution. For instance, Cambrian human bones would falsify not evolutionary theory but the general comparative method in biology, codified before Darwin as the theory of 'threefold parallelism'—between the succession of fossils in the stratigraphic record, the transformations of embryonic development, and the hierarchy of natural classification, based on homologies.

Evolution may seem to be an inescapable deduction from that theory, but the biologists who proposed and upheld it in the nineteenth century would not agree. Those who argue that evolution is falsifiable seem to demonstrate the weakness of that position by the conviction, which shines Page 243

through their prose, that they know the truth. The only thing forbidden by evolution is that there should be species unrelated to others by descent, and since we have no access to unambiguous records of descent, no decisive test is forthcoming. Nevertheless, evolution explains important discoveries unforeseen by Darwin, such as the universality of the genetic code, and comparisons of nucleic acid and protein sequences.

One may reject testability as a criterion, and appeal instead to the fruitfulness of evolutionary theory as a research programme. That criterion has no necessary connection with*truth, for phlogiston chemistry and Ptolemaic astronomy were fruitful research programmes. Or one can point to the explanatory power of the theory, the quantity of disparate areas of knowledge it unites. Darwin used this argument: 'It can hardly be supposed that a false theory would explain in so satisfactory a manner ... several large classes of facts.' A different strategy for evolutionists is not to analyse or defend their own theory, but to attack the opposition, alternative explanations of life. Only two seem to be on offer. The first is spontaneous generation or creation, necessarily on multiple occasions and locations rather than the one required by evolution. The second is the notion that Earth has been seeded from space, and again seeding on multiple occasions is required to distinguish this from evolution. The difference between the three explanations, when considered in terms of testable predictions, explanatory power, fruitfulness, or whatever, seems to come down to the principle of parsimony, or Occam's razor: evolution is superior because it does not multiply entities unnecessarily. For creation and seeding both imply repeated intervention (intelligent or not), whereas evolution implies no more than one such intervention. When treated as a criterion of truth, this has been called the 'bestinfield fallacy'.

Fallacious it may be, yet evolution has no real competitors. (See FALSIFICATION.) Turning to mechanism, the specifically Darwinian aspect of neoDarwinism, we are on surer ground with natural selection. Darwin offered several potential tests of the mechanism: for example, 'If it could be proved that any part of the structure of any one species had been formed for the exclusive good of another species, it would annihilate my theory.' But he also wrote: 'I am convinced that natural selection has been the main but not the exclusive means of modification.' That is also the stance of modern neoDarwinians, who allow genetic drift and other nonDarwinian means of modification such as polyploidy and less radical chromosomal saltations. In these terms, natural selection is clearly beyond criticism, for it is expected to explain only that which is explicable by it. Cases which are beyond the most ingenious selective explanation have another cause at hand, in random effects due to drift or inbreeding. Comparison of DNA sequences indicates that 'silent' substitutions are about four times as frequent as nonsilent ones (with an effect on the phenotype): in other words, the majority of evolutionary change is immune to natural selection. This important conclusion is summed up in 'Kimura's rule' (Motoo Kimura is the father of the neutral theory of molecular evolution): Molecular changes that are less likely to be subject to natural selection occur more rapidly in evolution. One corollary of this is the 'molecular clock', the inference that in each lineage DNA evolves at a roughly constant rate. This contrasts with evolution of form or phenotype, which seems to occur in jerks in some lineages, hardly at all in others (so-called 'living fossils'), and never at a constant rate. If, at the molecular level, the majority of evolutionary change takes place in spite of natural selection rather than because of it, natural selection seems to be false as the general explanation of evolutionary change.

The effect of Darwin's theory was to give a mechanistic explanation of apparent intelligent design: the appearance was illusory, for the creative power was in natural selection. The effect of the large neutral or 'nonDarwinian' component discovered in molecular evolution is further to downgrade the role of design: the apparent creative power of natural selection was illusory, if it is outweighed by chance effects. In other words, the role of chance increases. It is this that seems to be the nub of the matter. The reductionist line of neoDarwinism, aiming to reduce the diversity of life to the laws of chemistry and physics, leads to randomness. Instead of the relentless mill of natural selection, 'daily and hourly scrutinising, throughout the world, the slightest variations ... silently and insensibly working... at the improvement of each organic being' (Darwin's words), buttressed by the equations of population genetics, modern neoDarwinians seem to be turning on the one hand to pure randomness (neutral theory and the molecular clock), and on the other to explanations which approach the miraculous (to use a provocative word), unique events perpetuated by inbreeding. The latter has echoes in the biblical account of the genesis of mankind. Natural selection has been called a mechanism for generating the improbable, and if the role of natural selection is diluted, the improbability of the results increases. The ultimate in reduction is a recently fashionable idea, that the whole of life is an accidental excrescence, a byproduct of selfish DNA, whose structure is such that it survives, multiplies, and diversifies. That view seems to lead nowhere, but there are two lines of research which might lead out of the impasse. One is into the structure of the genome (the genetic equipment of the individual), where surprising things like 'jumping genes' and spontaneous amplification of bits of DNA are being discovered. Perhaps the permanence we attribute to DNA is also illusory. The other line is in epigenetics, the link between the genes and the organism. It is here

that the mystery of transformation can be approached most directly.

EXISTENTIALISM. See SARTRE, JEANPAUL.

EXPERIENCE. See CONSCIOUSNESS.

EXTERNAL WORLD. The very use of the phrase 'the *external* world' suggests that there may be something problematic about the existence and nature of the reality 'out there', beyond what is immediately given in subjective experience. This way of viewing the matter is probably due to *Descartes, whose philosophical startingpoint was his conscious awareness of his own existence as a thinking thing; he was then faced with the difficulty of moving on from this subjective startingpoint to conclusions about the existence and nature of the physical universe. Another source of the idea of the external world as problematic is the notion of a 'veil of perception' between our subjective experience and the world: if we are directly aware only of our own impressions (*Hume) or sensedata (*Russell and others), then the problem seems to arise of how we know that these immediate objectsofexperience resemble anything in the 'real world' outside us.

Twentiethcentury philosophers have become increasingly dubious about the genuineness of many of these supposed problems about the 'external world'. First it has been argued that the idea of a 'veil of perception' rests on a philosophical confusion: the fact that we do not always see things as they are does not license the inference that all we ever see are subjective appearances. Second, the arguments of *Wittgenstein have suggested that the traditional, solipsistic presentation of these problems ('How do I, the lone isolated conscious subject, know that an external world exists?') may be incoherent. According to Wittgenstein's celebrated 'private language'

argument (see WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE), the use of the very linguistic concepts necessary for the raising of such questions already presupposes the existence of an objective world of public rules, and public criteria for the application of terms.

See also APPARENT; BERKELEY ON PERCEPTION.

EXTINCTION OF CONDITIONED REFLEXES. Also known as 'habituation', though 'habituation' may be used rather more generally, without reference to reflexes. Extinction is the gradual loss of the stimulusresponse (SR) associative link (see CONDITIONING) in such situations as the reflex salivation given by the sight of food (unconditioned stimulus) being elicited by, for example, a buzzer (conditioned stimulus). Extinction occurs when the buzzer is repeatedly presented without the food. This is the classical experimental situation studied by the great Russian physiologist Ivan *Pavlov.

Pavlov showed that conditioned reflexes remained intact over many years in animals kept in conditions where experimental extinction did not occur—for example in sheep allowed to graze normally outside the laboratory. This led to the view that*forgetting may not occur spontaneously, but that it is due to experimental extinction, by events occurring repeatedly without reward. This, however, seems too extreme a view: memories and skills can almost certainly fade spontaneously, though generally far more slowly than by extinction.

EXTIRPATION. The removal of parts, especially regions, of the brain.

EXTRASENSORY PERCEPTION. There are those who hold that man is an exclusively material being, living in an exclusively material universe; and there are also those who hold that he is a spiritual or psychic entity, inhabiting a material body in a universe which has both physical and nonphysical aspects. The first view is a relative newcomer in philosophical terms: it has come to be widely held only since the advance of scientific materialism in the nineteenth century. The second view is of course much more venerable, lying at the heart of most systematized religions; and despite

Page 245

the fact that it is scientifically unfashionable, it nevertheless commands wider support, even today, among the population at large. Given our present very limited understanding of the brain and mind, it is possible to support this view without being in any way irrational or unscientific, though most scientists would probably lean toward a more agnostic position, which can be roughly summarized as: 'I will suspend belief in the existence of a nonphysical entity such as mind, soul, or spirit until I have good evidence to indicate that it exists.'

Is there evidence that it exists? The nonmaterialistic view of the universe claims that there is, and that it comes from studies of the various types of phenomena clustered under the heading 'extrasensory perception' (ESP). This phrase, which was coined by J. B. Rhine, onetime head of the world's first university parapsychology department, retains, despite popular usage, a fairly specific meaning. It refers to any mental faculty which allows a person to acquire information about the world without the use of the known senses. Such faculties are generally classified as (i) telepathy, (ii) clairvoyance, and (iii) precognition. A fourth phenomenon, (iv) psychokinesis, while not involving perception in the recognized meaning of the word, is almost always studied alongside ESP. The systematic investigation of these four faculties is the subjectmatter of psychical research or parapsychology, whose history and achievements are considered in the articles on PARANORMAL

PHENOMENA: THE PROBLEM OF PROOF, and PARAPSYCHOLOGY: A HISTORY OF RESEARCH. Here we will merely consider what each term implies.

(i) Telepathy refers specifically to the transmission of information from one mind to another, without the use of language, body movements, or any of the known senses.

Because of the difficulty of ruling out normal sensory cues when humans are within sight or earshot of each other, most scientists are impressed by telepathic evidence only when it involves two people

separated by a considerable distance or when at least one of them is isolated under the most stringent conditions. (ii) Clairvoyance refers to the acquisition by a mind or brain of information which is not available to it by the known senses, and, most important, which is *not known at the time to any other mind or brain*. To give examples, if one could read the pages of a closed book, or give the sequence of a shuffled but undealt pack of cards, then one would be demonstrating clairvoyance. (iii) Precognition refers to the acquisition of information about an event before it takes place. Common anecdotal 'evidence' for precognition comes in the form of dreams about the future which subsequently come true, but evidence in a laboratory setting is, for example, ability to predict the order in which cards will be dealt from a pack, with shuffling carried out *only after the prediction had been made*. As for (iv) psychokinesis, it refers to the supposed power of the mind to manipulate matter at a distance without any known physical means. At its crudest and most dubious level, 'evidence' for this faculty comes from the performances of Uri Geller and others. More serious evidence comes from laboratory experiments into willing the fall of dice from a mechanical shaker.

Establishing the reality of one or all of these faculties would be of great interest to anyone engaged in studying the brain and nervous system. Not only would strictly mechanistic models of psychology—such as those exemplified by Skinnerian behaviourism (see BEHAVIOURISM, SKINNER ON)—have to be scrapped, but many of the assumptions and theories of physical science would need at least to be thoroughly overhauled. Perhaps the least challenging is telepathy, for all that is alleged is that information can pass from one mind to another without the *known* senses. There could be other senses, equipped with appropriate sense organs, hidden somewhere in the brain and acting as transmitters and receivers. It is now established that information can be sent across vast distances by radio—a fact which would have been considered highly improbable a century ago—and perhaps some parallel system, as yet unidentified, operates in human brains. But what of the remaining three faculties? What possible mental mechanism could allow the mind to inspect the sequence of a shuffled deck of cards *before the shuffling has taken place*? Or how could the mind physically operate on matter from a distance, causing a die to fall with one face rather than another uppermost?

Clearly, if ESP exists, in one or more of the forms discussed, then the idea of a nonmaterialistic component to the universe becomes more plausible. If the mind can roam more or less at will, then it would seem that man is, in part at any rate, a nonphysical being, capable of exercising far greater control of his own destiny and of his environment than is usually assumed by science. Fortunately—or unfortunately—systematic laboratory research, once full of promise, has yielded little in the way of concrete evidence for ESP, while anecdotal evidence, however superficially convincing, so often withers away under close inspection.

C. E.

EXTRAVERSIONINTROVERSION. The terms 'extraversion' and 'introversion' entered popular use in England, with pretty much their current meaning, during the nineteenth century; they can be found in several popular novels, referring respectively to sociable, impulsive, carefree behaviour, and unsociable, responsible, thoughtful behaviour. C. G.*Jung popularized the terms on the Continent, and linked them with a very complex and difficult psychoanalytic set of theories; these theories are not now widely entertained, and the Jungian meaning of the terms is only accepted by a few followers

of his. Jung suggested that there were links, in neurosis, between extraversion and hysterical symptomatology, and introversion and depressive/*anxiety symptomatology; this connection has been verified Page 246

by later workers. The behavioural patterns which underlie the notion of extraversionintroversion were of course observed long before the nineteenth century; they go back at least to*Hippocrates and*Galen, the Greek physician who elaborated the earlier system of the four temperaments (choleric, melancholic, phlegmatic, sanguine) which has lasted in some form or other for two thousand years, and is still popularly used by many people.

The relation of this system to modern conceptions of personality was first suggested by Wilhelm*Wundt, the founder of modern psychology, just before the turn of the century. The four temperaments, until then, had been conceived of as qualitatively different types; you belonged to one or the other of these groups, but you could not show traits and qualities belonging to more than one group. This is patently untrue; many people do seem to belong to one or other of these types (otherwise the system would not have survived), but equally obviously others do not. Wundt pointed out that the melancholic and the choleric types had something in common that set them off against the phlegmatic and the sanguine types, namely a strong emotional reaction; this suggests a dimension of personality ranging from high to low emotional reactivity, or 'emotionality' (also often called 'neuroticism' or 'anxiety' by modern psychologists). Equally, the choleric and sanguine types have something in common which sets them off from the melancholic and phlegmatic types. Wundt called this quality 'changeableness', but we would nowadays call it extraversion, as opposed to introversion. Wundt was very perceptive: changeableness is indeed one of the most characteristic traits of the extravert—but it is not the only one, and consequently a less specific name for this personality dimension was required.

With this important change from four entirely discrete personality types to two separate dimensions of personality, with individuals located at any point on each scale, Wundt rescued the ancient scheme from oblivion and made it capable of reflecting the complexity of real life. The four Greek temperaments lie in the four quadrants generated by these two intersecting dimensions of personality. Melancholics are introverted and emotional (Jung's anxious and depressed neurotics), while choleric are extraverted and emotional (Jung's hysterics, and, as modern research has shown, psychopaths and criminals as well). Phlegmatics are introverted and stable, while sanguinics are extraverted and stable. We can now measure the degree of emotionalitystability a person shows, or the degree of extraversion or introversion; and we can show that on both these scales the distribution of people is roughly in line with the Gaussian probability curve, i.e. most in the middle, with fewer and fewer towards the extremes. We do not, then, divide the population into extraverts and introverts: we measure the degree of extraversion or introversion shown, and allocate the person in question to some place along the continuum—very much as we would do if we measured his height, or weight, or*intelligence. When in what follows we speak of extraverts or introverts, we mean people falling towards one or the other end of this distribution; those in the middle are usually referred to as ambiverts.

Two problems are raised by the postulation of a concept such as extraversionintroversion. The first is

a *descriptive* one: is it in fact true that the traits postulated to characterize the extravert, or the introvert, actually occur together? This is fundamentally a statistical problem, concerned with correlations. We can rate the degree of sociability, impulsiveness, changeableness, talkativeness, outgoingness, activity, liveliness, excitability, optimism, etc., of a few hundred persons, chosen at random, and determine whether all these traits are positively correlated—i.e. if a person showing one of these traits is also likely to show the others. We would not expect perfect agreement, of course, but we should expect reasonable correlation between these traits if the concept of extraversion were to have much meaning. Hundreds of empirical studies have shown that these various traits do indeed hang together to a degree which exceeds chance by a large amount; furthermore, these studies have demonstrated this general cohesion between traits for adults and children, men and women, different social classes, and different nations (including Japanese, Indian, European, and American). There is little doubt that descriptively the personality dimension of extraversion/introversion is amply supported by relevant research.

The second problem is the *causal* one—given that some people are extraverted, others introverted, others ambivert, can we say why these personality differences occur? The evidence suggests that genetic causes are very strongly implicated: something like two-thirds of the total variation in extraversion/introversion is probably due to heredity, with only one-third left for environmental causes. There is no evidence of dominance in the hereditary determination; this suggests that from the evolutionary point of view neither extraversion nor introversion is more successful in adapting to environmental stress. But this answer is unsatisfactory: heredity cannot determine behaviour, only structure. Underlying extraverted or introverted behaviour there must be some physiologico-anatomical structure, presumably in the central nervous system, which mediates these personality differences. Recent experimental work has suggested that this is indeed so, and that extraversion is linked with resting states of low cortical arousal, introversion with resting states of high cortical arousal. At first sight this would seem to be the wrong way round; one would have thought that the active, uninhibited extravert would be the person with high cortical arousal. However, the main function of the cortex is one of inhibiting lower centres;

effective functioning of the cortex, due to high arousal, produces inhibited

Page 247

(introverted) behaviour. In the same way alcohol, a depressant drug which lowers the arousal of the cortical centres, produces extraverted, uninhibited behaviour; it frees the lower centres from cortical control. Cortical arousal in turn is determined by the so-called ascending reticular activating system, a group of cells lying in the brainstem and responsible for reacting to incoming sensory messages by alerting the cortex so that it may be better able to deal with these messages. Here, theory suggests, is the causal locus of extraverted and introverted behaviour.

The evidence for this theory is by now quite strong. Part of it is direct, based on electroencephalographic measurement of resting level brain waves and other psychophysiological measurements of arousal (see ELECTROENCEPHALOGRAPHY). Part of it is indirect, based on laboratory investigations of certain psychological functions which are known to be determined in part

by arousal level (conditioning, sensory thresholds, habituation, etc.). These studies are as yet not conclusive, but they do on the whole suggest that this theory is along the right lines. Unfortunately it is still impossible to record directly from the ascending reticular activating system in humans, so that the part played by this system must rest on work done on cats and other animal preparations in the laboratory; the evidence for the cortical part of the theory is much stronger. Certainly no other aspect of personality is as widely studied, or has given rise to such clearcut theories and experimental investigation, as has extraversion/introversion; we probably know more about this trait (or system of traits) than about any other.

H. J. E.

A general survey of the field is offered in Eysenck, H. J. (ed.), *Readings in Extraversion/Introversion*, 3 vols. (London, 1970). The genetic and physiological theories of extraversion are discussed in detail, together with the evidence, in Eysenck, H. J., *Biological Basis of Personality* (Springfield Illinois, 1967). Alternative theories are considered in Nebylitsyn, V. D. and Gray, J. A. (eds.), *Biological Bases of Individual Behavior* (London, 1972). A more general approach will be found in Brody, N., *Personality: research and theory* (London, 1972). Jung's theory is described in detail by Hall, C. S. and Lindzey, G., *Theories of Personality* (New York, 1968). For the most recent summary of the evidence, see Eysenck, H. J. and Eysenck, M. W., *Personality and Individual Differences* (London, 1985).

EYECONTACT, or 'mutual gaze', occurs when two people look each other in the area of the eyes simultaneously. During conversation, two people seated 2 metres apart will each look at each other for about 60 per cent of the time (with wide individual differences), and there will be eyecontact for about 30 per cent of the time.

This otherdirected gaze consists of glances of 15 seconds in length, with mutual glances of about 1 second. Each glance in turn consists of a number of fixations of 0.3 seconds on different parts of the other's face, especially eyes and mouth, linked by saccadic movements; there are repeated cycles of such fixations. Eyecontact and glances can be recorded by observers who activate an interaction recorder, either observing directly or using a videorecording. The sequence of fixations requires an eyemovement recorder.

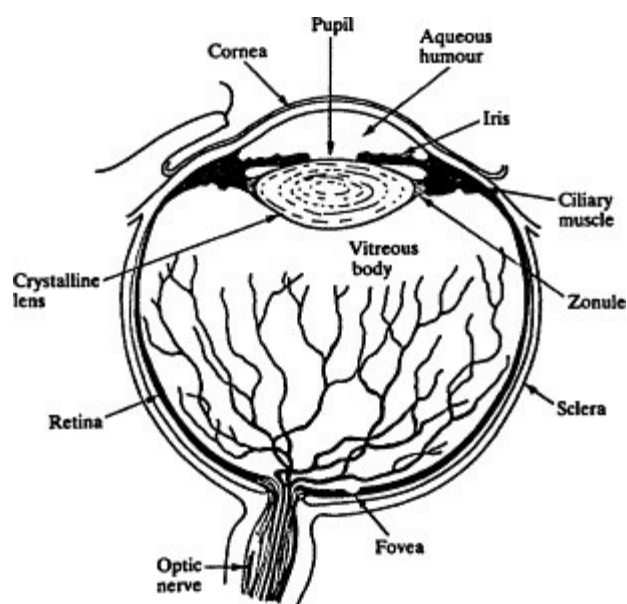

Eyes are responded to as a social signal by animals, some of whom have developed eyespots as a threat signal. Human infants respond to their mother's eyes and establish eyecontact by the fourth week of life—which may be partly an innate response—and gaze plays a central role in the earliest sequences of social behaviour with the mother (see INFANCY, MIND IN). These gaze phenomena occur in all cultures, though they vary in the levels of gaze which are regarded as appropriate, and gaze may acquire special meanings, as in the case of the Evil Eye.

Gaze nets as a social signal: for example, if A likes B he will look at B a lot, and B correctly decodes this in terms of liking. In this situation, gaze is rewarding, and results in favourable evaluation of the person gazing. The basic effect of gaze is to show attention and to increase arousal, but the meaning can vary with the situation and facial expression—from threat to sexual attraction. Eyecontact is

experienced as a special form of intimacy. Gaze is used and received as a signal for sexual attraction; couples who are in love have a high level of mutual gaze; girls enhance the stimulus properties of their eyes by cosmetics and dark glasses. Pupil dilation acts in a similar way, and can be produced artificially by drops of belladonna. The eyebrow flash is used in courting in many parts of the world.

The pattern of glances is closely coordinated with speech. Interactors look nearly twice as much while listening as when talking; they look during grammatical breaks and at the ends of utterances, and look away at the beginning of utterances. Glances act as signals of attention or emphasis, help to indicate the grammatical structure, and as 'terminal gazes' are one of the signals announcing the ends of utterances, but the same glances are also used to collect visual information. When relevant objects of mutual interest are present, a lot of gaze is deflected to them; there is more gaze at others when they are further away, less when intimate topics are discussed. Gaze plays an important role in greetings, farewells, and other ritualized social sequences.

There are large individual differences in amount of gaze. Autistic children scarcely gaze at all, for reasons not yet understood; schizophrenics have a low level of gaze when talking to psychologists but not when talking to each other; depressives look little and look downwards; some neurotics avert gaze and some stare; extraverts gaze more than introverts (see EXTRAVERSIONINTROVERSION), females more than males, children and adults more than adolescents. Assertive or powerful people look as much while speaking as while listening. These findings help to explain the reasons behind gaze—it is a product of affiliative and other motiva

Page 248

tions—and various kinds of gaze aversion.

It is now realized that gaze plays a central part in social behaviour: the perception of others' reactions is essential, and gaze is necessary for this to occur. While the primary purpose of gaze is to collect visual information, it has acquired meaning as a social signal—in the course of evolution for animals, but mainly by learning for humans. While gaze is important for animals as well as humans, in human social behaviour it forms part of an intricate sequence in which it is closely coordinated with speech.

EYE DEFECTS AND THEIR CORRECTION. We have become accustomed to marvel at the electronic miracles which made possible the pocket-size transistor radio and the small computer that fits into one's briefcase. But such great accomplishments are still not comparable to the extraordinary miniaturization of the complex structure of the human eye. Only about 24 mm in diameter, the eyeball contains several hundred millions of working parts, all carefully arranged to allow for a vast range of functions (such as vision of contrast, colour, form, and space) to be performed over many years and in all weathers. The optical system of that structure is no less remarkable although far simpler. The system often becomes faulty and errors of refraction such as myopia or hypermetropia occur. However, the other extraordinary aspect of the optical system of the eye is that its errors can be corrected simply and even relatively cheaply.

Optics of the eye. For a long time the eye has been compared to a camera but, although there are similarities since the eye is partially an optical instrument, the differences are fundamental. The camera gives an image which is the end result and has to be as perfect as possible. The eye, on the other hand, provides an image on the retina which is only the beginning of an extraordinary process. (For further discussion, see VISUAL SYSTEM: ORGANIZATION.) This image is not to be looked at, as such. It sends coded neural signals to the brain where it is eventually decoded and perception emerges. Thus what the optics of the eye provide to the retina need not be as perfect or even similar to that formed by a traditional optical instrument. Indeed, when they are examined with the same criteria as are used for an optical instrument we find that the optics of the human eye are rather imperfect. Helmholtz, the nineteenth-century giant of physiological optics, noted that if any optician were to build an optical instrument of such poor quality as the eye he would undoubtedly become bankrupt!

Contribution of the surfaces of the eye. The eye consists of a series of refracting surfaces (that is, surfaces which change the direction of light that traverses them) separated by clear media. These surfaces are the front and back surfaces of the cornea and of the lens (Fig. 1). The media are the cornea, the aqueous humour, the lens, and vitreous humour. The dioptric power of each surface is a function of its curvature and of the differences in the index of refraction of the media on each side of that surface. The front surface of the cornea is the most refractive as it separates air from the corneal medium; whereas the back surface of Fig. 1.

Schematic diagram of the eye.

Page 249

Fig. 2.

Vision under water. Light is refracted by the crystalline lens only.

the cornea, with about the same curvature as the front, is the least refractive as it separates two media of about the same index of refraction. Specifically, the front surface of the cornea contributes about twothirds of the power of the eye, the rest being provided by the surfaces of the crystalline lens. The optical power of the eye is equivalent to a magnifying lens with a magnification of $\times 15$.

Thus when a person is swimming under water without a mask, the cornea is bathed in water of approximately the same refractive index and so its effective power is almost eliminated. This situation produces an outoffocus retinal image and vision is hazy. In this case, the optical power of the eye depends only on the crystalline lens, which contributes only onethird of the total power. Hence the image of a distant object is formed very far behind the eye and only a blur circle appears on the retina (Fig. 2).

On the other hand, if the crystalline lens is removed, as happens following the surgical intervention for cataract due to old age or to an accident, the power of the eye is reduced by about onethird and the image of a distant object is also formed behind the eye (although not as far back as Fig. 3).

a. Retinal image in an aphakic eye.

Fig. 3.

b. Corrected aphake.

in the case of our swimmer). To correct such an eye, which has now become aphakic, a powerful lens of positive power (with a thick centre and thinner edge) is needed to replace the outoffocus image onto the retina (Fig. 3). However, in the last few years, rather than using spectacle lenses to correct aphakia, an intraocular lens implant may be placed within the eye in lieu of the crystalline lens, during the surgical intervention. This method has proved to be very popular with a lot of people.

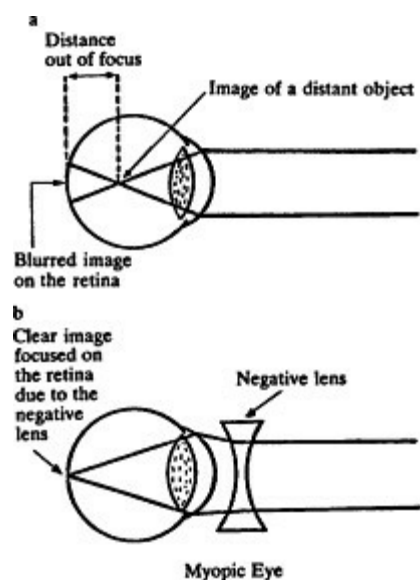

Accommodation. When the crystalline lens is missing, another important mechanism is disturbed and that is the*accommodation, or the autofocus system of our

'camera'. Thus adjustment of the optical system to enable near objects to be seen is no longer possible: the eye is set for distance vision only.

The phenomenon of accommodation can be readily understood by making the following observations: Draw a small mark on a window with a felttip pen, then look at a distant object through that mark (cover the other eye with your hand). You will notice that the mark on the window is blurred. Then look at the mark and you will notice that now the distant object has become blurred. In fact, to view the mark on the window you must make a conscious effort, whereas the eye seems to return naturally to the distant object. These observations demonstrate that the eye cannot be in focus at both distances simultaneously, the eye must accommodate to see the near object clearly. This complex involuntary mechanism is under the control of the central*nervous system which innervates the ciliary muscle inside the eye, and in turn produces accommodation by altering the shape of the surfaces of the crystalline lens (especially the front surface). Thus any interesting object in front of you which attracts your attention automatically triggers the accommodative reflex and in about 300 milliseconds the eye will be focused on that object.

Presbyopia. With age, the eye loses its ability to accommodate and there comes a time between 40 and 50 years when focusing on near objects becomes difficult, if not impossible. Presbyopia has set in and positive lenses are needed to enable near objects to be seen clearly.

Presbyopia is the most common eye defect in man. It affects everybody. Unsurprisingly, a lot of research is done to understand how it develops and how best to correct it. Yet presbyopia always comes as a shock to middleaged people, who find their arms too short to hold reading material far enough away to still see it clearly. People who have worn corrective lenses for other eye defects need additional correction, often in the form of bifocals. Others who have never worn any correction and had perfect eyesight all their life are now faced with this new condition and need to wear spectacles to read and write—and to look at the screen of their visual display unit (often referred to among eye

practitioners as a 'visual discomfort unit'). In a good number of cases the person has in fact had a slight eye defect for distance vision, which was insufficient to cause problems but now needs to be taken care of, as with age the visual system is far less adaptable; in such a case the person now has to wear spectacles continuously.

People react with various levels of anxiety to presbyopia. Many feel handicapped, others will try to hide the fact and wear invisible contact lenses, others will simply ignore it and do without spectacles and perhaps occasionally use a magnifier surreptitiously. But inevitably in the very old, the acuity of vision even with the best correction may leave a lot to be desired, and many elderly people should begin to prize their insight rather than their sight. (For further discussion, see AGEING: SENSORY AND PERCEPTUAL CHANGES.)

The errors of refraction. Even when all the refractive surfaces of the eye are present, the image of a distant object may not be formed on the retina. If it does so, all is well and the eye is optically normal; it is then referred to as emmetropic. About half of the prepresbyopic population is emmetropic. Considering the number of components of the optics of the eye (14 in fact) this figure is rather surprising, especially as a lack of harmony of the various optical elements needs only to be very slight to give rise to a lack of emmetropia, namely ametropia. For example, if the length of the eye varies by 1 mm, this produces a significant error of refraction of over 3 dioptres.

Thus, on the basis of chance alone the number of emmetropic eyes should be less than half of the prepresbyopic population. The distribution, however, of errors of refraction in the general population is disproportionately peaked around the zero value. This phenomenon, in which nature seems to be on our side, has been called emmetropization. It refers to a presumed visual feedback mechanism which would control the development of the optical components of the eye to maintain a state of emmetropia, whenever possible.

If the image of a distant object does not fall on the retina, the eye is said to be ametropic. There are three types of ametropia: myopia (or shortsightedness), hyperopia (or longsightedness), and astigmatism, which may accompany either myopia or hyperopia. Presbyopia, which is an error of refraction occurring in near vision, is not usually considered among the errors of refraction (for distance vision) and has already been mentioned.

Myopia. This is a condition in which near objects appear clear while distance vision is blurred, with practically no other symptom except perhaps the discomfort of squeezing the eyelids, which does improve vision. From the optical point of view, the image of a distant object is formed not on the retina but in front of it (Fig. 4). In other words, the power of the eye is either too strong or the eye is too long; the latter is usually the case. In some cases the amount of myopia does not stop at maturity but continues to progress. This is a pathological condition in which degenerative changes in the retina and other tissues occur and eventually vision is impaired even when corrected. It is important for these people not to engage in vigorous sports or activity (e.g. boxing or digging the garden) as the retina is liable to detachment with this condition.

Myopia usually develops in the early teens. However, an increasing number of people have been noted to acquire it in the late teens and early twenties, commonly in association with a great deal of visual stimulation, such as reading or working at a visual display unit. Hereditary influence as well as environmental factors both contribute to its development. In the general population approximately one person in five is myopic, although that figure varies with age, race, and geography (e.g. this figure doubles among Chinese and Japanese).

Correction of myopia. Correction of myopia, which can be done with either spectacles or contact lenses, is made by arriving at a negative lens which diminishes the power of the eye by an amount such that the image of a distant object coincides with the retina (Fig. 4). In the last few years, a surgical technique pioneered in the Soviet Union and called radial keratotomy has become relatively popular in some parts of the world (such as California). It consists of making incisions in the cornea, under anaesthesia, for the purpose of reducing its curvature and consequently its power. The optical result, however, is not very predictable and many patients (40 per cent in one report) still had to wear

Fig. 4.

some corrective lenses after the intervention. In a small percentage of cases, vision was even made worse by the operation. Nevertheless, a great deal of research is being devoted to this subject and new techniques attempt to reshape the cornea without producing scars which hinder its transparency. In particular, experiments are carried out using ultraviolet lasers (called Excimer lasers) which can produce controllable, repeatable, and clear corneal incisions. Thus, in the next few years, we may observe considerable progress in the surgical correction of myopia, and even hyperopia.

Hyperopia. This is a condition in which the image of a distant object is formed not on the retina but behind it (Fig. 5). In other words, the power of the eye is either too weak or the eye is too short. The latter is usually the case, but in diabetic people the power of the eye can sometimes vary due to a transitory decrease in sugar concentrations in the blood, which results in a change of the index of refraction of the vitreous body, and consequently the quality of vision fluctuates. Hyperopes, unlike myopes, see objects clearly at all distances (provided they are not presbyopes) but they must accommodate continuously to increase the power of their eyes.

This incessant effort often gives rise to eyestrain or even headaches. Where these symptoms are not evident, many hyperopes go without a correction, especially those with small errors.

Hyperopia usually develops soon after birth and strong evidence seems to indicate that hereditary factors play an important role in determining this ametropia. It is more frequent than myopia, affecting about one person in three in Western countries, but is very rare in Asia.

Correction of hyperopia. Correction of hyperopia, which can be done with either spectacles or contact lenses, consists of increasing the power of the eye with a positive lens of an amount such that the image of a distant object coincides with the retina (Fig. 5). This is in fact similar to the correction of presbyopia.

Astigmatism. In the perfect eye all refractive surfaces are spherical, with equal curvatures along all meridians. Alas, most human eyes do not fall into this category and the cornea, in particular, may have slightly different curvatures in various meridians, therefore it is astigmatic. As a result the image of a distant object will not be a single point but a complex image with two principal lines. Astigmatism is a term derived from the Greek: *a* meaning 'without' and *stigma* meaning 'point'. A good example of an astigmatic surface is a rugby ball which is more steeply curved in one direction than the other. The amount of astigmatism represents the difference in power between the meridians of most and least curvature. Astigmatism is a condition which is superimposed on myopia, hyperopia, presbyopia, or emmetropia since it is a lack of symmetry of the surfaces of the eye irrespective of its total power.

The effect on vision is less marked than myopia of the same amount, as the eye probably sees clearly the features in one direction, namely that of the image closest to the retina. Small amounts of astigmatism do not usually reduce the quality of vision significantly, but often tend to produce visual

discomfort as the eye keeps focusing on one part of the image or the other, always (involuntarily) attempting to improve vision. Large degrees of astigmatism produce blurred vision. Astigmatism is tested using a chart made up of black lines orientated in different directions (see Fig. 6). A person who has astigmatism will see some lines more sharply and others, at right angles, more blurred.

Correction of astigmatism. This is accomplished

Fig. 6.

Bar patterns used to test astigmatism.

Page 252

with a spectacle lens which has astigmatic surfaces producing astigmatism of the same amount but opposite sign as the eye; it therefore collapses the interval between the two images into a single one. The fact that the cornea may not have the same curvature in all meridians makes the fitting of contact lenses which rests on that surface somewhat delicate. However, because the tears fill the space between the lens and the cornea the front surface of the contact lens effectively becomes the new cornea and corrects astigmatism of the eye (at least that of the cornea) automatically with a new front spherical surface. When the astigmatism of the cornea is very large it may, however, be necessary to incorporate some astigmatism on the back surface of the contact lens as otherwise it is not possible to fit the lens.

Binocular vision anomalies. Defects and correction of the eye would probably be relatively simple if we had only one eye. However, in that case our perception of space would be distorted and the world would appear basically twodimensional, although there are a few clues which help us appreciate depth with only one eye. In normal vision, the image of a distant object must not only fall on the retina of one eye (specifically on the fovea where the quality of vision is the greatest) but of both eyes. In many cases, however, the extraocular muscles (six for each eye) do not manage to synchronize perfectly and there is a tendency for one eye to converge too much or too little. But this is usually kept under control in normal vision and there is no obvious deviation. Such a condition is called heterophoria and some adjustment in the optical correction, with prisms in particular, or eye exercises, are sometimes necessary. Until the condition of heterophoria is diagnosed a patient, although sometimes already wearing an optical correction, may have visual discomfort and sometimes double vision or headaches.

Strabismus. In rare cases (about 2 per cent), the two eyes cannot turn toward the same object of regard, due to a paralysis of a muscle or very poor vision in one eye, or a difference in the refractive error of each eye, or cataract in one eye, or orbital fracture, etc., and one eye turns away from the other. This condition is called *strabismus* (or squint). The management of strabismus begins with the imperative need to correct, by optical means, whatever refractive error is present in the child and this should be done as young as possible so that clear images are provided to each eye. In babies, contact lenses are most appropriate. Otherwise an outoffocus image in one eye may lead to cell degeneration in the brain such that optical correction in adulthood no longer restores quality of vision. The eye has

then become amblyopic.

Eye exercises may also be necessary, but the child must be sufficiently mature to cooperate and these must be carried out not only in hospitals but at home as well.

However, in some cases strabismus is not cured by either of the above methods and surgery must be undertaken, if only for cosmetic reasons. Following surgery, visual binocular function is not necessarily restored and more exercises and correction of refractive errors are often again needed.

Conclusion. We have reviewed briefly the most common optical defects of the eye and the means which are commonly used to correct them. Optical correction is essential as early in life as possible. It results in good vision with equal visual input to both eyes, elimination of visual discomfort, and often restoration of personal confidence. It hinders the development of amblyopia and strabismus, and facilitates the development of the threedimensional sense of space.

In today's highly industrialized society where the use of the eyes predominates, optimum visual correction is a prerequisite for the enhancement of visual efficiency. To achieve this objective, the correction must not only be precise but appropriate for the distance, or distances, at which the eyes function; it must also be related to the wearer's occupation, for example tinted if the overall illumination is too bright, and must take into account whatever binocular anomalies may exist. The correction of the eyes may be an exact science, but to make the patient reveal his visual needs and wear and adapt to his new prescription is indeed an art, in which the mind of the wearer plays a major role.

FABRE, JEAN HENRI (1823-1915). French entomologist, born at St Leon, Aveyron. Fabre taught at Carpentras and Avignon before retiring to Sérignan, where he carried out remarkable investigations on the behaviour and sensory capacities of insects. He carried out controlled experiments: for example, by putting cotton wool, on which a female butterfly had spent some time, in a jar in one part of the room and the female herself in full view under a glass dome in another part of the room. He found that the males would fly straight to the jar, ignoring the female. This showed that the males were guided by a remarkable sense of smell, dependent upon their antennae. Fabre is also celebrated for his work on the behaviour of the praying mantis and the hunting wasp, which he believed incapacitated larvae without killing them so that they remained available as food over long periods.

His fullest work is *Souvenirs entomologiques* (10 vols., 1879-1907, collected edn. Paris, 1925, with a *Life* by Lenoir).

FACIAL EXPRESSION is a primary source of information for judging another's mood, and even his character. Attempts to classify expressions and facial types were made by the physiognomists. *Essays on Physiognomy* by John Lavater (1741-1801) appeared in many versions and editions from 1775 and throughout the nineteenth century. Much of it is based on comparisons of human faces and expressions with those of animals, as well as on Lavater's wide experience with people. It has little, if any, scientific validity, but the fact remains—we do, all the time, 'read faces'.

Charles Darwin's *The Expression of the Emotions in Man and Animals* (1872) is a companion to, and was originally conceived to be part of, his great book *The Descent of Man* (1871). Both works are concerned with drawing conclusions from the hypothesis, startling at the time, that man as a species is derived by processes of natural selection from other species, and especially from his near relations, the great apes. Darwin argues that the facial expressions of man, which are now important as social symbols, were originally functionally important—often in ancient and even extinct species. For example, frowning shaded the eyes; drooping of the mouth rejected bitter or poisonous fruit; widening of the eyes improved vision for emergencies, and so on. His studies were meticulous, leading him to consider the development of particular muscles, and identifying reactions in his own children, sometimes even making them cry for experimental purposes, though he was the kindest of men and most deeply attached to his family. *Expression of the Emotions* is well worth reading today: it has not been overtaken by later scholarship.

A popular treatment is *Manwatching* by Desmond Morris (1977), which brings out subtle and sometimes clearcut regional and class differences. These are interesting in their own right and provide evidence of racial migrations. We are affected by other people's expressions; and our expressions affect our friends' and colleagues' behaviour to us—so expressions may not only influence responses to other people but also generate basic aspects of individual and social behaviour.

A curious logical point was raised by the philosopher C. D. Broad (in *Mind and its Place in Nature*, 1925). He points out (p. 325) that we could hardly learn by association to read moods in others from their facial expressions by analogy with our own expressions and moods, because we only see our own faces and expressions in mirrors. He considers the possibility of some kind of telepathic association, or link, from which we know other people's moods from their expressions.

An alternative and surely more plausible explanation is that expressions are largely innate (which would be Darwin's view), though, as Desmond Morris and others have shown, they are modified by social interaction.

FACTOR ANALYSIS. See LEARNING AND LEARNING THEORY.

FACULTY PSYCHOLOGY. The theory, in vogue particularly during the second half of the eighteenth and first half of the nineteenth centuries, that the mind is divided up into separate inherent powers of 'faculties' such as *memory, *learning, *intelligence, *perception, and will. The faculties might be contrasted with those other powers which the individual could acquire through use, exercise, or study, and which were generally known as 'habits'. The theory was associated with *phrenology, which supposed that the various faculties were more or less represented in each individual according to the size of bumps which could be seen or felt on the skull.

Similar divisions are still made in textbooks of psychology, but the notion that they are strictly distinct and localized individually in different regions of the brain has very largely been abandoned.

It is now held that abilities and skills result from

Page 254

the interplay of very many brain mechanisms and that these do not show up as 'bumps'. Even if they did, it would be necessary to know a great deal about the organization of the brain to 'read bumps'. It is, however, the case that through the evolution of species some functional brain regions have grown and others have shrunk—with a general development of the cerebral cortex in mammals. (See PRIMATES, EVOLUTION OF THE BRAIN IN.) A related objection to the notion of faculties is that, for example, perception involves memory and no doubt various kinds of intelligence. For convenience we separate perception, memory, and intelligence, even though each is involved with the others and it is hardly possible to see any one in isolation.

There has recently, however, been some return to the old notion of 'faculties', as the brain is now seen to be organized with many 'modules' of cells in small regions, each responsible for a particular ability (such as face recognition) though of course many other parts of the brain must also be involved. The new ideas are fully discussed by the American philosopher Jerry Fodor (1983).

FAIRBAIRN, RONALD (1889-1964). British psychoanalyst, born and educated in Edinburgh. After graduating with honours in philosophy, he qualified in medicine and served in the First World War. Influenced by the work of Sigmund *Freud and by Anna *Freud's *The Ego and the Mechanism of Defence* (1936, English translation 1937), Fairbairn evolved a systematic theory of 'object relations'—i.e. interpersonal relationships—which involved an appreciable modification of the Freudian position (see FREUDIANISM: LATER DEVELOPMENTS). This is set out in his *Psychoanalytical Studies of the Personality* (1952), which has had considerable influence on psychoanalysis in Britain and further afield.

See FREUDIANISM: LATER DEVELOPMENTS.

FALSIFICATION. Scientists have generally been more concerned to justify their theories than run the risk of falsifying them with counterevidence. This is a criticism of science which has been argued most powerfully by Sir Karl Popper (1902). Unusually for a philosopher of science, Popper with his comments and criticisms actually changed the way science is carried out, establishing especially that hypotheses should be formulated in such a way as to be falsifiable. Popper based his ideas on examples in early twentiethcentury physics, especially on how Einstein's ideas challenged Newtonian physics, but his strictures are also applicable to biology and clinical hypotheses, as Sir Peter Medawar has discussed most cogently (1967, 1969).

One usually thinks of science as producing new truths by observation and experiment, and the more secure the better—so Popper's idea that it should be possible to falsify a hypothesis, if it is to be acceptable as a 'good' hypothesis, came as a considerable shock. The point is not that a hypothesis cannot be good unless it is likely to be false; rather it is that a hypothesis should be conceived and formulated in such terms that experiments or observations could deal it a mortal blow. The hypothesis thus attacked might die or might be merely wounded, to recover in a changed form; but Popper prefers sudden death to hanging on to life. For him a hypothesis that staggers on, mutilated, generally does so because it was not formulated with sufficient vulnerability to die cleanly and be forgotten.

As an example of a hypothesis which refuses to die because inadequately formulated, we may consider Freud's notion of trauma at birth having significant effects in adult life. Suppose to test this we looked at adults who were born by Caesarean section, and suppose we found that they had, as adults, the characteristics that Freud attributed to birth trauma. If the postFreudians accepted this as falsifying evidence for the birth trauma hypothesis, then in Popper's terms well and good—for the hypothesis was evidently set up in such a way as to be falsifiable. And in showing it to be false something has been learned: that these characteristics are not due to birth trauma. But the postFreudians would have lost their hypothesis, and losing hypotheses can itself be traumatic. Popper would object to the postFreudians responding by redefining 'birth trauma'—so that, let's say, it is not the birth itself but the shock of coming into the world that produces the trauma—for then the hypothesis would have changed, rather than decently died, and it is hard to see how any evidence could count against it.

Popper would probably prefer that the whole idea be abandoned at this point; but it might be that such forced redefining is a way in which science can work well, cumbersome though it seems. For could not some hypotheses be refined and improved in this way? There is surely a danger of throwing out the baby with the bath water.

Popper has compared falsification as a way of gaining knowledge (and for him it is the *only* way, as he completely rejects*inductive generalizations) with the deaths of individuals leading to improved species in evolution by natural selection of the fittest to survive. There is now, based on this analogy, an active school of epistemology led by Donald Campbell (1967) and Stephen Toulmin (1972). It goes back at least to the American philosopher Charles Sanders*Peirce (18391914) with the view that hypotheses die by competition, much as species die out when they are inadequate, for the

cumulative good of life and science. There are objections, however, to saying that it is *only* by

Page 255

falsifying hypotheses that we gain new knowledge. It is very hard to believe that animals such as ourselves, with all the evidence of learning curves and so on, never actually learn by induction (Gregory, 1981).

It seems clear that, strictly speaking, hypotheses cannot be falsified by observational or experimental evidence alone, for all evidence has to be interpreted according to subjective background knowledge or assumptions which may be wrong. Thus, we take it as obvious that the stars appear to move across the sky because the earth is rotating daily on its axis; but before this was accepted the stellar observation was differently described. Aristotle thought he had falsified the hypothesis of daily rotation of the earth by jumping up and then finding that he landed on the same spot, when according to his assumption of earthly rotation he should have come down west of where he took off; and there should have been a continuous easterly wind.

Is there a fundamental difference between *falsifying* and *predicting* as a means of testing hypotheses? Isn't a successful *surprising prediction* excellent evidence for the hypothesis suggesting it? Perhaps there is no asymmetry between falsifying and predicting (logically, the failure of a prediction is no different from any other discordant evidence), except that dramatic true predictions may be rarer than equally surprising falsifications. Falsifications of the stationary and the flat earth hypotheses were extremely surprising—and so conveyed a very great deal of information. But there are comparably surprising predictions, such as the apparent shift of positions of the stars near the sun photographed during its eclipse in 1919, which *supported* Einstein's ideas against Newton.

FATIGUE in living beings refers to deterioration of their performance with the passage of time. It is associated with feelings of tiredness, slowing down, and making simple errors. More severe effects include disturbance of reasoning and judgement, depression, and disturbances in perception (mainly visual) leading to florid*hallucinations. A broad view of fatigue in people involves consideration of the extremes of physical and psychological hardship, when they are trying to accomplish some task.

Fatigue most commonly occurs from lack of sleep. A deterioration in the performance of (albeit dull) laboratory tests after one night with only two hours of sleep, or after two consecutive nights with only five hours of sleep each, can be reliably demonstrated. Highly motivated people— such as doctors on duty, soldiers in battle, adventurers in hostile environments—are able to keep going longer, but after one night without sleep most of them will be functioning inefficiently, although they may not realize it themselves.

The effects of fatigue. The effects are increased by adverse conditions such as cold, excessive heat, hunger and thirst, noise and vibration, isolation, lack of oxygen, being wet or seasick, or being under the influence of alcohol or drugs. They may also be increased by anxiety, which can occur in people who doubt their ability to perform a task in hand, or who have worries about separate matters such as money, employment, or relationships.

The effects include:

Simple errors, poor concentration, and forgetfulness. The initial slowing down is not usually noticed by the individual, though it is plain to observers who are rested. Later on, tasks are started but not completed, things are put down and cannot be found afterwards, a cup of coffee is made and the fatigued person forgets to drink it. Doctors who have to work excessive hours can be shown, for example, to make errors in their interpretation of laboratory reports and electrocardiograph tracings.

Faulty judgements and perceptions. In practice it is not possible to determine whether an error of judgement exists directly as a result of, say, tiredness, or whether it is the consequence of a faulty perception. At a traffic junction where there are tired and frustrated motorists about, a driver wants to go straight ahead but the light is red. A green arrow lights up, permitting traffic to filter off to one side. The tired driver very much wants to see a green light, and so misperceives the filtering light as the signal for going straight ahead, and drives off. He will correct the error in a shorter or a greater time according to the degree of fatigue. Other such circumstances are the overhead railway gantries that carry signals for several adjacent tracks, and harbour lights with many opportunities for 'seeing' the lights a ship's navigator wants to see, indicating a particular channel.

As a second example, a driver when rested and relaxed takes in all relevant information—his car's speed and position in the road relative to other traffic, the condition of the road, proximity to junctions and other hazards, the mechanical state

of the car, and weather conditions and visibility— and then responds in a logical manner, having evaluated the relative importance of the different factors; but the fatigued driver may instead concentrate exclusively on one aspect—such as his position in the middle lane—to the neglect of the other factors, and drive remorselessly along the middle lane without regard for speed, visibility, or other vehicles.

Either poor or extremely good visibility, moonlight, high vantage points (with nothing intervening)—all can lead to perceptual errors, especially among the fatigued, so that distances are overestimated or underestimated. Small objects seem to move in the distance, rocks high up on mountains appearing as people.

Ordinary phenomena can be misinterpreted by fatigued people. For instance, a very tired sailor thought the bow wave of his yacht was a flat fish, like a ray; another sailor, in midAtlantic, thought he saw a Ford car which later he realized was a small whale; another thought a sleepingbag laid out on a bunk to be his wife. These are called misinterpretations because they are in due course corrected by closer examination.

A severely fatigued person will not be able (or try) to correct the initial impression. A dramatic example of an uncorrected illusion concerned Shackleton and his two companions as they struggled across South Georgia. All three felt there was a fourth person with them, a presence that was felt to be friendly and supportive. Such experiences are indicative of the limits of endurance.

Ecstasy, depression, and frustration. These are states which can afflict those who are fatigued, and increase the risk of danger.

Ecstatic states of mastery over, or of oneness with, all things are to be treasured, but they can lead to overconfidence if experienced, say, while climbing a mountain or piloting an aircraft. Depression is part of ordinary experience and commonly accompanies fatigue, especially if the person is isolated at the time, and can lead to lethargy and carelessness. Frustration, like depression, can be induced by inactivity, especially among the normally energetic. People accustomed to solving problems by increased effort can become very disturbed when no amount of physical effort is of any avail, as when becalmed in a small boat on the ocean or marooned in a tent in a blizzard. Then the ability to relax and go with events, rather than try to combat nature, has great survival value; the art is to cultivate a kind of alert inactivity.

Disorganization and psychological breakdown. Deprivation of fifty hours or more of sleep at one stretch is likely to lead to visual hallucinations and paranoid delusions, and to render the deprived person incapable of effective action. Experiments in which subjects are given impossible tasks—such as trying to fly a particular course in a trainer cockpit programmed to make the course impossible to steer—bring most subjects, eventually, to a state of complete incapacity.

A traumatic event such as seeing a relative or companion killed may lead to a period of shockinduced

inactivity followed by acute distress or engagement in some activity which is useful only in that it distracts. Another response to traumatic crisis is denial of its happening at all: a ship may be sinking but the distressed person simply denies that he is at sea at all. These are instances of the psychological process compensating for circumstances to which the individual cannot adapt.

Panic is not a common reaction to a crisis unless there is imminent danger, as in the case of risk of escape routes closing in the event of fire or flood, or there is repetition of a crisis that has occurred.

Lessening of effects. Exceptional people (such as Shackleton) and ordinary people at times of extreme need can accomplish quite extraordinary physical feats.

Most people on most occasions— say, those who have to make accurate observations, exercise rational judgements, or carry out complicated tasks over prolonged periods—can do something to maintain their efficiency. It helps to observe strict routines for rest and eating, especially when any prolonged activity is called for; and when in the middle of intense activity, to take every opportunity to rest and eat, rather than make a kind of virtue of keeping going. It is also useful for people to monitor themselves—to remain aware of how tense, tired, frightened, or hungry they are— and to make due allowances by taking extra care with observations and decisions.

See also STRESS.

Bennet, G. (1983). *Beyond Endurance: survival at the extremes*. London.

FEAR AND COURAGE. Although the word 'fear' is used without difficulty in everyday language to mean the experience of apprehension, problems arise when it is used as a scientific term. It cannot be assumed that people are always able, or even willing, to recognize and then describe their fears. In wartime, admissions of fear are discouraged. Similarly, boys are discouraged from expressing fear. In surveys carded out on student populations, it has been found that the admission of certain fears by men is felt to be socially undesirable.

The social influences that obscure the accurate expression of fear complicate the intrinsic difficulties in recognizing and describing our own experiences or predicted experiences. For instance, it is regularly found that some people who state that they are fearful of a particular situation or object are later seen to display comparatively fearless behaviour when confronting the specified fear stimulus. Subjective reports of fear tend to be of limited value in assessing the intensity of the experience because of the difficulties involved in translating phrases such as 'extremely frightened', 'terrified', and 'slightly anxious' into degrees on a quantitative scale with stable properties.

Page 257

For these reasons among others, psychologists have extended the study of fear beyond an exclusive reliance on subjective reports by including indices of physiological change and measures of overt behaviour. It is helpful to think of fear as comprising four main components: the subjective experience

of apprehension, associated physiological changes, outward expressions of fear, and attempts to avoid or escape certain situations. When these four components fail to correspond, as they commonly do, problems arise. People can experience subjective fear but remain outwardly calm and, if tested, show none of the expected psychophysiological reactions. There can also be subjective fear in the absence of any attempt at avoidance. The fact that the four components do not always correspond, makes it helpful in speaking of fear to specify which component one is referring to.

In our everyday exchanges we rely for the most part on people *telling* us of their fears and then supplementing this information by interpreting their*facial and other bodily expressions. Unfortunately this kind of interpretation, when made in the absence of supporting contextual cues, can be misleading. Moreover, facial and related expressions register only certain kinds of fear, particularly those of an acute and episodic nature; diffuse and chronic fears are less visible. We may easily observe signs of fear in an anxious passenger as an aircraft descends, but fail to recognize it in a person who is intensely apprehensive about ageing.

While there are many types of fear, certain of them, such as neurotic fears, have understandably been studied more intensively than others. Among the many types, a major division can be made between acute and chronic fears. Acute fears are generally provoked by tangible stimuli or situations and subside quite readily when the frightening stimulus is removed or avoided (see PHOBIAS): the fear of snakes is an example. (A less common type of acute fear is the sudden onset of panic which seems to have no tangible source, can last for as long as an hour or more, and often leaves a residue of discomfort.) Chronic fears tend to be more complex but are like the acute types in that they may or may not be tied to tangible sources of provocation. The fear of being alone is an example of a chronic, tangible fear. Examples of chronic, intangible fears are by their very nature difficult to specify; one simply feels persistently uneasy and anxious for unidentified reasons—a chronic state of aching fear that has been better described by novelists than by psychologists.

Repeated or prolonged exposure to fearsome stimulation can give rise to enduring changes in behaviour, feelings, and psychophysiological functioning. Clear examples of such changes are encountered during war conditions and after. Adverse reactions can be classified in two broad categories: *combat neuroses*, which are persisting fear and related disturbances, and *combat fatigue* (far more common), which is a temporary disturbance readily reversed by rest and sedation. Wartime observations and research on animal subjects suggest that the fear and*anxiety experienced by many patients with psychological troubles may well give rise to enduring psychophysiological changes, as well as to the more obvious behavioural changes such as marked and persistent avoidance of the frightening stimuli. However, given the nature of chronic anxiety, it can be difficult to confirm causal connections between it and specific psychological and physiological changes (a major problem, incidentally, in studying*psychosomatic disorders).

A distinction is sometimes made between fear and anxiety: fear is taken to refer to feelings of apprehension about tangible and predominantly realistic dangers, whereas anxiety is sometimes taken to refer to feelings of apprehension which are difficult to relate to tangible sources of stimulation. Inability to identify the source of a fear is often regarded as the hallmark of anxiety; and, in psychodynamic theories such as psychoanalysis, is said to be a result of repression.

A clinically useful distinction can be made between focal and diffuse fears. Generally speaking, focal fears are more easily modified, despite the fact that they are often of long standing.

The distinction between innate and acquired fears is an interesting one, although it may be of little practical value. The impact of early behaviourism, with its massive emphasis on the importance of acquired behaviour, led to the demise of the notion that some fears may be innately determined. Even the possibility of such fears existing in animals was only reluctantly conceded. In recent years, however, the possible occurrence of innately determined fears in human beings has once again come under serious consideration.

The major causes of fear include exposure to traumatic stimulation, repeated exposure to subtraumatic (sensitizing) situations, observations (direct or indirect) of people exhibiting fear, and the receipt of fearprovoking information. Fears usually diminish with repeated exposure to a mild or toned down version of the frightening situation. This decline in fear as a consequence of repetition can be facilitated by superimposing on the fearful reactions a counteracting influence, such as relaxation.

Fears can be thought of as existing in a state of balance, in which repeated exposures to a fearevoking situation may lead to an increase in fear (sensitization) or, at other times and in other circumstances, to a decrease (desensitization). The balance tilts in the direction of increased or decreased fear according to the type of exposure, intensity of stimulation, the person's state of alertness, and other factors.

Fear and its first cousin, anxiety, play a major part in most neurotic disorders, and clinicians and their research colleagues have explored the effects

of a variety of therapeutic means. Leaving aside the pharmacological methods which are often capable of dampening fear (but seldom of removing it), we are left with psychological methods. These can be divided into two main types: those which attempt to reduce the fear or anxiety directly (as in behaviour therapy) and those which attempt to modify its putative underlying causes (as in psychoanalysis and related techniques). The direct methods are comparatively new and are largely products of experimental psychology. The best established and most extensively used, desensitization, has been joined recently by *flooding* and by *modelling*, methods which involve repeated practice in confronting the frightening situation. Of the indirect methods, psychoanalysis is of course the most famous and influential, and it has spawned many derivations. Most of them, like psychoanalysis itself, were developed by psychiatrists or psychologists. The most widely practised is psychotherapy (a confusingly wide term covering many types of activity), and not psychoanalysis, which is a comparatively rare form of therapy. Although there are many different techniques, the indirect methods share the assumption that a thorough exploration of matters seemingly unrelated to the pertinent fear is a prerequisite for its reduction.

There is no generally accepted theory to account for the genesis and persistence of fears. The psychoanalytic theory, originally proposed by Freud, has undergone little revision, despite a great deal of criticism. The conditioning theory, derived from the work of Pavlov, appears incapable of providing a comprehensive account.

The conditioning theory postulates that any neutral object or situation which is associated with painful or fearful experiences will acquire fear-evoking properties.

Although there is some evidence to support this theory, there remain important observations that cannot be accommodated by it, such as the nonrandom distribution of human fears, and the nonappearance of fears in predicted circumstances.

Although fearlessness is often regarded as synonymous with courage, there is some value in distinguishing it from a particular view of courage: the occurrence of perseverance despite fear, which is perhaps the purest form of courage—it certainly requires greater endurance and effort. Despite frequent exposure to dangerous and stressful situations, most people acquire few lasting fears. Wartime surveys testify to the resilience of people subjected to air raids. Experimental analysis of programmes designed to train people in such dangerous tasks as parachute jumping provides further information about the nature of courage. Although fear during or immediately after exposure to danger is a common reaction, we apparently have the capacity to recover quickly. And our capacity to persevere and adapt when faced by fear and stress is remarkable.

Training for courage plays an important part in preparing people to undertake dangerous jobs, such as firefighting or parachuting. One element of such training, gradual and graduated practice in the tasks likely to be encountered, seems to be of particular importance. This aspect of courage training is strikingly similar to the clinical method of reducing fear known as desensitization.

In the early stages of courage training, the probability of success is improved if the subject's motivation is raised appropriately, encouraging perseverance despite subjective apprehension. The successful practice of courageous behaviour should lead to a decrease in subjective fear and finally to a state of fearlessness. Novice parachutists display courage when they persevere with their jumps despite subjective fear; veteran jumpers, having successfully adapted to the situation, no longer experience fear when jumping: they have moved from courage to fearlessness.

FECHNER, GUSTAV THEODOR (1801-1873). German philosopher and physicist, the son of a village pastor. He took his degree in medicine in the University of Leipzig, where he remained for the rest of his life. Fechner's interests soon turned to mathematics and physics, and for a time he earned his living by translating scientific texts from French into German. He also undertook some research on electricity which won him the chair of physics at Leipzig at the early age of 33. Owing to a serious

nervous breakdown, he resigned from his chair after a few years and, on recovering, with a deepened religious consciousness, he became a convinced pantheist.

Fechner's fame rests largely on his two-volume work *Elemente der Psychophysik* (1860). Basing his argument on E. H. Weber's work on differential sensitivity, Fechner argued that, in a series of sensations of increasing magnitude, say brightness or pressure, the intensity of the stimulus must increase in geometrical proportion if a just noticeable difference (j.n.d.) in sensation is to result. Further, if such just noticeable differences could be regarded as units each greater by one than its predecessor, it follows that the intensity of sensation is proportional to the logarithm of the stimulus. This is known as the WeberFechner Law (also known as Weber's Law), which Fechner regarded as basic to our understanding of the relationship between body and mind. It is the first formulation of this relationship in quantitative terms (see PSYCHOPHYSICS for further discussion).

Fechner insisted that what he called 'outer psychophysics', i.e. the correlation of sensory magnitude with the intensity of physical stimulation, would eventually be replaced by 'inner psychophysics', i.e. the correlation of subjective

Page 259

magnitude with the intensity of the central excitatory process. He thought that ultimately it would make possible a quantitative treatment not only of sensory magnitude but also of images, feelings, and indeed states of consciousness generally. Unfortunately, techniques were not available in his time to achieve this aim, but developments in contemporary neuropsychology might at least suggest that such an aim is not wholly fanciful.

FEEDBACK AND FEEDFORWARD. When we move to catch a ball, we must interpret our view of the ball's movement to estimate its future trajectory. Our attempt to catch the ball incorporates this anticipation of the ball's movement in determining our own movement. As the ball gets closer, or exhibits spin, we may find it departing from the expected trajectory, and we must adjust our

movements accordingly. This is an example of the visual system providing inputs to a controller (our brain) which must generate control signals to cause some system (our musculature) to behave in some desired way (to catch the ball). *Feedforward* anticipates the relation between system and environment to determine a course of action; *feedback* monitors discrepancies which can be used to refine the actions. In general terms, therefore, a *control problem* is to choose the input to some system in such a way as to cause its output to behave in some desired way, whether to stay near a set reference value (the regulator problem), or to follow close upon some desired trajectory (the tracking problem). A control signal defined by its intended effect may not achieve that effect either because of the effect of disturbances upon the system, or because of inaccuracy in the controller's knowledge of the controlled system.

Feedback is then required to compare actual and intended performance, so that a compensatory change in the input may be determined. Overcompensation yields instability; undercompensation yields poor adjustment to 'noise'. Thus, not only is feedback necessary, but it must be properly apportioned if the controller is to obtain smooth coordinated behaviour.

It is important to note that feedback can only be used effectively if the controller is 'in the right ballpark' in his (or its) model of the controlled system. However, in the real world the exact values of the parameters describing a system are seldom available to the controller, and may actually change (compare shortterm loading effects on muscles and longerterm ageing effects and weight changes). To adapt to such changes, the outer, feedback, loop of Fig. 1 must be augmented by an *identification* algorithm*. The job of this algorithm

Fig. 1.

To render a controller adaptive, an identification algorithm monitors control signals and feedback signals to provide the controller with updated estimates of the parameters that describe the controlled system.

is to monitor the output of the controlled system continually and to compare it with the output that would be expected on the basis of the current estimated state, the current estimated parameters, and the current control signals. On the basis of these data, the identification algorithm can identify more and more accurate estimates of the parameters that define the controlled system, and these updated parameters can then be supplied to the controller as the basis for his (or its) state estimation and control computations.

If the controlled system, or the disturbances to it, are sufficiently slowly timevarying for the identification procedure to make accurate estimates of the (system plus disturbance) parameters more quickly than they actually change, the controller will be able to act efficiently, despite the fluctuations in the system dynamics. The controller, when coupled to an identification procedure, is precisely what is often referred to as an 'adaptive controller': it adapts its control strategy to changing estimates

of the dynamics of the controlled system.

Marvin Minsky (1961) has observed that it may also be necessary for the identification procedure to generate some of the input to the controlled system—in other words, to apply test signals to try out various hypotheses about the parameters of the controlled system—trading off the loss of control caused by an inaccurate estimate of the parameters against the degradation resulting from the controller intermittently relinquishing control.

Note that the identification algorithm can only do its job if the controller is of the right general class. It is unlikely that a controller adapted for guiding the arm during ballcatching will be able, simply as a result of parameter adjustment, properly to control the legs in the performance of a waltz. Thus the adaptive control system of Fig. 1 (controller plus identification procedure) is not to be thought of as a model of the brain; rather each such control system is a model of a brain 'unit' which can be activated when appropriate. We may

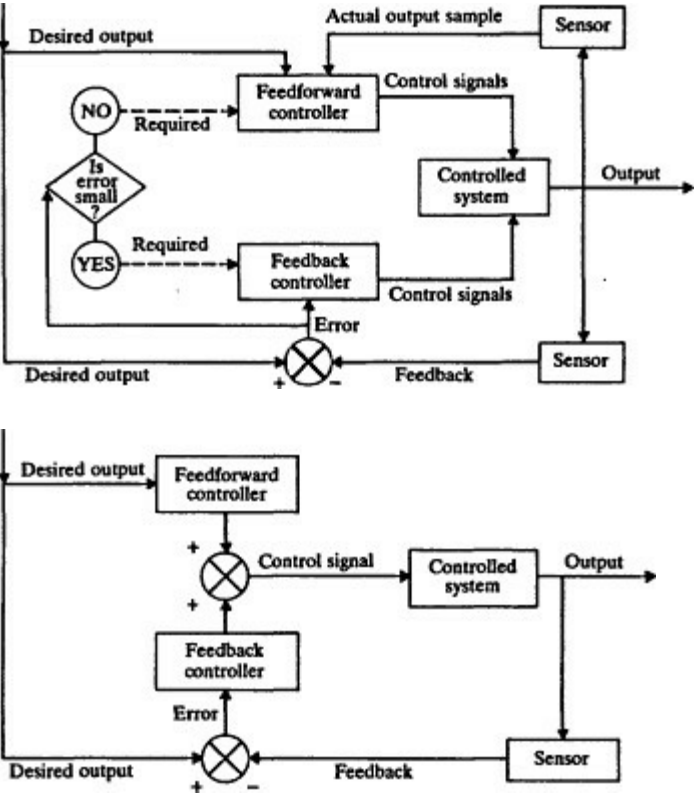

Fig. 2.

Discreteactivation feedforward—one of various possible configurations in which feedback and feedforward controls are explicitly separated. Here feedforward is active for large errors to get the controlled system

'into the right ballpark', while feedback provides 'finetuning' in the presence of small errors. The dashed lines marked 'required' indicate the supply of necessary activation if the system supplied is to function.

Nondashed lines indicate 'data flow'.

think of it as a*synergy. An important problem in analysing human movement is that of the coordinated phasing in and out of the brain's various synergies (control systems).

Feedforward is that strategy whereby a controller monitors a system's environment directly, and applies appropriate compensatory signals to the controlled system—

rather than waiting for feedback on how changes in the environment have affected the system before giving compensatory signals. The advantage is speed—such changes may be compensated before they have any noticeable effect on the system—but the cost is paid in controller complexity: for the controller must have an accurate model of the effect of all such disturbances upon the system, if it is to compute controls which will indeed effect the necessary compensations.

Feedforward generates large control signals which rapidly correct large discrepancies from the desired output. The resultant change in output may be too fast for longlatency feedback paths to play a major effect.

Feedback and feedforward are separate control strategies and thus may have separate structural embodiments, as shown in Fig. 2 (which does not show the identification algorithms which may provide the adaptive components for each strategy). Note that feedforward is 'pulseactivated' in the hypothetical scheme of Fig. 2.

It is activated when the error is not small. If well calibrated, the feedforward controller will, with a single brief timepattern of control, return the system to the 'right ballpark', i.e. making the error small enough for feedback control to function effectively. The system should thus have a 'refractory period' based Fig. 3.

Coactivation feedforward—one of various possible configurations in which feedback and feedforward are explicitly separated. Here the feedforward controller continually supplies a control signal which can maintain the output of the controlled system 'in the right ballpark', while the feedback controller utilizes error feedback to provide the necessary finetuning to compensate for inaccuracy in the feedforward controller's model of the controlled system, as well as for disturbances. Such a mode of control is appropriate only when the controlled system has a functional relation between maintained input and maintained output.

on the timeconstants of the controlled system—it should not generate a second control signal before the control system has had time to respond fully to the first control signal. The reader should note

what at first appears to be a semantic trick. The sample of the system's output is called 'feedback' when fed to the feedback controller, yet is called 'actual output sample' when fed to the feedforward controller. This looks like a way of avoiding the admission that feedforward requires feedback! But the difference is, in fact, a genuine one. A feedforward controller will, in general, need to know the actual state of the controlled system before generating its control signal) but need not monitor that output while the control signal is actually emitted. By contrast, the feedback controller continually monitors the error signal in generating its controls. As suggested by our ballcatching example, the situation in Fig. 2 might be refined so as to have the feedforward controller monitor the relation between the actual trajectory and a predicted trajectory, changing strategy if the discrepancy or error exceeds a threshold. But, again, we have a discreteactivation form of feedforward.

Fig. 3 shows a different strategy, which appears to describe better the control of muscle. Here, the control neurone must maintain a specific level of firing to hold a limb in a desired position—there is a functional relation between a desired output (e.g. muscle length) and a necessary input (e.g. maintained tension). In this case, the feedforward would be *coactivated* with the feedback system, so that feedforward sets and maintains the control level specified by the functional relationship, while feedback compensates for minor departures.

FEMALE SEXUALITY. Within the*Freudian tradition a good deal of controversy has arisen concerning the relevance of male sexual function as the model for female sexual function. As an example of theory going down a blind alley, creating a superstructure of assumptions around it, and then being rescued by the adequacy of more detailed clinical observation backed by discoveries in the parallel science of physiology, the Freudian statement on female sexuality bears some examination.

Freud's model of female sexual functioning is derived from the genital primacy of male functioning. In the male the reproductive act requires orgasmic release of seminal fluid. Hence, in the absence of contraception, ejaculatory orgasm and the reproductive act are not differentiated in the male.

In women such is not the case. There is no direct equivalent of ejaculation in the female, and she does not need to be orgasmic in order to be reproductive. This raised the theoretical problem of what should be thought of as constituting psychosexual maturity in women. In the psychoanalytic formulation, while the *process* for both men and women in reaching their psychosexual maturity is to reconcile their sexual drives with the requirements of their superegos, the *experience* of that integration is not necessarily similar at all. Because of the different requirements concerning reproduction and orgasm, it might even be thought to be necessarily dissimilar. But if the only test of psychosexual maturity was the reported experience, and an experience of the male kind was not necessary to or possible for women, what was to be the test of the psychosexually mature female?

Freud recognized that the biology of the early twentieth century did not offer a satisfactory explanation of the physiology of female sexual response. So, in the absence of facts, he made the assumptive leap that the clitoris is a rudimentary male sexual organ—hence, *inter alia*, the penis envy of the female who can never aspire to the grandeur of the male, and the castration fears of the male that he might be left with a rudimentary female knob. In consequence it was reasoned that gratification arising from the clitoris must also be rudimentary or immature. Thus clitoral arousal became the province of the immature woman, while vaginal orgasm was the prerogative of the woman whose sexual conflicts were successfully resolved and the demands of her id integrated with those of the superego. Consequently the clitoris is to be abandoned as a source of gratification, and the desideratum of female gratification is to be from the vaginal experience of penile insertion. In further consequence, the woman knows herself sexually only through the presence of the male.

As a consequence of W. H. Masters and Virginia Johnson's studies (1966) it is now clearly understood that the clitoris and vagina are separate but mutually dependent parts of a continuous sexual process that is stimulated from a quiescent state through arousal to orgasm and a return to quiescence. They are thus *interdependent* rather than, as in the Freudian view, *independent* sites of sexual pleasure. Physical sexual stimulation is received via the clitoris (among other sexually responsive areas of the female body), while the orgasm is mediated by involuntary contractions of the pubococcygeal muscles surrounding the lower (outer) third of the vaginal barrel. The experience and perception of orgasm is widely different from woman to woman, and for many women from occasion to occasion. Thus the type of orgasm is not indicative of psychosexual maturity.

Interestingly, clinical observation had begun to

Page 262

establish this view before the publication of Masters and Johnson's work, and such psychoanalytic observations were beginning to be incorporated in the revision of theory. Thus Helen Deutsch (1961) arrived at a clinical description of Masters and Johnson's subsequent physiological findings through her own analytical observations, when she expressed her conviction that

... the female sexual apparatus consists of two parts with a definite division of function. The clitoris is the sexual organ and the vagina primarily an organ of reproduction. The central role of the clitoris is not merely the result of masturbation but serves a biological destiny. Into it flow waves of sexual

excitement which may more or less successfully be communicated to the vagina. The transition of sexual feelings from clitoris to vagina is a task performed largely by the active intervention of the man's sexual organ.

While the last part of this formulation would not now be accepted, as the transfer process is related to arousal threshold phenomena in the woman in which the penis may or may not play a part, the shift in assumptions from the maledominated Freudian view is apparent. Therese Benedek (1961) asserted that there was a need for a theory of female sexuality which did not derive from the male model of sexual maturity, observing that when sexual sensations begin in the clitoris, spread to the vaginal walls, and finally encompass the whole body in orgasm, it is the woman's personality integration (her ego organization) that allows the clitoral stimulation to spread and be experienced as orgasm. Again, the latter part of this observation would now be questioned. W. C. Lobitz and J. LoPiccolo (1972) have shown that extensive masturbation may effectively produce orgasmic release where none has existed before, and in which the socially conditioned inhibitions of female sexual arousal appear to be much more dominant causal factors than personality integration.

In trying to integrate the physiological studies of Masters and Johnson into psychoanalytic thinking, Moore (1968) proposed that personal satisfactions deriving from sexual experience, rather than a continued preconception about desirable intensity and location of orgasmic experience, should be the criteria of adequacy/maturity in women, and the intrapsychic changes in the woman should be more the hallmark of personality integration than the presumed consequences of orgasm.

Finally, W. H. Gillespie (1969) provides the resolution of a debate that had been going on for over sixty years when, as an analyst himself, he observes that

... it seems probable that we must agree that an orgasm is an orgasm, and that one differs from another not in kind but in degree of completeness, or in the emotional satisfaction that accompanies it. I wish to propose that in future when the term 'vaginal orgasm' is used, we should no longer think of this as something excluding an outgrown clitoral erotogenicity; the term should instead be used exclusively to denote an orgasm that is *brought about* by thrusting movements in the vaginal barrel, whether or not such movements are indirectly producing excitation of the clitoris. The term 'clitoral orgasm' would then denote *orgasm produced by local stimulation* in the vicinity of the clitoris, not by thrusting movements in the vagina. Having in this way eliminated the probably misleading idea that female maturity necessitates an outgrowing or 'repression' (to use Freud's early description) of clitoral erotogenicity, we can proceed to consider what obstacles naturally stand in the way of vaginal orgasms as defined above; but here we shall find ourselves on familiar psychoanalytic ground and shall be concerned with many psychological problems, such as fear of penetration or invasion, penis envy, masculine identification, and countless others, but one bogey will be out of the way, and I believe this will be a real advance in the psychoanalytic understanding of female sexuality.

FERRIER, SIR DAVID (1843-1928), British physician, was born near Aberdeen and went to university there. He graduated in classics and philosophy in 1863, having studied under Alexander**Bain*, and went on to study medicine at Edinburgh in 1865. He was appointed physiology lecturer at the Middlesex Hospital in 1870 and in 1871 moved to King's College, London, where he spent the rest of his working life. The post of professor of neuropathology was created specially for him.

In 1873, Ferrier became interested in electrical excitation of the brain. He devised a method of faradic stimulation whereby he could explore the brains of various types of vertebrates including the monkey. The results confirmed his belief that cerebral functions were localized and enabled him to establish their areas. He noticed that if certain areas of a monkey's brain were destroyed, symptoms similar to those of a '*stroke' in humans were produced. He was now convinced that operations to treat brain injuries and diseases could be undertaken—if Lister's precautions against sepsis were observed—and these began to be successfully performed, thus changing the outlook in this field totally.

Ferrier was elected a Fellow of the Royal Society in 1876 and a lecture named after him was endowed.

FICTIONS IN PERCEPTION. See ILLUSIONS.

FIGURAL AFTEREFFECTS. These are changes in the appearance of a visual display consequent upon relatively prolonged fixation. These changes may affect size, shape, brightness, and location in space.

Figural aftereffects were first described in 1933 by J. J.*Gibson, who observed that after fixating a curved line for several minutes it appeared to be curved in the opposite direction. Somewhat similar aftereffects were studied in greater detail by the*Gestalt psychologists, Wolfgang*Köhler and Hans Wallach in 1944, and their work attracted considerable interest. Although these effects are often striking, unfortunately it cannot be said that their nature and mechanisms are fully understood.

Köhler's method of inducing figural aftereffects in two dimensions may be briefly described. Two identical rectangles separated by about 25 cm. are displayed on a white ground and a fixation point provided midway between them. After the subject has satisfied himself that, when viewed from a distance of a few metres, the figures look identical, one rectangle, known as the Test or Tfigure, is concealed by a screen, and the subject is instructed to fixate the remaining rectangle, known as the Inspection or Ifigure, for three minutes. The screen is then swiftly removed and the subject is required to describe the appearance of the two figures. The typical response is to say that the Ifigure appears smaller, dimmer, and lying further back in space than the Tfigure. Although these effects vary appreciably as between subjects, very few fail to report them in whole or part. Furthermore, they may persist for a short period after the Tfigure has been exposed.

Köhler satisfied himself that these aftereffects are of central rather than peripheral origin. In particular, he claimed that if the Ifigure is viewed with one eye and the Tfigure with the other, the outcome is the same as with binocular vision throughout.

Köhler and Wallach attempted to explain figural aftereffects in terms of an electrical field theory,

often referred to as the 'satiation' theory. This theory is based in part on classical physics and in part on the tenets of Gestalt theory, in particular the concept of isomorphism. Although ingenious, it can hardly be said that this theory carries conviction. An alternative theory, put forward by C. E. Osgood and A. W. Heyer, and owing much to W. M. Marshall and S. A. Talbot's excellent work on the mechanism of vision (1942), is altogether more plausible than Köhler's theory though not perhaps without difficulties of its own.

Köhler and his colleagues subsequently recorded some other varieties of figural aftereffects, the most striking of which are figural aftereffects in the third dimension, as described by Köhler and Emery in 1947. According to Osgood (1953), these find ready explanation if we assume that size changes are interpreted in terms of changes in distance. More perplexing are the accounts of figural aftereffects in kinaesthesia reported by Köhler and Dinnerstein, also in 1947. These appear to continue very much longer than those reported in the visual experiments and may, it seems, persist for several days. Even Köhler was obliged to conclude that aftereffects in the third dimension of visual space and those in kinaesthesia 'appear at present almost inaccessible to the theorist!' Indeed we are driven to conclude that whereas figural aftereffects merit recognition as convincing perceptual phenomena, they still evade convincing psychological explanation.

FIGUREGROUND. A term used in technical discussions on visual perception. In 'ambiguous figures', the *figure* alternates with the *ground* (Fig. 1) or with alternative figures or objects (see ILLUSIONS, Fig. 4). 'Figure' corresponds roughly to seeing *objects*. These important phenomena were investigated by the Danish psychologist Edward*Rubin, among others, and may be thought of as

Fig. 1.

One of Rubin's figureground reversing figures.

Here there are two equally held figures,

which in turn are relegated to ground.

Regions accepted as figure are subtly

changed perceptually in the process: if

the concentric cross is seen as figure after

the radial one, it is possible to note a characteristic change in the concentric markings, which depends on whether they belong to the figure or the ground. When they are part of the ground, they do not appear interrupted but seem to continue behind the figure. This is not noticed when the concentric cross is seen as the figure.

FLOURENS, (MARIE JEAN) PIERRE (1794-1867). French physiologist, born at Maureilhan, Hérault, and who studied medicine at Montpellier, qualifying in 1813. He moved to Paris, where he was helped by the anatomist Georges Cuvier. He became a member of the Académie des Sciences in 1828, professor of comparative anatomy at the Collège de France in 1835, and a member of the

Academic française in 1840. He was a pioneer in techniques of ablation for investigating brain function.

An accomplished experimentalist, his findings led him to conclude that there is considerable diversification of function in the central nervous system: 'All sensory and volitional faculties exist in the cerebral hemispheres and must be regarded as occupying concurrently the same seat in these structures.' He likewise concluded that '...

feeling, willing, and perceiving are but a single and essentially unitary faculty residing in a single organ (i.e. the cerebral hemispheres)'. These findings have been widely taken to imply that the various categories of psychological function are not discretely localized in the cerebral cortex—a view that held sway for some sixty years until Paul*Broca's claim that articulate speech in man is localized in a small area of the left cerebral hemisphere.

As might be anticipated, Flourens was a convinced opponent of phrenology and his work did much to discredit the standing of F. J.*Gall. And he is often held, not wholly with justice, of having anticipated the views of Karl*Lashley on the cerebral localization of psychological function. His important work on the effects of cerebral ablation

in animals is *Recherches expérimentales sur les propriétés et les fonctions du système nerveux dans les animaux Vertébrés* (1824).

FLUGEL, JOHN CARL (1884-1955). British experimental psychologist and psychoanalyst. Born in Liverpool, he became interested in psychology when, as a student at Oxford, he met William*McDougall, at that time Wilde reader in mental philosophy there. This led him to spend some months in Würzburg studying under*Külpe and, on his return, to becoming first assistant to Charles*Spearman at University College London. Here he carried out experiments on fluctuations of*attention under Spearman's direction and some years later published the monograph *Practice, Fatigue and Oscillation* (1928).

As well as being a dedicated university teacher, Flugel trained as a practising psychoanalyst and wrote several books on Freudian themes, among them *The Psychoanalytic Study of the Family* (1921), *The Psychology of Clothes* (1930), and *Men and Their Motives* (1934). He also produced *A Hundred Years of Psychology* (1933), a contribution to a series very popular in its day and still interesting.

O. L. Z.

FORGETTING. There are three possible causes of forgetting. First, relevant information may have been lost from the storage system of the brain—'storage loss'.

Second, there may be failure to retrieve or to use stored information—'retrieval failure'. Third, insufficient information may have been put into storage to permit of differentiation between wanted and unwanted information—'encoding deficiency'. (Strictly, this is only one form of encoding

deficiency. *How* information is encoded can also affect retrieval, as the success of mnemonic systems testifies.)

Storage loss can occur in several ways. There may be decay of the physical representation of the information. Decay is a plausible explanation for the very rapid forgetting which takes place in the first second or so after an experience has occurred—for example, the fading perception of the visual world that occurs if you close your eyes. Another possibility is that information is displaced from storage by new information; the idea of displacement is used, for example, in the 'slot' theory of the memory span (see SHORTTERM MEMORY). Or information may be modified by new information rather than be displaced by it, as in Bartlett's 'schema' theory.

Modification of schema may underlie the way our memory for a changing feature of the environment is updated, whether the feature is transient, such as our own location in space, or one that changes only slowly, such as the face of a friend. Schemas provide a basis for record

Page 265

ing abstractions from events without recording the events as such.

There is no direct evidence for storage loss. If such evidence is obtained it will be physiological. However, the total absence of storage loss would mean that, in a sense, nothing is ever really forgotten. This view was popularized by Freud but it is doubtful whether he meant that every trivial detail of every trivial experience remains stored. There is suggestive evidence of storage loss in postencephalytic amnesia, since the amnesia is characterized by unusually rapid forgetting. (Typically, amnesia is characterized by poor learning rather than rapid forgetting.) Suggestive evidence for storage loss, without any association with disease, comes from an extensive investigation of memory for schoollearned Spanish: there was forgetting for the first 5 years after study, no forgetting for the next 25 years, and additional forgetting with the onset of middle age. The interpretation of such evidence is, however, controversial.

Without physiological evidence it is impossible to be sure that storage loss occurs, for retrieval failure can never be excluded as a reason for forgetting. There is plenty of everyday evidence for retrieval failure: for example, we all forget names we know that we know and which we can later recall (the tip-of-the-tongue phenomenon).

The likelihood of successful retrieval is greatly affected by the presence or absence of relevant cues—stimuli, logically or associatively related to the information to be retrieved—especially if they were present at the time of learning. Mood, which provides internal cues, has been shown to have quite a powerful effect on retrieval. It is easier to remember happy events when we are happy than when we are unhappy and vice versa (thus reinforcing a current mood state). Hypnosis can be used to alter mood state and can thereby affect retrieval. However, the common belief that hypnosis produces a dramatic increase in retrieval (thereby supporting the notion that there is no true forgetting) has been shown to be false, and the memories produced under hypnosis have proved to be highly unreliable.

An event is difficult to remember if it is one of a number of similar events (What did you have for lunch on Tuesday last week?)—a difficulty which has been extensively studied under the heading of proactive and retroactive interference. The difficulty probably arises partly because insufficient information has been stored to enable differentiation of one event from another—that is, from encoding deficiency. Immediately after an event has occurred, its recency is a sufficient basis for its identification, but later it can be distinguished from similar events only by some form of stored code of adequate precision. The difficulty also arises because retrieval failure becomes more likely; according to cueoverload theory, this is because retrieval of similar memories tends to depend on the same cues, and the effectiveness of a cue falls as the number of memories associated with it rises.

We think of forgetting as undesirable. However, the difficulty of remembering similar events suggests that there is a positive advantage in forgetting, through storage loss, the great majority of our moment-to-moment experiences: such forgetting should reduce retrieval loss for information of importance to us. Can we, then, voluntarily discard information? Experiments suggest that the extent to which we can is very limited and probably confined to ceasing active maintenance of recently acquired information. Sadly, the mind does not seem to have at its disposal anything corresponding to the erase button of a taperecorder.

FOURIER ANALYSIS. A method of analysing into simpler components any complex sound or other waveform (whether it describes fluctuations over time or over place). The analysis uses the Fourier theorem, which states that any function or waveform can be described as a series of sine waves of multiple frequencies and various amplitudes. Conversely, the characteristic timbre of musical instruments can be produced by combining separate sine wave oscillations (Fourier synthesis).

Fourier analysis is useful for studies of electroencephalography and*speech recognition by machine. The more recent notion that visual*pattern recognition may employ Fourier analysis is due largely to the work of F. W. Campbell at the University of Cambridge.

The Fourier theorem was formulated in 1826 by the French mathematician and physicist Jean Baptiste Joseph de Fourier (1768-1830), who was a professor at the École polytechnique in Paris from 1795 to 1798; he accompanied Napoleon to Egypt as scientific adviser and was for a time Governor of Lower Egypt. He was created baron in 1808 and in 1827 became president of the council of the École polytechnique.

FRANKENSTEIN. The creator of a monster in a story, suggested in a dream, written by Mary Wollstonecraft Shelley (1797-1851) for her future husband, the poet Shelley, and their friend Lord Byron during a wet holiday on Lake Geneva in August 1816. The monster, created from parts of dead men, represented the fearful power of science to create uncontrollable beings and forces that threaten and might destroy us. The title page of the novel (published in 1818) reads: Page 266

FRANKENSTEIN

or,

THE MODERN PROMETHEUS.

in Three volumes.

Did I request thee, Maker, from my clay

To mould me man? Did I solicit thee

From darkness to promote me?—

Paradise Lost.

Mary Shelley gives the full story of how it came to be written in the 1831 preface to the novel.

Frankenstein has been reborn in many films (Daniels, 1975), the first made in 1910 by the American inventor Thomas Alva Edison; sadly, this is lost, though there remain photographs of the first film monster: Charles Ogle. Boris Karloff played the monster in Universal Pictures' classic *Frankenstein* of 1931; his creator, Dr Frankenstein, vitalizes the monster most impressively by harnessing the powers of lightning with a wonderful apparatus. The same studio made seven sequels, while many other Frankenstein monsters appeared from other studios, demonstrating the power of a myth that represents fears of our time.

FRANZ, SHEPHERD IVERY (1874-1933). American neuropsychologist, educated at Columbia and Dartmouth, and best known as the man who was largely responsible for instructing the youthful Karl Lashley in the techniques of cortical ablation, upon which Lashley relied exclusively in his later and celebrated studies of brain mechanisms and intelligence in the rat and monkey. Indeed Franz in some respects anticipated Lashley's claim that psychological functions are not controlled by small and strictly localized areas of the brain, and he collaborated with Lashley in several early studies of the effects of focal lesions of the cerebral cortex.

Unlike Lashley, however, Franz was active in studying the effects of brain lesions in human patients as well as in animals. He was particularly interested in the functions of the frontal lobes, on which he

contributed several monographs and papers, several of them in collaboration with Lashley.

Franz was also interested in the variability of motor centres and in various aspects of aphasia, and was one of the most distinguished early representatives of what is now known as clinical neuropsychology. His later work was based at the University of California.

FRAZER, SIR JAMES GEORGE (1854-1941). British social anthropologist and scholar of myths and comparative religions. Born in Glasgow, he graduated at Cambridge in 1878 and became a Fellow of Trinity College. His major work is *The Golden Bough* (1890; third edition, rewritten in twelve volumes, 1911-15;

abridged 1922). He also wrote *Folklore in the Old Testament* (1918), *Belief in Immortality* (1913-24), *Fear of the Dead* (1933-6), and *Magic and Religion* (1944). He became professor of social anthropology at Liverpool in 1907, was knighted in 1914, and awarded the Order of Merit in 1925. Strangely, although his scholarship extended to the mythology of many countries, his sources were entirely from books, as he never travelled.

FREE ASSOCIATION. Sigmund Freud gave a new direction to the study of the association of ideas as he developed his therapeutic techniques in clinical practice.

He came to claim that the unforced remarks made by patients during treatment unwittingly revealed their wishes and motives, and thereby enabled the therapist to circumvent resistance to personal disclosure. In 1912, in *The Dynamics of Transference*, he described his fundamental principle of psychoanalysis as the requirement that the patient repeats whatever comes into his or her head without criticizing it.

Interest in applying principles of organization to the headlong abundance of thoughts, images, memories, and perceptions that distinguish mental life had previously overlooked the possible importance of personal experiences and preoccupations. Aristotle's description of the formal (similarity, contrast) and accidental properties (contiguity in time or place) that linked thoughts, had been taken up by Locke and Hume to provide a detailed but highly abstract explanation of the contents of the stream of consciousness. No attempt to account for the individual colouring of associations was made by the British empiricists, even after an experimental approach had been introduced by Francis Galton. Of course Freud's clinical findings had been intuitively anticipated by dramatists and novelists, and perhaps most powerfully realized in their depictions of suffering so great as to effect disintegration of syntax. Hamlet's wordplay though dark is not impenetrable, and it has the effect of drawing the anxious listeners into the drama of his distress.

Jung, who in so many of his researches followed where Freud led, had in fact begun to study free association before they met. He approached the subject from a different angle but also came to focus on the personal significance of associations. His interest had been aroused by his application, as an instrument of clinical investigation, of the word association test invented by Galton. This test had provided a technique for putting the mechanism of association under scrutiny, although it suffered the limitation of being so atomistic as to produce highly artificial results. The procedure was very

simple: the experimenter worked through a list of prepared words, perhaps fifty or sixty, calling out each one in turn. The subject was required to respond as quickly as possible with the first word that came into his or her mind, and the experimenter

Page 267

recorded this together with the timelapse between stimulus and response. The early work looked at formal relations between word pairs and attempted a variety of classifications of responses. The vast amount of data collected, particularly by Wilhelm*Wundt and his associates, attracts little interest now, being regarded as a recalcitrant body of facts without practical application. Jung temporarily breathed new life into the procedure by noticing that the responses of psychiatric patients often revealed their most intimate concerns. He described a group of responses bound together by a pervasive feeling as a*complex, and transformed the test into a diagnostic tool. He also used it to make interesting observations on speech disturbances in psychotic states, regarding intense emotional preoccupation as a handicap to rational thought. In extreme disturbance, the Aristotelian principles of association became stronger than the influence of any particular directing idea, leading to a loosening of logical associations, and sometimes to a loss of any unifying feeling tone. Even so, beneath the fractured surface of psychotic communication, it was possible to find evidence of profound hurt and compensatory aggrandizement. That this early work made him receptive to the more sophisticated innovations of Freud is dearly indicated in the conclusion to his paper 'Association, Dream and Hysterical Symptom', published in 1906, a year before he met Freud. He wrote there that

'the interferences that the complex causes in the association experiment are none other than the resistances in psychoanalysis as described by Freud'.

Freud's approach to the treatment of neurotic disorders evolved over many years. In its final form, after he had abandoned the use of hypnosis, he would sit behind his patient who lay on a couch. There was no agenda of problems or topics to be discussed, and the session would be facilitated by Freud's nonemotive promptings.

Although the therapeutic alliance required that the conscious attitude of the patient should be desire for change, Freud recognized that there would inevitably be unconscious resistance, as the abandoning of neurotic defences involved the renunciation of cherished illusions. The degree of resistance was a principal factor determining the length of therapy. The method of free association enabled him to capitalize on the unintended candour of the patient and make interpretations which could then be reflected on. Central to this endeavour was the examination of dream material, which provided a 'royal road to the unconscious' and a privileged glimpse of primary process thinking (see DREAMING). In this primitive style of thinking, the categories of space and time were said to be ignored and images tended to become fused and distorted by condensation and displacement. The key to understanding unconscious mental activity was the pleasure principle, which determined that all frustration of instinctual drives was repaired by hallucinatory wishfulfilment. Freud regarded his longest book, *The Interpretation of Dreams* (1900), as his seminal work, and thirty years after its first publication described it as containing the most valuable of all his discoveries. So it was that dreams, supplemented by recollections and anecdotes, provided the raw material which through

interpretation revealed the motives and wishes of the patient. At first these were illdiscerned but later became clearer through the lessening of resistance and the resolving of transference feelings for the analyst. It was not uncommon for a powerfully charged and unusually lucid dream to coincide with a therapeutic breakthrough. Freud insisted on the objectivity of the method, contrasting his approach, in which the interpretation of associations is drawn from the patient by gentle probing, with the classical account of Artemidorus (2nd century AD), in which the adept authoritatively imposed his view on the dreamer.

Nowhere more clearly than in *The Interpretation of Dreams* does Freud display his extreme rationalism. It is as though he employs a psychological principle of sufficient reason, as every feature of a dream is explained in terms that illuminate the conflicts of the dreamer. While the sheer analytical power of his thinking is impressively demonstrated, there are perhaps few therapists today who would interpret with such complete confidence or not allow for undecidable or meaningless elements. Moreover, it is difficult not to feel that Freud's strength of personality imposed itself both on the material he analysed and on the patients themselves.

Accounts by patients of their therapy with him tend to confirm this impression and contradict his own description of assumed emotional detachment during therapy.

Perhaps Freud's patients tended to have Freudian dreams, as later Jung's patients had Jungian dreams. Nevertheless, the points of agreement between Freud and Jung seem much more profound than the points of difference. Jung subsequently developed his own therapeutic style to suit his temperament, and one of his innovations was to invite the patient to fantasize in the therapeutic sessions and thereby actively promote free association.

As psychotherapeutic practice has proliferated, so ways of conducting therapy have multiplied. The most important general feature of newer therapies has been the attempt to reduce the length of the procedure, from years to months, or even to a fixed number of sessions agreed in advance. In order to abbreviate therapy, various devices have been employed for breaking down resistance. Some examples of this trend are: structuring the therapy sessions, strategic focusing on specific problems, concentrating on patient-therapist interactions in the here and now, and more aggressive styles of interpretation. However, the common denominator in all these approaches is the use of the free associations of the patient to point up contradictions between unconscious attitudes, wishes and motives, and the self-image which unin

Page 268

tentionally announces alienation from fundamental impulses.

FREE WILL. See CHOICE; DETERMINISM AND FREE WILL; INTENTIONALITY; MAINE DE BIRAN.

FREUD, ANNA (1895-1982). Born in Vienna, the sixth child of Sigmund*Freud, Anna was the only member of the family to follow in her father's footsteps and make her career in psychoanalysis. She was admitted to membership of the Vienna Psychoanalytical Society in 1922 and for a time became its chairman. After the Nazis occupied Vienna, she emigrated to England with her parents, and after the outbreak of the Second World War organized the Hampstead War Nurseries in cooperation with her close friend and admirer Dorothy Burlingham. In 1945, this enterprising venture was succeeded by the Hampstead Child Therapy Course and Clinic, which for long led the field in the training of child psychotherapists in the London area. Anna Freud's work, like that of her contemporary Melanie*Klein, was based not on the earlier Freudian ideas about child development, which derive largely from the analysis of adults, but on the direct observation of the behaviour of young children. This approach did much to make possible the remedial treatment of psychologically disturbed children.

Although she never held a formal medical or psychological qualification, Anna Freud's significant contribution to child psychology and psychiatry was acknowledged by her election to an Honorary Fellowship of the Royal College of Psychiatrists and the conferment of honorary degrees from a number of wellknown universities, including Harvard, Yale, Sheffield, and Vienna.

Anna Freud is best remembered for her book on *The Ego and the Mechanisms of Defence* (German, 1936; English translation, 1937), which carried further some of the ideas developed by her father in his book on *The Ego and the Id* (1923) and played a very real part in the genesis of what later came to be known as 'egopsychology' (see FREUDIANISM: LATER DEVELOPMENTS).

O. L. Z.

FREUD, SIGMUND (1856-1939). Sigmund Freud, who was born of Jewish ancestry at Freiberg in Moravia, was educated in Vienna, in which city he spent almost the whole of his long life. Here he enrolled at the university as a student of biology and medicine in 1873 and while still a medical student embarked on some research under the distinguished physiologist Ernst Brücke, whose interests lay predominantly in the vertebrate nervous system. In 1878, this work resulted in Freud's first published scientific paper, on the histology of the spinal cord in a primitive fish. He qualified in medicine in 1881 at the age of 26, somewhat tardily, and after working for a time in Theodor Meynert's Institute of Cerebral Neurology, decided to specialize in clinical neurology. He was appointed to a lectureship in neuropathology in 1885 and, soon after, was awarded a travelling fellowship to enable him to study in Paris with the worldfamous neurologist J. M.*Charcot. This

proved to be the turningpoint in Freud's career; from it can be dated his metamorphosis from a clinical neurologist into a medical psychologist in the modern sense of the term.

While still active in neurology, Freud published several papers and two books. One of the latter, on disorders of speech (*aphasia) resulting from lesions of the brain, attracted considerable interest and has since been regarded as well in advance of its time. It has also been argued that his ideas about aphasia provided some basis for his later psychological thinking. It may be added that, as a young doctor, Freud only narrowly missed becoming the first to recognize the anaesthetic properties of cocaine.

In 1885, he arrived at the Salpêtrière in Paris, which then enjoyed a worldwide reputation as the Mecca of clinical neurologists. At this period, Charcot had become much preoccupied with the so-called functional nervous diseases, in particular *hysteria, in which no clearcut somatic basis had been established. This protean disease was at that time widely treated by hypnosis, upon which Charcot held strong views. First, he maintained that only those of innate hysterical disposition are amenable to hypnosis; and secondly, that hypnosis provides a kind of laboratory for the induction and modification of hysterical symptoms. But whereas Charcot still believed that hypnosis had a physical basis, Freud became increasingly convinced of its psychological origin. It is not without interest that some years later he paid a special visit to M. Bernheim, of Nancy, who was perhaps the first to insist upon the overriding role of suggestion in bringing about hypnosis, and to stress its applicability to a wide range of individuals who sought his aid as a physician. Although Freud later repudiated hypnosis as a clinical tool, it is most improbable that, had it not been for Charcot's influence, he would have been led to collaborate with Josef *Breuer and ultimately to evolve the psychoanalytical method.

This work with Breuer began soon after Freud's return to Vienna. Breuer had been interested for some time in using hypnosis in the treatment of hysterical illness, and came to place great reliance on the therapeutic benefit of what came to be called abreaction. This was essentially a kind of reenactment, during hypnosis, of stressful and disturbing experiences which appeared to have precipitated

Page 269

the illness, and the free and uninhibited expression of emotion was actively encouraged. While seeing some benefit in abreaction, Freud quickly came to realize not only that the structure of neurosis was much more complex than Breuer, at least, was prepared to admit, but also that it involved active processes of defence (repression) against the reproduction, or even the mere acknowledgement, of painful, distressing, or otherwise emotionally disturbing memories. He surmised that many of these had to do with sexual life, a conclusion which Breuer appears to have been ill-disposed to concede. Freud also came to appreciate that the understanding and disarming of these defences could often be achieved more effectively in the waking than in the hypnotic state. In consequence, hypnosis was replaced by the so-called method of *free association, from which psychoanalysis as a technical psychotherapeutic procedure gradually evolved.

Over the next few years, Freud was essentially concerned in developing his brilliantly original, if to

many people extremely disconcerting, ideas about the causation and treatment of neurotic illness. He was led increasingly into study of the sexual life of his patients, at first believing that much neurosis is attributable to distressing sexual experiences in early adult life. Soon, however, he discovered that many of these supposed experiences existed only in imagination and were the products of fantasies evolved at a very much earlier age, often in quite early infancy. Analysis of these fantasies led him to believe not only that psychosexual life has its origins in early infancy but also that it involves intense and often complicated emotional relationships, both positive and negative, with the parents. These ideas were brought together in his *Three Contributions to the Theory of Sex* (1906), a book which shocked many people but which nevertheless had wide influence on modern conceptions of personality and its development. It also marks the transition from psychoanalysis conceived as a special theory of neurosis to psychoanalysis as a general theory of human personality.

This period, too, was marked by Freud's herculean attempt at selfanalysis, using many of his own dreams to furnish clues as to his own early development and emotional relations with his parents. It further provided the occasion for the writing of what is often regarded as his greatest book, *The Interpretation of Dreams* (1900). As Freud's views on dreams are considered in a separate article, FREUD ON DREAMS, it is unnecessary to say more here than that dreams, in his view, have meaning and are largely the product of infantile wishes and thought processes, and that their personal significance can be assessed if their language can be understood and translated into the currency of adult, waking thought.

Although Freud's ideas incurred much odium in medical circles, his work none the less attracted a small but devoted band of followers, many of them neurologists who, like Freud himself, had felt challenged by the ubiquity of neurosis among their patients. Among them were Karl Abraham, Sandor Ferenczi, Alfred*Adler, Carl Gustav*Jung, Otto Rank, and the Welsh physician Ernest Jones, who became for many years Britain's foremost Freudian. Shortly before the outbreak of the First World War, this group was weakened by two major defections, those of Adler and Jung. Adler's defection was less important, as it is doubtful whether he was ever a committed Freudian, and Freud himself thought little of his ideas. (None the less, after Adler's death, some of his views, in particular those associated with the nature of aggression, came to exert considerable influence on neoFreudian theory.) Jung, on the other hand, was a man of real distinction of mind and impressive literary productivity. As a psychiatrist, he did much in his early days to extend Freudian thinking to the psychoses, in particular*schizophrenia, and is remembered as the originator of the wordassociation test at one time much in vogue as a 'liedetector'. There can be no question that Freud thought of Jung as his eventual successor in the leadership of the psychoanalytical movement, and his defection caused him very real chagrin. Subsequently, Jung wrote widely (if somewhat obscurely) on individual development, psychological types, and the cultural frontiers of psychology.

In his later writings, Freud displayed an admittedly speculative turn of mind, and though some of his ideas are of great interest, their empirical foundation became decidedly weaker. Among them are *Beyond the Pleasure Principle* (1922), *The Ego and the Id* (1923), *Inhibitions, Symptoms and Anxiety* (1936), and, finally, the work of his old age, *Moses and Monotheism*, published a year before his death. Some of the ideas expressed in these writings are discussed in the article FREUD

ON MENTAL STRUCTURE.

Freud's work came to be widely known to the general reader, particularly through such works as *The Psychopathology of Everyday Life* (1904), *Wit and its Relation to the Unconscious* (1905), *Introductory Lectures on Psychoanalysis* (1922), and *New Introductory Lectures on Psychoanalysis* (1933). In America, the five lectures which he delivered at Clark University in 1910 (at the invitation of the veteran psychologist G. Stanley*Hall, then president of the University) subsequently appeared in English and enjoyed a certain vogue. But Freudian thinking did not seriously penetrate American psychiatry until after the end of the Second World War, when it came to dominate psychiatric practice for some years, possibly to the detriment of other and less doctrinaire approaches. It has also had wide influence on literature, particularly on biography, on some aspects of painting (for example, surrealism), and on much contemporary thinking in anthropology and the social sciences. Indeed many people nowadays regard psychoanalysis in the light of a social rather than a biological or medical discipline. Even so, its roots, Page 270

as those of Freud himself, are wholly within the biological domain.

Following the Nazi invasion of Austria, Freud, by then a very sick man, fled from Vienna and lived quietly in London for the last year of his life. Shortly before his death, he was made a Foreign Fellow of the Royal Society, a belated though none the less imaginative tribute to his world stature and influence on modern thought. His daughter, Anna*Freud, a pioneer in the psychoanalytical study of children, became a leading member of the British psychoanalytical community. As a person, Freud is remembered by those who knew him as a man of some austerity but unchallenged personal integrity.

FREUDIANISM: LATER DEVELOPMENTS. Sigmund*Freud's legacy of psychoanalytic theory and technique was essentially complete by 1926, when he turned 70, although until his death in 1939 he continued to represent it, rethink its implications, and apply it in new ways. He had a small group of adherents from 1902, and in the twenty years 1906-26 a group of colleagues in Vienna and elsewhere developed along with him the concepts of psychoanalysis and their practical applications. By 1926 Freud's legacy itself owed much to them directly, as well as to their stimulation of his work and writing, sometimes by opposition but usually by their independent use of his and their ideas. This was a new way of thinking about man and his mental functioning and development; even though it had important roots in the work and writings of predecessors and contemporaries (see Ellenberger, 1970). In an amazingly short time Freud and his colleagues had applied psychoanalytic ideas beyond psychiatry in anthropology, sociology, and the criticism of art and literature, to biographical writing,

and to the theories of mythology and of language.

Although Freud chose to think of psychoanalysis as a science, he often acknowledged the provisional character of statements of its findings, and even of its fundamental hypotheses. In an unfinished paper first published in 1940 he says of them, 'it is hard to say whether they should be regarded as postulates or as products of our researches'. The simple modesty of that remark is equal to the profundity of its truth: to verify psychoanalytic researches and to distinguish what one has found there from what one has put there are much harder things to do than, as a psychoanalyst, to relieve a patient's anxiety or, as a patient, to recover things forgotten and rework the significance of past experiences. Only the naive and the obsessional will see it as a weakness rather than a strength of psychoanalysis that, like other behavioural sciences (Devereux, 1967), its practice and theory operate with provisional concepts and with metaphors and sustained hypotheses rather than with accepted laws of a science.

Nearly fifty years after Freud's death it is possible to estimate what parts of his legacy later psychoanalytic practitioners and writers have found most useful and have accepted as valuable. Most important are the casestudies, fulllength and vignettes; they are valuable both as accounts of what Freud himself did, or said he did, with the kinds of patient one may still encounter, and as models of writing which give the psychoanalyst's thought and organization of material as well as his description of how the patients presented it. Along with the casestudies go the papers on technique, in which Freud's thoughts about the reasons for his own behaviour are matched with the behaviour of patients and with various statements of the aims and the mode of action of the treatment.

In psychoanalytic theory three sets of concepts have lasted: one set closely relates to practice and comprises* *free association, symbolization,* transference, identification, resistance, and interpretation*; another set relates to theories of mental structure and functioning and comprises *defence (repression being one of the defences), splitting of the mind (and of its objects), and unconscious mental processes, including fantasy* (not all now agree on using *Unconscious* as a noun); a third set comprises those concepts concerned with early human development, namely *infantile sexuality, fixation, and regression (separationanxiety, castrationanxiety, and the Oedipus complex* are also largely accepted and used).

Freud's short book of 1923, *The Ego and the Id*, gave rise to two different schools of psychoanalytic thought, one known as 'egopsychology' and the other as

'objectrelations Theory'.

'Egopsychology' has until very recently prevailed in the USA and in countries, such as Israel and Japan, which have derived their psychoanalytic teaching from the US. In Britain, Freud's youngest daughter, Anna, was the leading proponent of these views, which have concentrated interest on the ego, considered as a structure and as a set of mechanisms, and have seen the development of the personality and of 'egostrengths' as due to successful defence against instinctual drives and to adaptation to social realities (Freud, 1937). These changes have meant less interest in the id, Freud's latest term for the Unconscious considered as a system, and in the superego, that part of the ego most

closely identified with the parents at the end of the Oedipal period (age 56), since the very concept of adaptation meant that the external authority vested in society came to be of greater interest to egopsychologists than the primitive internal authority developed during the individual's childhood. Accordingly the defences have been more emphasized than the splitting of the mind and of its objects, or than fantasies; but this school has kept the stress on the topographic

Page 271

metaphor to describe the mind (its division into the regions of conscious, preconscious, and unconscious), the dynamic metaphors to describe the opposed forces of the unconscious and of the preconscious maintaining repression, and the economic metaphors of psychic energy and its disposal.

Egopsychologists have until recently given less attention than other psychoanalysts to processes of identification, and have in practice regarded transference (the carrying over on to the person of the analyst intensities of feeling originally developed towards parents and other important figures of childhood) chiefly as one of the inevitably met resistances to treatment. Interpretation, particularly of transference feelings, is therefore used more sparingly by this group of psychoanalysts than by others.

Like other groups, egopsychologists, in searching for the sources of psychopathology, have steadily concentrated their interest upon the early stages of childhood.

One of their great contributions has been the annual publication (from 1945) of *The Psychoanalytic Study of the Child*. Infantile sexuality and the anxieties of early childhood have filled much of the picture, but this group has done its share in focusing the interest of clinicians and other workers on the processes of adolescence, and on the help which adolescents often need and the conditions upon which it may be tactfully offered and received.

A clear, sympathetic statement and examination of the tenets of this school was made by Roy Schafer, himself a former adherent of it, in a book which also contains a valuable bibliography (Schafer, 1969). *Aspects of Internalization* was for him a transitional work before he attempted a statement of psychoanalytic theory and technique eschewing metaphor; but it remains a most useful critique of egopsychology.

In 1951 E. R. Dodds, then Regius Professor of Greek at Oxford, wrote *The Greeks and the Irrational*, inspired by Freud's writings and generally on the lines of egopsychology; it has had an influence not only upon classical studies but more widely upon historical thinking.

One of the central weaknesses of egopsychology is that ego as a set of mechanisms cannot be convincingly divorced from ego as self or personality. Ego cannot therefore be ultimately distinguished from id. Furthermore, since, according to *The Ego and the Id*, ego as personality has grown by the internalization of renounced loverelationships ('abandoned objectcathexes' was Freud's phrase in English translation), the ego cannot be clearly distinguished from its objects (or 'other persons') with whom it has identified, certainly in health and to some extent in pathology. (Freud himself occasionally acknowledged both the impossibility of distinguishing ego from id and also, in

some normal circumstances, the lack of boundaries between ego and object.) For these and other reasons, American psychoanalysts are now showing a new interest in 'object relations', a term used by Karl Abraham in a long and seminal paper (1924, in Abraham, 1927). Section II, the shorter section of that paper, is entitled 'Origins and Growth of ObjectLove'; upon it as much as upon *The Ego and the Id* is founded the theory of 'object relations'.

The term 'object' had been used early by Freud to denote the person (or thing) required in order to mediate instinctual discharge. It has survived probably because in grammar it is complementary to the term 'subject', subject and object being joined through a verb in a context. It now means the person(s), or his (their) inner representative(s), with whom the subject is intensely concerned emotionally.

In Section I of his paper Abraham showed that severe*depressions and*obsessional neuroses, similar in many ways, could be distinguished in treatment by the different vicissitudes of their 'objects'; the obsessional lived on the verge of losing his but never did, while the depressive at the onset of a depression lost his and had to restore it. Melanie*Klein and Ronald*Fairbairn, both profoundly but differently influenced by Abraham, evolved theories of personal development based on the child's need of, and*attachment to, his mother. Donald Winnicott, during his first ten years as a paediatric consultant (192332), began to do likewise but independently of Abraham;

his chief papers date from the period 194569, though 'The Manic Defence' is dated 1935.

By using, as the equivalent of free association, children's spontaneous play with suitable toys provided and kept in the treatmentroom, Melanie Klein found a way to psychoanalyse quite disturbed children even as young as 3 or 4, interpreting their play particularly in terms of their implicit fantasies about their parents' bodies and their own. In her early papers sexual fantasies have first place but, having inherited from her second analyst, Karl Abraham, a deep interest in depression and its connections with the first pregenital (the 'oral') stages of sexual development, she soon put the relationship of feeding mother and infant at the centre of the picture;

later relationships came to be interfered in terms of that one, by her and by her followers, who form a distinct group of the 'objectrelations' school (Klein, 1975).

The characteristics of the Kleinian group are: (i) in technique, a concentration upon the twoperson relationship and upon the interpretation of transference manifestations, using frequent interpretations particularly of the mental defences of projection and introjection; (ii) a theory of infantile development in two stages. In the first stage, denoted the 'paranoidschizoid position', the issue for the child is seen as the survival of the self against his own (projected) deathwishes; the defences of psychical 'splitting', 'idealization', 'projection', and 'introjection' make up the survivaltechnique he evolves. The second stage is called the 'depressive position', and the child enters it once he sees his mother as a whole, separate person; the issues

for the child are now the survival and restoration of his 'object', the loved and needed figure upon

whom he himself depends but whom, because of his ambivalence, in fantasy he damages or annihilates through envy of her or in anger with her.

Melanie Klein preferred the term 'positions' to 'stages' because she saw later pathology as due to failures to work through the different issues characteristic of them, to renounce inappropriate defences, or to overcome the ambivalence of love. In her attempt to explain both development and pathology in terms of forces within the individual child she kept a version of Freud's instinct theory, and attributed behaviour, emotions, and attitudes to the action of his life instinct and death instinct (projected as destructive instinct), ascribing to the second of these the innate envy which she held to be a crucial element in her patients' makeup.

The theoretical problem of the separateness of subject and object, a problem which makes it difficult to imagine how the infant makes the transition from the paranoid to the depressive position, is dealt with in Kleinian theory by use of the terms 'introjective' and 'projective identification', the latter a collective label for several defence mechanisms previously described by psychoanalysts but now considered by Kleinians as tending both to jeopardize and to facilitate identification and object relationships.

Donald Winnicott (1965, p. 177) held that Melanie Klein was temperamentally incapable of allowing the importance of environmental provision to the child's early life and mental functioning, but he speculated that only somebody so incapable could ever have worked out as fully and as clearly as she did the very early forms of mental mechanisms in two person relationships.

The other division of psychoanalysts who use 'object relations' theory has formed the central core of the British Psychoanalytical Society, but the psychoanalysts composing it tend less to operate as a group than did the Kleinians and the egopsychologists round Anna Freud (all three groups are component units of the Society, as Charles Rycroft describes in the introduction to his *Critical Dictionary of Psychoanalysis*).

All three groups understand the patient's present in terms of his past, and so interpret clinical material. But whereas the egopsychologists have interpreted primarily in terms of the three person, Oedipal relationship, and the Kleinians in terms of the two person, 'pre-genital' relationship of child and mother, the so-called independent group interprets in terms of either the Oedipal or the pre-Oedipal relationship and operates more readily with the concept of identification. Transference for this group comes to mean the unconscious repetition and reenactment in the psychoanalytic relationship of past relationships and not, as before, the transfer of psychic energy or primarily the carryover of feeling or of images of past figures. The technique of the psychoanalyst is, as always, important in the successful development and undoing of transferences, and this depends on his own (unspoken) free associations, on his capacity to recognize symbolization and to spot identifications, and on his respect for the patient's own insight and analytic work.

The four British psychoanalysts who by their writing and teaching have had the biggest influence on psychoanalysis since 1939 are Ronald Fairbairn, Michael Balint, John Bowlby, and Donald Winnicott. Balint, an immigrant to Britain of Hungarian origin and, like Melanie Klein in her first

analysis, psychoanalysed by Sándor Ferenczi, took an early interest in the mother-infant relationship. In his book *Primary Love and Psychoanalytic Technique* (1952), a key paper on 'Primary Object Love' dates from 1937. Later he took up an idea of John Rickman's (Rickman died prematurely in 1951) that mental function is quite different, and needs to be described differently, in three-person and two-person relationships, and different again in creative activity alone. Later still, Balint formulated an idea of what he called 'the basic fault': this was that there was often the experience in the early two-person relationship that something was wrong or missing, and this carried over into the Oedipal period (age 25); the resulting fault or flaw affected all subsequent dealings with people and also, of course, creativeness. Balint's books include one with that title (1968). He also applied psychoanalytic ideas in seminars with general practitioners, who took the opportunity to discuss with each other and with him aspects of their work with patients for which they had previously felt ill equipped. Since his death the continuance of this work has been assured by the formation of the Balint Society.

Ronald Fairbairn, a student of Hellenistic Greek and theology before he studied medicine and psychoanalysis in the 1920s, was piqued by Abraham's schematic account of child development through six phases (two oral, two anal, and two genital) into a restatement of early development based on the notion of ego-splitting that resulted from tensions in the period of greatest dependence (the oral phases, which he accepted) and the period of lessening dependence. He reworked an account of the 'origin and growth of object love', which was fully in the spirit of Abraham and Freud. Most of his papers were collected in his book *Psychoanalytic Studies of the Personality* (1952), but he continued to write, and in 1958 described the nature and aims of psychoanalytic treatment as a technique for the analyst's efforts to breach and turn into an open system that closed system which the neurotic patient did his best to maintain in his dealings with the world.

In rethinking the theory of defence and repression, Fairbairn described the 'moral defence' as the depressive neurotic's way of warding off a feeling of helplessness through the illusion of having himself been responsible for the failures of his early environment; the cost to him was a greatly increased sense of guilt, the advantage an illusory

Page 273

sense of independence. Fairbairn held that repression led to often crippling divisions in the self through keeping at bay two categories of internalized figures—highly sexualized ones, and strongly dominating ones that rejected sexuality; aspects of the self were closely associated with each of these and became repressed along with them.

Fairbairn's official work brought him in contact with assaulted children and with war neurotics. He was a clear thinker and his writings have influenced all later thinkers.

His own primary interest was in the early structuring of the mind, according to the various stages of dependence in which object relations were disturbed, and according to the defences that worked for the young child in his family.

In technique, Fairbairn argued for more flexibility than in classical psychoanalysis (this was not so different from the behaviour of Freud, who would sometimes give a patient tea or even food), and he pointed to the serious drawback for some patients in the use of the couch.

One of the chief exponents of all these ideas was Harry Guntrip. With his book *Personality Structure and Human Interaction* (1961) he gave the first synoptic, historical view of psychoanalytic schools and their development. In *Schizoid Phenomena, Object Relations, and the Self* (1968) he applied Fairbairnian ideas to clinical work as well as to the development of theory. Although he himself never qualified as a psychoanalyst, he gave psychoanalysts a comprehensive view which filled a great need.

Here is the appropriate place to mention the work of John Bowlby. In *Attachment and Loss* (1969, 1973, 1980) Bowlby managed to replace the largely outofdate and philosophical 'instincttheories' of earlier psychoanalysis by studying the actual motherinfant and motherchild relationships and by considering the effects upon the child's behaviour when the bonds are unduly strained, prematurely broken, or not even allowed to form. He introduced ethological concepts into psychoanalytic theory and gave it fresh life. For further details, see his article on ATTACHMENT.

Donald Winnicott came to psychoanalysis from paediatrics, and not through reading Abraham but through his analysis with James Strachey, later the editor of the standard edition of Freud's collected works in English translation. In his paediatric clinics Winnicott studied mothers' relationships with their infants and small children, and eventually formulated his own views of the ways in which a child comes to be a separate individual. He never lost sight of the idea that for the infant at first his mother has a dual role: she is his environment and she is his object. Bit by bit she becomes a person.

Winnicott saw the attachmentbonds developing and then becoming loosened, while the mother responds appropriately, leaving the child at every stage to choose between living in his own illusions and acknowledging her provision for his needs. The 'ordinary devoted mother' who offers 'good enough mothering' will allow her child rights over his own first possessions. Many children use a 'transitional object' in one early stage of becoming independent. This is Winnicott's term for a child's indispensable possession, a thing which in use and possession stands for the dimly remembered unity of mother and infantself. Contact with it both gives security and facilitates switches in identification between mother, self, and other people.

Winnicott's three volumes of collected papers (1958, 1965, 1971), replete with clinical experience and paradox, are an inexhaustible source of ideas for psychoanalysis. As theoretician he is often elusive, but partly because his writings up to 1960 often had the subsidiary aim of trying to get Melanie Klein to modify her views. The very title of the second volume, *The Maturational Process and the Facilitating Environment*, sums up his view of psychosexual development; the title of the third (posthumous) one, *Playing and Reality*, shows that he came to look upon the activity of playing as the basis of all creative and spontaneous living.

Like Fairbairn, Winnicott saw egosplitting, consequent upon the parents' premature demands or failures, as the origin of many problems of personality. He saw classical psychoanalysis as designed

to help neurotics, and Kleinian as developed for some depressives, but considered that only a technique which could allow and even facilitate regression might help people for whom the earliest experiences of being mothered had not been good enough.

From different startingpoints and using mainly different terminologies, these four psychoanalytic writers evolved ideas that have a strong similarity to each other. In pathology, Winnicott's distinction between 'true and false selves' corresponds to Balint's 'basic fault' and to Fairbairn's 'compromised ego'. In health, Winnicott's concept of the 'transitional' (object, space, or experience), through which or in which the selfother boundary is transiently dissolved, corresponds in some ways to Fairbairn's repressed egoobject structures with their fluctuating states of fusion, bonding, and separation; this is not far removed from Balint's idea of reexperiencing primary love in states in which a third person is unthinkable. Bowlby describes behaviour rather than subjective experience, but for him even more than for Winnicott the adequacy of the early environment is allimportant. Related ideas have been developed and applied by such writers as Marion Milner (1969) and Charles Rycroft (1968, 1968, 1979, 1985).

In Britain, intensive psychoanalysis is within the reach, economically and geographically, of only a very few people. But psychoanalysts are more and more giving personal help by psychotherapy, teaching, and supervision, as well as by full analysis, to many people who will apply it widely in the community—to young psychiatrists, psychotherapists, social workers, probation officers, teachers, civil servants, and managerial staff. (The London Clinic of Psychoanalysis has a limited number of vacancies for full psychoanalysis at

Page 274

reduced rates. Information about opportunities for psychoanalysis and for psychotherapy can usually be obtained from it.) In 1974 a professorship in psychoanalysis was endowed and constituted. It is held at University College London and the aim stated in establishing the appointment was 'to promote the study and critical examination of psychoanalysis, including its theoretical aspects and its cultural implications.' It is intended also to facilitate studies and research into the subject (Lighthill and Jaynes, 1983).

From 1974 to 1984 the professorship was held annually but since then the appointment has been extended to a period of three to five years. The first holder of the Chair with longer tenure is Joseph Sandler, who, besides giving his own inaugural and other lectures, has invited psychoanalysts from Britain and abroad to present to the public their own work and ideas and to discuss its relevance to psychoanalysis.

Anybody intending to train in psychoanalysis in Britain, unless he does his best to discover the differences between the three groups of the Society (egopsychologist, Kleinian, independent), will soon find himself having to make the judgement of Paris—to choose without knowing the basis for his choice. More hangs on this than at first appears, since psychoanalysts rarely change groups.

FREUD ON DREAMS. 'Find out all about dreams and you will find out all about insanity.' This prophetic remark was made by the English neurologist John Hughlings*Jackson, whose main contribution to its truth lay in establishing that certain curious alterations in*consciousness, in some respects akin to dreaming, might occur in a particular variety of epilepsy. But we owe almost entirely to Freud such little as we know regarding the relationship between dreams and the history and development of personality, normal no less than abnormal. Although Freud became interested in dreams largely in connection with psychoanalytical techniques, and more particularly in relation to his own selfanalysis, it may be said that his work has given rise to the only theory of dreams which

has so far won general acceptance (Freud, 1900).

Freud's approach to the interpretation of dreams was by way of the method of free association he had evolved in the course of his early studies of neurosis as a substitute for hypnosis, with which he had become increasingly dissatisfied (see FREUD ON HYPNOSIS). As in psychoanalysis proper, the subject is required to relax and allow his mind to wander freely from elements in the dream to related ideas, recollections, or emotional reactions which they may chance to suggest. By this route, he is gradually led from the dream as recollected, which Freud termed the *manifest content*, to the underlying thoughts and wishes, called by Freud the *latent content*—this, he believed, is typically based upon wishes, recollections, and fantasies related to the deeper emotional reactions of early infancy. In short, the dream is a heavily disguised form of infantile wishfulfilment expressed as a hallucinatory experience in the course of sleep.

The activity which transforms the latent into the manifest content is known as the *dream work*. This makes use of three principal mechanisms, known respectively as *condensation*, *displacement*, and *dramatization* (also known as *representation*). To these is sometimes added a fourth, *secondary elaboration*, or *revision*. The major function of the dream work is to evade what Freud picturesquely calls the *dream censorship*. This is envisaged as the continued operation of the mechanisms of repression which serve in waking life to protect the individual from the effects of potentially disturbing wishes and fantasies originating in early life. In spite of its name, the censorship was not envisaged as primarily of social or cultural origin, i.e. as an instrument of society. As Freud saw it, repression, whether operating during sleep or during wakefulness, is an essentially biological process, supervening after the age of 5 or thereabouts with the onset of the so-called latency period. *Inter alia*, it is responsible for the onset and maintenance of childhood amnesia, as a result of which very little can be recalled of the experiences or emotions of earlier infancy. At the same time, repression can of course be reinforced as a result of identification and social learning in childhood and after; and its derivative, the dream censorship, may in consequence be in some degree acquired.

Of the activities constituting the dream work,

Page 275

the most familiar is almost certainly condensation, which few people fail to notice on occasions when recalling their own dreams. For example, a visual image in the dream may embody the features or manner of two or more quite distinct people, being evidently a composite figure. The same may also occur with places, buildings, and the like. Condensation also affects words; some neologisms in dreams are produced by condensing parts of two or more words or phrases. In a more general way, condensation of ideas may frequently be traced in dreams, often indicating that more than one theme or motive is being expressed in the same dream situation ('overdetermination'). In view of the drastic ideational compression brought about by condensation, it is not surprising that Freud referred to the manifest content as

'meagre, paltry and laconic' as compared with the richness and variety of the latent dream content.

Whereas Freud regarded condensation as, in part at least, intrinsic to the dream process, displacement he attributed wholly to the effects of the censorship. It consists in attributing emotional significance to some element in the dream that, on analysis, turns out to be essentially trivial. For example, a dream image may recur for some hours after awakening and seem to possess a disturbingly haunting quality. Yet analysis may reveal that it is operating essentially as a decoy to lure the attention of the dreamer from more dangerous themes. In Freud's view, a great deal of the disguise making the memory of the dream so obscure originates from the vicissitudes of displacement.

The term 'dramatization' refers to the transposition of thoughts into imagery, largely, though not exclusively, visual. Inevitably, this mode of representation of thought is highly concrete, and it has therefore been disputed whether abstract ideas can feature in dreams. While dream thinking is certainly concrete in much the same sense as the thinking of the young child or the braindamaged adult, this does not mean that abstract ideas may not be represented metaphorically in the dream by concrete images. At the same time, it seems unlikely that genuinely creative abstract thinking can take place in dreams.

Secondary elaboration refers to the further distortion or elaboration of the dream that occurs after awakening. As much of this proceeds by rapid and often progressive omission of elements in the manifest content, 'secondary revision' is probably a better term for it. Although it is often held that the power of memory is intrinsically weaker in dreaming than in the waking state, the rapidity and completeness with which many dreams are forgotten only a few moments after awakening undoubtedly suggest that its basis is in part at least psychogenetic. It would be interesting to compare the repeated reproduction of dreams with that of stories or pictures in the manner described by F. C. Bartlett (1932). In so far as the writer is aware, such an experiment has not been attempted.

Although Freud relied for the most part on free association to 'undisguise' dreams, i.e. to provide clues to the nature of the persisting wish or motive behind the dream, he noted that on occasion no relevant associations were forthcoming. In some cases, Freud considered it legitimate to appeal to what he called 'primal symbolism', i.e.

modes of representation which occurred so consistently in dreams that he could attribute a meaning to them independently of associative context. Among these are the familiar symbols of the male and female genitalia, based quite evidently on association by similarity. But Freud, unlike Jung, always supposed that such symbolic devices were acquired through individual experiences and should not be regarded as inborn modes of symbolic representation, independent of history and culture. The Jungian universal symbols, or 'archetypes', found no place in his theory.

Freud's hypothesis of the dream as wishfulfilment and as representing the 'primary process' of human thinking, unaffected by realities of space, time, and logic, underwent some modification in his later thinking. In particular, he came to accept the existence of a class of dreams which in no sense embody the fulfilment of infantile wishes. These are the repetitive dreams in which the dreamer reenacts a traumatic episode in his recent experience. Freud was obliged to concede that dreams of this character, not infrequently associated with war neuroses, do not accord with the 'pleasure principle' and merit explanation in other terms. It is also of interest that W. H. R. Rivers (1923), likewise on the

basis of experience of war neuroses, was led to the view that many dreams could be interpreted in terms of an attempt in fantasy to resolve current emotional problems.

Although the respective parts played by infantile and adult experiences in the motivation of dreams remain controversial, and the concept of dream symbolism is undoubtedly treacherous, it is probably true to say that the dream is a mode of symbolic expression that has certain affinities with language. As Wollheim (1971) has pointed out, however, the dream lacks what is most characteristic of language: a grammar or structure. Moreover, it lacks any real communicative function. None the less, as a form of personal expression it merits attention as a modest manifestation of human*creativity.

FREUD ON HYPNOSIS. In spite of his repudiation of hypnosis as a clinical tool, Freud maintained his interest in the topic and returned to it many years later in connection with his speculative ideas concerning the structure of the mind. In his *Group* Page 276

Psychology and the Analysis of the Ego (1922), he drew an interesting parallel between hypnosis and the state of falling in love. 'From being in love to hypnosis', he wrote, 'is evidently only a short step.' In hypnosis, he continues, there is '... the same humble subjection, the same compliance, the same absence of criticism, towards the hypnotist as towards the loved object'. While the hypnotic relation reflects the 'unlimited devotion of someone in love', sexual satisfaction is of course excluded so that no lasting relation can be formed. But hypnosis, Freud urges, also bears a certain relation to the formation of social groups: the hypnotic relation can, indeed, be viewed as a group of two members. It is distinguished from other groups by the limitation of numbers just as it is distinguished from being in love by the absence of explicit sexual trends. The ultimate implication of Freud's argument seems to be that hypnosis involves a strong element of identification, the hypnotist being unconsciously equated with a significant figure, such as a parent who was both loved and admired, in the subject's early history. In other words, the hypnotist has been put in the place of what Freud at that time called the 'ego ideal'.

Freud of course concedes that this is by no means a complete explanation of hypnosis. As he points out, the manner in which it is produced and its relation to*sleep are far from clear. Further, his theory

fails to account for individual differences in susceptibility to hypnosis or for the fact that some people resist it completely. It is of some interest that some later studies, for example that of Hilgard (1965), although supporting Freud's view that personal influences and identifications appear to play an important part in governing hypnotic susceptibility, do not find any very predictable relationship between these factors and the Freudian theory of psychosexual development. Indeed, resemblance in temperament to the parent of the opposite sex appears to favour hypnotic susceptibility equally in male and female subjects.

Interestingly enough, it seems to be similarity in leisure activities that is important to identifications, rather than similarity in work or professional values. Where, however, there is no appreciable identification with either parent, the individual is likely to be little susceptible to hypnosis. These findings may be regarded as giving qualified support to Freud's view that the key to hypnotic susceptibility lies in the emotional relationships of early life.

FREUD ON MENTAL STRUCTURE. Freud's first essay in psychological theory was his draft *Project for a Scientific Psychology*, hastily written in 1895 under the stimulus of his eccentric friend Wilhelm Fliess, but published only many years after his death. This essay, which has proved to be very important for much of Freud's later thinking, might be described as a speculative theory of mental development envisaged in terms of the anatomy and physiology of the brain. Today, it might perhaps be called a neuropsychological model of the mind.

In the *Project*, Freud viewed the brain as composed of discrete nerve cells (neurones) organized in networks through which coursed an unspecified form of energy, presumably electrochemical. The operations of the system as a whole were governed by what, following G. T.*Fechner, he called the Constancy Principle, according to which the overall energy level is kept as low as the prevailing conditions permit, ideally zero. Two classes of neurones were distinguished. The first, constituting what Freud called the 'phsystem', was conceived to operate strictly in accordance with the*reflex principle, its energy being derived wholly from peripheral stimulation and immediately discharged in motor response. Some of these neurones relayed their input to a second system, the 'psisystem', in which*memories might be laid down and energy stored. This latter system, however, received its main input not from peripheral but from central sources, particularly those arising from internal bodily needs, such as hunger, thirst, or sex. In general, psineurones were thought to be more resistant to the outflow of energy than phineurones, i.e. less 'permeable', and in consequence more capable of storing energy and discharging it in a graduated fashion. This investment of neurones with energy Freud referred to as 'cathexis', a terra which was later taken over into psychoanalysis, although with a

very different meaning, namely investment of an object or idea with sexual energy or libido.

The psisystem was envisaged by Freud as the instrument of adaptive learning. Thus the degree of resistance of its neurones to the passage of excitation was conceived to depend on both the quantity of energy stored and the frequency of discharge. Following Theodor Meynert (and after him William*James), Freud held that the repeated passage of excitation along nervous pathways facilitated transmission, thus providing the neural basis of habit. For example, discharge of psineurones responsive to the bodily needs of a hungry infant becomes linked by association with the perception of the mother and thereby comes to initiate appropriate motor response, i.e. suckling. Regulation of this discharge, he supposed, is governed by the pleasurepain (better 'unpleasure') principle, according to which pleasure attendant on the gratification of a biological need results from discharge of stored energy, and unpleasure either from an overload of the psineurones ('hypercathexis'), corresponding to frustration, or from failure of a protective mechanism (*Reizschutz*) which Freud (following Fechner) supposed to afford protection to the peripheral receptor system

Page 277

from excessive or unduly prolonged stimulation. (Such a mechanism was at one time widely held to provide the physiological basis of pain.) As has often been pointed out, Freud's 'Psychology for Neurologists' (as the *Project* was subtitled) owed much to the writings of Brücke and Meynert, with whom Freud had worked as a young man, and the relevance of at least some of his ideas to contemporary thinking in the neurosciences has been touched on by Pribram and Gill (1976). What does *not* seem to have excited comment, however, is how much Freud's conception of the learning process in infancy has in common with the learning process in animals as formulated by E. L.*Thorndike (1898). Indeed Thorndike's 'law of effect', with its emphasis on the effects of pleasure and pain in respectively strengthening or weakening the nervous connections established by learning, may be regarded as closely analogous to Freud's pleasureunpleasure principle in human development.

Although the *Project* remained unpublished in Freud's lifetime, several of the ideas embodied in it reappear in the development of psychoanalysis. For example, the reflex schema and the idea of perception and memory processes having different loci reappeared in the theoretical chapter (Ch. VIII) of the *Interpretation of Dreams* (1900). Further, the distinction between the primary process of thought, supposedly governed by the pleasure principle, and the secondary process, reflecting the demands of reality, both clearly foreshadowed in the *Project*, became basic to psychoanalytical thinking. In spite of the fact that Freud soon came to repudiate models of the mind based explicitly on considerations of anatomy and physiology, many of the concepts first introduced in the *Project* feature in his later

'metapsychological' writings. These include the concepts of force or energy, which reappears as libido (sexual drive), and cathexis, later redefined as emotional investment in an object or idea. Even the *Reizschutz* makes it return many years later in *Beyond the Pleasure Principle* (1922). Yet, notwithstanding this transition to purely mental models, Freud never wholly lost his early belief that psychology would one day have to be placed on its organic, i.e. bodily, foundations.

After the *Project* was written—and indefinitely put aside—Freud's work took him increasingly into the domain of neurotic conflict and the unconscious. Here his ideas have been much misunderstood. It must be clearly recognized that Freud at no time saw neurosis as a simple trial of strength between the conscious and the un *conscious* parts of the mind. As he saw it, certain emotionladen memories, fantasies, or thoughts are subject to repression because they are too painful to dwell upon or are otherwise unacceptable to an individual's selfesteem. The associated emotion, on the other hand, is *not* repressed; it is only its links with the repressed material that are severed. Moreover, Freud insisted that the scope of the unconscious is far from restricted to that which is repressed. As he saw it, mental life is originally unconscious and only becomes conscious, or preconscious, i.e. potentially conscious, in the course of adaptation to external reality. In short, the evolution of consciousness is linked essentially with the development of perception, learning, and language, and is expressed preeminently through the medium of verbal communication.

Although the concept of the ego appears in the *Project*, it did not feature at all prominently in earlier psychoanalytical thinking. Its importance derived from Freud's increasing recognition of the facts that repression may be instigated without conscious knowledge or intention and that mental events of which the individual appears to have been at no time aware may undergo repression.

It was facts such as these that led Freud to undertake a systematic revision of the concept of the ego. In a short but important study (1927), he envisaged the ego as evolving gradually out of the unconscious substructure of infantile mental life. Like William James, he placed particular stress on the corporeal activities upon which the ego is built and which indeed constitute its primary components (James's 'material self': see James, 1891, vol. 2, ch. 10). But, in keeping with his general theory of sexual development, Freud's ego is to an important extent a product of infantile sexuality and its suppression during the 'latency period', and is to this extent heavily

'sexualized'. Indeed, investment of libido in the ego itself ('egolibido') is conceived by Freud to lie at the roots of narcissism and its derivatives.

None the less, Freud's ego is far from being a mere product of the infantile unconscious. Although rooted in the corporeal ego, it develops from, and through, its transactions with the environment, both physical and social. The ego is viewed throughout as the agent of perception and learning and as the instrument of volitional activity. It reflects the operations of the reality principle and much of its activity is conscious, i.e. open to introspection.

It is at this point, too, that Freud introduces his concept of the 'superego'—a term that has since passed into everyday discourse. Referred to in his earlier writings as the 'egoideal', this entity is envisaged as an internal standard which acts as a crude regulator of moral conduct. It is thought to originate in early infancy and to derive from a process whereby feelings of hostility directed towards either or both parents are neutralized by a process of introjection, i.e. by becoming embodied in the child's own mind. This can be traced most convincingly in the male child, in whom hostility towards the father is often tempered by a degree of positive identification.

The result is a crude amalgam of positive and negative feelings derived from the parent figures which

alized controller of one's own behaviour. In Freud's famous phrase, the superego is the heir to the Oedipus complex.

Obviously, Freud did not intend to give a complete explanation of the origins of conscience. He wished only to stress that conscience originates in the early identifications and repudiations of childhood and subsequently comes to embody influences derived from teachers, admired friends, and social and moral education generally. His ideas had value, however, in providing a measure of explanation of what we may call the pathology of conscience, i.e. the quite excessive sense of guilt or need for punishment provoked in some individuals by trivial transgressions. (As is well known, this is a common feature of depressive states.) Thus Freud's theory did to some extent account for the savagery of conscience, though not, perhaps, for its equally common deficiencies. This savagery is derived from the largely unconscious hostility shown by the very young child and the unrealistic character of his thinking.

Freud's recognition that the superego is in large degree unconscious and itself the principal instrument of repression led him to seek a new name for what he had previously called simply the 'unconscious'. The latter was essentially the instinctual substrate of conscious mental life and its associated memories and fantasies. These, for the most part infantile, strata of unconscious mental life Freud chose to name the 'id'—a term adapted from the work of a speculative Swiss philosopher, Georg Groddeck. But in Freud's later thinking, those unconscious activities of the id were no longer conceived as concerned exclusively with instinctual gratification and as operating wholly in accord with the pleasure principle. He came increasingly to appreciate the importance of certain repetitive and selfdestructive elements in the pattern of human destiny that, literally, lay 'beyond' the pleasure principle (Freud, 1942). These constitute the Freudian 'deathwish', the deeply unconscious impulse to seek nirvana, the extinction of individual existence.

In short, the final Freudian model of mental structure is somewhat as follows. The *id*, wholly unconscious, embodies the instincts related to psychosexual gratifications (libido) and operates without relevance to the dictates of logic or external reality. While governed essentially by the pleasure principle, it incorporates certain regressive and destructive potentialities that are inherent in the biological makeup of the organism. The *ego*, wholly conscious, is essentially the mind as ordinarily conceived. It is the instrument of learning and of adaptive relationship to the environment. The ego is concerned essentially with perception, memory, and the control of speech and volitional activity. The *superego*, while closely related to consciousness, is in part unconscious and derives its energies vicariously from the id. It operates as a monitor of conduct and a major source of control through repression. The superego constitutes the nucleus of conscience and provides the foundation of adult morality.

FREY, MAX VON (1852-1932). German physiologist, best known for his investigations into the sensations of pain and touch. In 1882 he became a university lecturer in physiology at Leipzig, eventually being appointed to a professorship there, which he held from 1891 to 1898. He later taught for a year at Zurich, and then at Wurzburg. Developing the earlier studies of Blix (1882) and Goldscheider (1884), who had established that the skin has separate spots for cold, warmth, and touch, von Frey showed that pain is a special skin modality, separate from these sensations and also from pressure. He went on to map out 'pain spots'.

The set of hairs, carefully graded from soft to stiff (and including human hair), which he used in experiments investigating tactile senses became known as 'von Frey's hairs'.

FRISCH, KARL RITTER VON (1886-1983). Austrian ethologist. Born of an academic family in Vienna, Karl von Frisch worked at several universities, in particular Breslau and Munich. His research was on the light sensitivity of sea anemones. He collaborated with his uncle Sigmund Exner (1846-1926), who became professor of physiology in Vienna and worked on both reaction times and cerebral localization. Von Frisch went on to show by behavioural experiments that fish are not, as had been thought, colourblind. In more detail, he found that in dim light using 'rod' vision they are, like us, colourblind; but with brighter light stimulating the retinal 'cone' cells, they do have colour vision. He went on to demonstrate, by whistling to catfish, that fish are not deaf.

Having established unexpected sensory capacities in many animals, von Frisch carried out his celebrated experiments on how scout honeybees convey information of where they have found nectar. He started by assuming that the other bees recognized the successful scout by odour; but he found evidence that the scout could convey infor

mation of direction and distance of the food source, which was surprising. Following experiments to discount the odour theory, he arrived at the wild conjecture that they signal by a symbolic dance, which he learned to interpret. Direction was normally signalled by reference to the sun; but on cloudy days it was established by the polarization angle of the light of the overcast sky, which the bee's compound eye can detect. Distance of the food source was signalled by different kinds of dance—a 'round' dance when near, and a 'waggle' dance when distant; and the speed of the dance was greater for greater distances. The direction of the food source with respect to the sun was signalled by taking the vertical of the honeycomb as, symbolically, the direction of the sun. This discovery (which has been independently confirmed) that bees use a symbolic language, was wholly unexpected; and it forces us to accept that man is not unique in organizing society by means of language.

Von Frisch shared the Nobel prize with Konrad Lorenz and Nikolaas Tinbergen in 1973. His books include: *You and Life* (1940), *Animal Architecture* (1974), and the celebrated *Dancing Bees* (1954).

FROEBEL, FRIEDRICH WILHELM AUGUST (1782-1852). Friedrich Froebel was born in Oberweissbuch, Thuringia. His father was a busy pastor, and his mother died soon after his birth, an event he regarded as crucial to his development. His early childhood was unhappy and he was thrown on his own resources, developing the passion for selfcontemplation and selfeducation which he thought essential for all. Though he was moved by the mystical language of his father's hymns and sermons, he was critical of his schooling with its reliance on memorization of facts inculcated by stem teachers. At 15 he was apprenticed to a forester, and he wrote later of his religious communion with Nature at this period: 'I looked within myself and to Nature for help.' He began to develop his personal philosophy: a belief in the organic unity of man, God, and Nature. At the University of Jena he eagerly embraced the idealist philosophy of the time. He believed that all living things had an inherent form and purpose, not predetermined but developing through a kind of creative struggle with the environment. He studied the transcendental biology of the period, and was deeply impressed by the underlying pattern which seemed to unite all living things and by their growth from simple to complex structures. He had a romantic and mystical belief in universal harmony: 'Everything has a purpose, which is to realize its essence, the divine nature developing within it, and so to reveal God in the transitory world.'

Froebel early demonstrated an interest in education and in 1805 began in Frankfurt the work as schoolmaster and private tutor which was to occupy the rest of his life.

Like Rousseau he regarded man as essentially good, and his pedagogy starts from perceptive observation of children's behaviour. 'Educators', he wrote, 'must understand their impulse to make things and to be freely and personally active; they must encourage their desire to instruct themselves as they create, observe and experiment.' The teacher was to guide the child in his selfdiscovery, not direct him. Each stage of development was critical and had to be fully experienced. Play was the

young child's 'spontaneous expression of thought and feeling' and was central to learning. For this reason Froebel established the kindergarten, which provided the activities and materials needed by the preschool child. He invented toys and exercises which became the basis of a pedagogic system whose formalism was curiously at odds with the permissiveness of his philosophy. He laid great emphasis on the relationship between teacher and pupil and on the need for continuity and connectedness in the school curriculum. The child had naturally a sense of the unity of life: it was the business of the school to make him conscious of it. Starting from the child's own experience, the study of religion, nature, mathematics, and language would encourage his awareness of self, the world, and God. The arts would enable him to express his inner life, and physical work teach him the dignity of labour. At all times the school was to maintain close contact with family and community; only so could it remain relevant and vital.

Froebel was a visionary as well as a gifted teacher. He had great ambitions for his educational programme, believing it would unify Germany as well as mankind generally. In fact his influence in his lifetime was limited—a year before his death in 1852, Prussia banned the kindergarten for its 'revolutionary' tendencies. Devoted disciples in Europe and America continued his work, however, and from the 1870s it profoundly influenced the training of teachers and the education of young children. The importance of play, the unified curriculum, links with home and community, and nondirective rather than authoritarian teaching remain live issues. But Froebel's 'organic' theory of human development led him seriously to underestimate social influences in individual lives. When he was asked to plan the education of the poor in Berne, he was at pains to point out that 'there need be no fear that individual pupils will want to improve their position and leave their own class. On the contrary, this system will produce educated men, each true to his calling, each in his own position.'

FUNCTIONALISM. An American school of

Page 280

psychology based principally on the University of Chicago at the turn of the nineteenth century. It owes something to William*James but a great deal more to John*Dewey, who has been described by E. G.*Boring as the 'organizing principle' behind its emergence. Apart from Dewey, its principal advocate was James Rowland*Antell, for many years professor of psychology at Chicago, who stressed the functional significance of adaptive behaviour and viewed mind as mediating between the environment and the needs of the organism. As E. G. Boring wittily put it: 'Functionalism represented the Philosopher's approach to a science that had rebelled against Philosophy'; it was often contrasted

with*Wundt's structuralism.

As an outcome of functionalism, experimental work on animal behaviour and its neurological foundations developed rapidly at Chicago, particularly at the hands of C.

M. Child, G. E. Coghill, and J. B. Watson before he became a doctrinaire behaviourist. Indeed functionalism did much to lay the foundations of biological psychology as we know it today.

O. L. Z.

FUNCTIONALIST THEORIES OF THE MIND. Recent functionalist theories of the mind, though they may be characterized broadly as 'materialist', can be seen as a reaction against the physicalist theories that baldly identified mental states with physically characterizable types of brain state. A difficulty with such theories is that there seems no reason to suppose that a particular type of mental state, such as being in pain, or having a given belief, will always be realized by a specific type of neurophysiological structure. Indeed, it is a wellattested fact that if a certain brain structure is damaged, resulting in mental impairment (e.g. after a stroke), the brain is often, after a period of time, able to utilize alternative neurological networks so that the relevant mental activity is eventually restored. These and other difficulties with straightforward mindbrain identity theories led to the suggestion that mental states should be identified not with the brain's physical states, but with its *functional* states. Such states, the functionalist argues, can be specified in purely formal terms—in terms of the logical and computational processes involved—and so are neutral with respect to the actual way in which the processes are physically realized. In computer terminology, functional descriptions are 'software' descriptions; and these can be given in a fairly abstract way, using logical symbols, transformation rules, organizational principles, and so on, without any need to be specific as to the precise design of the hardware needed to realize the functions involved. Many researchers into artificial intelligence (AI) have adopted what may broadly be called a functionalist approach to the mind, which can encompass a variety of positions, from the radical thesis that mental states are nothing more than functional states of Turing machines, to the weaker claim that the computational states of such machines may at least be used as helpful models or analogies to illuminate our understanding of the phenomena of mind.

Two difficulties for functionalism may be mentioned here. (i) First, since a functional system could clearly be instantiated by a wide variety of physical systems, e.g. a computerized robot, or perhaps even a complex telephone exchange, it seems that the functionalist would be committed to ascribing mental states to such systems, provided that they exhibited the relevant organizational complexity. Yet (the objection runs) there is obviously no human parallel to being a robot; robots have no inner mental life. Hence mental states must be more than mere functional states. Against this, functionalists have argued that if we could build a robot that was complex enough to instantiate the kind of enormously complicated program needed to model human mental states, and if moreover, the robot was able to interact causally with the environment in all the appropriate ways, then the assumption that the robot could not possibly have a 'mental life' might begin to lose much of its plausibility. (ii) A second objection concerns the phenomenon of intentionality. Mental states have intentionality: they have representational content, or are 'about something'. Yet opponents of the strong AI programme (such as John Searle) have argued that functional specifications, being couched in terms of purely formal or syntactic operations, cannot possibly exhibit intentionality. A system might perform impeccably in manipulating symbols in accordance with complex operational rules, yet, for all that, it might be quite unaware of the meaning of the symbols, what they were 'about'; and hence (the argument runs) it could not be considered as having a 'mind' in the sense in which humans have minds. These matters are

currently the subject of vigorous debate among philosophers and AI theorists.

FUTURE SHOCK. Term coined by the American writer Alvin Toffler, to mean the trauma experienced by rapid changes—for example, to the environment, including destruction of familiar buildings, or customs of childhood. The trauma is similar to that often experienced by *émigrés*, but is even less reversible as it is in time.

Page 281

G

GALEN (CLAUDIUS GALENUS, second century AD). Greek physician, born at Pergamum in Mysia. He studied medicine there, and also at Smyrna, Corinth, and Alexandria, and became physician to Marcus Aurelius. He probably died in Sicily.

Galen wrote extensively on medical and on philosophical subjects and his extant works consist of eightythree treatises on medicine and fifteen commentaries on*Hippocrates. He dissected animals and developed, to our minds, somewhat fanciful physiological theories. His clinical discoveries include diagnosing by the pulse.

He was the authority from whom all later Greek and Roman medical writers quoted, with more or less accuracy.

Galen considered that the body worked by three types of spirit: natural spirit (located in the liver), vital spirit (located in the left ventricle of the heart), and animal spirit (located in the brain). He postulated several anatomical features, such as the *rete mirabile* (wonderful network) on the undersurface of the brain, which is found in some animals (especially those with hooves) but not in man, although on Galen's authority it was accepted as present in the human brain for over thirteen centuries. It was also believed on his authority that the septum of the heart contained minute pores—these were essential for Galen's physiological system as he believed that blood passes from the heart to the body from both the arteries and the veins, new blood being manufactured in the liver and supposedly burnt up in the tissues. The exhalation of breath, when concentrated, was known to be

asphyxiating, and was compared to the smoke of fire. Galen made considerable discoveries in neurology and especially the kinds of paralysis associated with damage at various places to the spinal cord (see GREEK INVESTIGATIONS OF THE MIND AND SENSES).

Kühn, C. G. (ed.) (1821/33). *Opera omnia* (the only complete edition of Galen's surviving works).

GALILEO (Galileo Galilei) (1564-1642). Italian physicist, astronomer, and inventor, born at Pisa. He preferred to be known by his first name, rather than by his surname Galilei. When a student of medicine at the University of Pisa, in 1583, Galileo noticed that the oscillations of a suspended lamp in the cathedral kept the same rate whatever the amplitude of its swing. This at once suggested a timekeeper for the pulse, and much later (dictated on his deathbed to his son) the invention of the pendulum clock. He greatly improved the refracting telescope (which was invented in the Netherlands in 1608) and discovered the four 'Galilean' moons of Jupiter (1610), lunar craters, and sunspots, and he described the Milky Way as made up of countless stars. He was probably the inventor of the compound microscope (1610), and he was the first to see the seven photoreceptors in each optical element of the compound eye.

Much of his work challenged Aristotle, initially by establishing that heavy and light weights fall at the same rate—though the story of dropping weights from the Leaning Tower of Pisa is most likely apocryphal, as the experiment would have been very difficult to perform reliably. He pointed out that if heavy and light weights were attached to each other with a string it would not stretch or break during the fall as one would expect if their rate of fall differed. For his experiments he effectively slowed down gravitational fall by rolling balls down sloping tracks; and little bells placed at intervals along the tracks told him of the speed of the balls by tinkling, so he made laws of nature observable. Some of his apparatus, including his telescope, can be seen at the Laurentian Library in Florence.

Galileo's challenge of Aristotle provoked such a reaction that as early as 1591 he was forced to leave Pisa and retire to Florence. A year later, however, he gained a professorship in mathematics at the University of Padua, where his lectures attracted immense attention and pupils from all over Europe, and where he remained for eighteen years (1592-1610). It was his book on sunspots (1613) that gave the explicit account of the earth moving round the sun which initiated the long tiring trial that cost him his freedom. This was a powerful defence of the Copernican view that the earth is not the centre of the universe, a view denounced in 1616 as a danger to the Catholic faith. Galileo's insistence on it was probably not intended as a deliberate attack on the Church, but rather as a defence of the right to make scientific observations and reasoned arguments, so saving the Church from the errors that science had revealed. After a long trial by the Inquisition he was imprisoned, and forced to recant his views, though probably he was not tortured.

Although Galileo wrote mainly on physics and astronomy (especially the work translated as *The Starry Messenger*, 1610) he also considered sensation and perception. His *The Assayer* (1623) has this passage:

To excite in us tastes, odours, and sounds I believe that nothing is required in external bodies except shapes, Page 282

numbers, and slow or rapid movements. I think that if ears, tongues, and noses were removed, shapes and numbers and motions would remain, but not odours or tastes or sounds. The latter, I believe, are nothing more than names when separated from living beings, just as tickling and titillation are nothing but names in the absence of such things as noses and armpits. And as these four senses are related to the four elements, so I believe that vision, the sense eminent above all others in the proportion of the finite to the infinite, the temporal to the instantaneous, the quantitative to the indivisible, the illuminated to the obscure—that vision, I say, is related to light itself. But of this sensation and the things pertaining to it I pretend to understand but little; and since even a long time would not suffice to explain that trifle, or even to hint at an explanation, I pass this over in silence.

Having damaged his eyes with his telescopic studies of sunspots, in 1637 Galileo lost his sight. Five years later he died, blind, in the year Newton was born.

GALL, FRANZ JOSEPH (17581828). German anatomist and founder of phrenology, who was born in Baden and settled in Vienna (1785) as a physician. He was an anatomist of some distinction and the man to whom we are really indebted for the ideas we now hold on the relations which the constituent parts of the nervous system bear to one another. He was the first to distinguish clearly between the white matter of the brain, which consists of nerve fibres, and the gelatinous grey matter, which forms the cortex of the brain, and the ganglia. For the speculative ideas as to the cortical localization of human faculties, see PHRENOLOGY. Gall's most important work, written jointly with J. C. Spurzheim (17761832) is: *Anatomie et physiologie du système nerveux en général, et du cerveau en particulier, avec observations sur la possibilité de reconnaître plusieurs dispositions intellectuelles et morales de l'homme et des animaux par la configuration de leurs têtes*, 2 vols. (1810, 1819).

O. L. Z.

GALTON, SIR FRANCIS (18221911). Francis Galton pioneered the application of measurement and statistics to the study of human individual differences, and introduced several specific methods of enquiry which are now standard. Association of ideas, for example, had been discussed for centuries, but he was the first to devise an experimental approach. Again, in asking people to fill in questionnaires about their*mental imagery, he not only inaugurated the scientific study of imagery but also the systematic use of psychological questionnaires. In attempting to tease out the contributions of nature and nurture, he became the first to gather systematic data about the lifehistories of twins, and about the family and educational backgrounds of people with exceptional talents in, say, literature or science or sport. He collected fingerprints, devised a method of classifying them, and introduced the fingerprint system into police work. He invented the statistic known as 'the correlation coefficient',

which is now a basic tool in education, biology, and psychology.

Born near Birmingham, Galton was the youngest of a large family which was wealthy, talented, and energetically involved with practical science and statistics. His intellectual precocity is shown by one of his early letters:

My dear Adèle, I am four years old, and I can read any English book. I can say all the Latin substantives, adjectives and active verbs, besides fiftytwo lines of Latin poetry. I can cast up any sum in addition and multiply by 2, 3, 4, 5, 6, 7, 8, 9, 10, 11. I read French a little and I know the clock.
Francis Galton. February 15th, 1827.

He attended private schools in England and France, studied medicine in Birmingham and London, and studied chemistry in Germany before entering Cambridge University in 1840 to read mathematics. During those early years, he developed strong interests in doing independentminded scientific experiments, constructing gadgets, and keeping orderly records of numerical data. These interests foreshadowed his adult preoccupations and the guiding maxim of his mature years: Whenever you can, measure or count.

In 1844, the year Galton graduated from Cambridge, his father died and he found himself, at the age of 22, with a substantial financial inheritance and no clear plans.

For six restless years he engaged in various enterprises, including a tour of the Middle East and an attempt to settle as a sporting English country gentleman. Then in 1850 he organized, financed, and led a scientific exploration of an unexplored part of Africa. When he returned from this twoyear journey, he married Louisa Butler, and wrote reports of his travels which gained him, in his own words, 'an established position in the scientific world'. He now entered upon a settled way of life as a Londonbased scientistatlarge.

From 1854 until his death, Galton contributed to the scientific life of London. Although he never had or sought paid employment, he held various responsible posts in the Royal Society, the Royal Geographical Society, the Anthropological Institute, the Royal Institution, and the British Association for the Advancement of Science. At the same time, he privately undertook miscellaneons investigations of a characteristic style. He sought some issue which might lend itself to quantitative treatment;

accumulated relevant data, often with singlehanded ingenuity; systematized the data to extract their implications; and promptly reported his findings in a memoir to one of his scientific societies. He produced hundreds of these memoirs, and his several books were mostly edited collections of them.

Throughout his long and industrious life, Galton maintained interest in many branches of science: for example, in meteorology he invented the idea and the name of

'anticyclone' and devised the nowfamiliar weather map which first appeared in *The Times* in 1875. In studying the threshold for high

pitched notes, he invented the calibrated whistle which later bore his name and became a standard piece of equipment in psychological laboratories until it was replaced by electronic equipment. However, after 1859, when his cousin Charles*Darwin published *The Origin of Species*, Galton's dominant interest was to study, by measurement, the influences of heredity upon the mental and physical characteristics of human beings. He accepted Darwin's view that evolution was a trialanderror process involving the inheritance, variation, and natural selection of organic characteristics. He applied this view to man, and conceived the enterprise of collecting the data necessary to understand human evolution. (See his books, *Hereditary Genius*, 1869; *English Men of Science*, 1874; and *Inquiries into Human Faculty*, 1883.)

This ambitious enterprise raised a host of challenging questions. What were the characteristics in terms of which people resembled, and differed from, each other?

How might they be specified and measured? How far did they arise from genetic inheritance (nature) or environment (nurture)? What were the cumulative, generationbygeneration effects of the fact that individuals contributed differing numbers of offspring to the next generation? How did different environments and social practices exert natural selection by affecting fertility and breeding patterns and, thereby, affecting the composition of what, nowadays, would be called the 'genetic pool' of human populations? (See GENETICS OF BEHAVIOUR.)

Such questions inspired Galton to conduct many enquiries which, if viewed out of context, seem unrelated and even eccentric. He examined, for example, the number of children in different families, and he related these numbers to the age at which the parents married, the migration of families from rural to urban environments, and the social tendency for the eldest sons of aristocratic families to marry wealthy heiresses. He accumulated data about the tendency for outstanding talents to run in families (his own family tree, and that of his wife, were cases in point). (See GENIUS.) He devised gadgets and methods for recording any mental or physical characteristic that seemed measurable: for example, bodily proportions, fingerprints, strength of grip, sensory acuity, and mental imagery. He used unconventional photographic techniques (composite portraits) to record facial resemblances among different members of the same family, among criminals, tubercular patients, and various national groups. Some of his enquiries led nowhere. Some led to findings which have not been confirmed by later studies. Some led to findings that have been confirmed and extended, but given varying theoretical interpretations.

Galton hoped that human evolution would, one day, be understood in terms which were strictly materialistic, deterministic, and unaffected by unaccountables such as

'divine intervention' or 'free will'. In order to discount divine intervention, he conducted ingenious but controversial studies which showed, to his own satisfaction, that prayer was ineffective in bringing about the events that were prayed for. His experiments about associationofideas were aimed at discovering whether people may

'freely' choose what they think. He concluded against the intervention of 'free will'. Psychologists, who are nowadays familiar with the tradition of experiments about word association and idea association (see FREE ASSOCIATION), are usually unaware of the motive which led Galton to found the tradition.

Galton was imbued with nineteenth-century ideas about human progress and about science as the chief practical instrument of such progress. He envisaged his ambitious enterprise as leading, in the fullness of time, to nothing less than a body of scientific knowledge by which men could rationally direct the future course of human evolution. He invented the word 'eugenics' for this science which would provide such far-reaching practical applications. He was, like many Victorians, deeply interested in, but ambivalent about, religion; and he supposed that eugenics would supply a new, universal religion to supersede those that men had devised hitherto. In his autobiography, published in 1908, he wrote with high-minded passion about this elevating new religion, and he bequeathed £45,000 to establish the study of eugenics at London University.

As a person, Galton was socially reserved, preoccupied by scientific labours, and inclined to be aloof. Yet his courtesy, generosity, and gentle goodhumour endeared him to the few people who knew him closely. He was widely respected, and honoured by, scientific circles, even though many scientists regarded him as crankish. He was knighted in 1909. Since his death, his eugenic ideals have remained deeply controversial and liable to misunderstanding. But his stature as a pioneering scientist has steadily increased. Modern genetics, mental measurement, and statistics owe much to the innovations which Galton introduced while pursuing his solitary enquiries into the human condition.

GALVANIC SKIN RESPONSE. See ELECTRODERMAL ACTIVITY.

GALVANIC STIMULATION. Named after Luigi Galvani (1737/98), Italian physiologist born at Bologna who became professor of anatomy there in 1762.

Galvani thought he had demonstrated animal electricity by showing that frog muscles twitch when touched by wires. He believed that the electricity flowed from the muscles to the nerve. We now know that the stimulation is produced by small currents applied to the nerve: the electricity in Galvani's experiment was produced by chemical reaction from acids present on the frog's skin. His

Page 284

work led, however, to the modern understanding of the electrical basis of neural activity.

GAME THEORY. See VON NEUMANN, JOHANN.

GANSER SYNDROME. See PSEUDODEMENTIA.

GAUSS, KARL FRIEDRICH (1777-1855). German mathematician, born at Brunswick. He was an infant prodigy, despite the fact that his father, a labourer, tried to keep him from an appropriate education; it was his mother who, though uneducated, encouraged him in his studies. His first great discovery was made just before he was 19 years of age, when he succeeded in constructing according to Euclidian rules the regular polygon of seventeen sides. He wished this to be inscribed on his tombstone, but the stonemason refused, saying it would be indistinguishable from a circle. Gauss kept a diary of his discoveries, which is a unique document of a genius, and establishes his priority in disputed cases as, except for a work on the theory of numbers which appeared in 1801, he published little of his work. He was among the first to realize the significance of nonEuclidian*geometries (especially from the work of Nikolas*Lobachevski). The Gaussian distribution (or 'normal'

distribution) is the basis of statistics.

Dunnington, G. W. (1955). *Karl Friedrich Gauss, Titan of Science: a study of his life and work*. Baton Rouge, Louisiana. The diary was published by Felix Klein (1901), and with notes in *Gauss Werke* (1917).

GENERALIZING. The deriving of general statements from individual instances. Generalizing occurs in learning, and is essential for deriving knowledge from experiences and for skills of all kinds. It is the basis of predicting future situations from past experience and for drawing analogies. See also INDUCTION.

GENETICS OF BEHAVIOUR. Behaviour genetics is the study of the genetical basis of behaviour and of psychological characteristics such as*intelligence, temperament,*learning, and*perception. Long before the emergence of behaviour genetics as a science, man practised selective breeding for behavioural characters.

The domestication of animals involved changing their behaviour in a number of respects by manipulating their genetic constitution (genotype) through selective breeding. The various breeds of dogs provide an interesting example, in that many breeds were produced for behavioural characteristics—for example, hunting dogs such as the spaniel and working dogs such as the sheepdog. The ancient world was also concerned with the relationship between heredity and behaviour. The Greeks anticipated eugenics with their belief that young men who distinguished themselves in war or other socially valued activities should be encouraged to breed, whereas depraved persons should not.

The importance of hereditary components of behaviour was the subject of much dispute and theorizing in psychology during the first part of the twentieth century, but little sound empirical work was undertaken. The arguments centred around the nature vs. nurture controversy (see GALTON), or in other words whether the characteristic patterns of behaviour shown by an individual were learned or innate. Some believed with the eminent geneticist William Bateson that the natural genetic distinctions differentiated men into types—artists, actors, farmers, musicians, poets, scientists, servants, etc. At

the other extreme J. B. Watson, the founder of behaviourism, made the proud boast that given a dozen healthy infants and the freedom to shape their environment he could train anyone to become any kind of specialist—doctor, lawyer, merchant, artist, etc. These sharply opposing viewpoints delayed a proper appreciation of the essential interdependence of genetic and environmental factors in the determination of behavioural and psychological characters. Both are essential, though the degree of contribution made by each depends on the character in question.

The effects of genes vary with differences in the environment in which the organism develops and lives. This can be appreciated by a gastronomic analogy. The taste, texture, and quality of a cake can be modified by both changing the ingredients and the way it is cooked, but it is not always easy to tell what has been changed by eating the cake. Both the ingredients and the cooking are essential to producing the cake, for without both there would be no cake. Much recent research in behaviour genetics has sought to identify the contributions of genetic and environmental factors in order to determine the causes of differences in behaviour, and to explore the mechanisms of behavioural development.

There are two broad areas of interest. The first involves tracing the pathways that link the genome (a set of chromosomes) with behaviour, and is consequently concerned with issues about how genes specify the properties and functioning of nervous systems. The second is about the genetic organization of behaviour itself, in the individual and in the population, and how genetically controlled differences in behaviour lead to population changes and ultimately to evolutionary change.

While the genetic constitution of an organism is called its genotype, the organism's form as perceived (or the character to be measured, such as height, personality, or intelligence) is called its phenotype. Genetics is concerned largely with examining the relationship between genotypes and phenotypes. A distinction is drawn between major genes (a single gene having a measurable effect on a phenotype) and polygenes (where many genes interact to produce phenotypic effects). Most of the known genetic effects on behaviour are due to polygenes: continuously variable characters such as intelligence or emotionality result from the

effects of polygenes which individually have tiny effects but which cumulate.

Quantitative or biometrical genetics is concerned with studying the effects of polygenes in populations. In respect of a given phenotype, the amount of variability in a population which is due to genetic factors is called the heritability (h^2), and is given by the equation V_g/V_p , where V is the sum of the phenotypic variance and V_g the

V_g

V_p

V_g

sum of the genetic variance. It is a characteristic of polygenes that their phenotypic expression—for example, measured intelligence—is subject to environmental modification. The interaction of genetic

and environmental factors during development leads to the enormous variability observed in populations. A few examples of the effects of a single gene on behaviour have been described in man. About 30 per cent of the population are unable to taste a substance called phenylthiocarbamide in very low concentrations. Now the ability to taste this substance is known to be due to the action of a pair of genes designated TT , which are carried on homologous chromosomes. In people who cannot taste the compound, the genes exist in another form, tt . A heterozygote, having the genetic constitution Tt at the relevant locus (address of a gene on a chromosome), can taste the compound. Thus in this case the effect of a single T gene is said to be dominant over t , which is recessive.

Various methods have been used to study the genetics of behaviour. Broadly speaking, they may be divided into the phenotypic and the genotypic. In the case of the phenotypic approach the investigators begin with a behavioural character and attempt to find a relationship between it and genetic variation. In the genotypic approach the investigator starts with a standard genotype and examines the effects on behaviour of changing the components of the genotype. The principal methods are as follows.

(*i*) *Selective breeding*. The aim here is to change the population in specified directions, usually for 'high' or 'low' expression of the chosen phenotype. The method is based upon an assumption of correlation between phenotype and genotype and entails breeding together high/low scoring males and females. The method has been used extensively with animals, and lines showing divergences in behavioural characters such as learning or emotionality in rats have been produced. The existence of such lines allows further genetic and behavioural analysis of the phenotype.

(*ii*) *Inbred lines*. Longcontinued inbreeding results in lines in which individuals are in effect genetically identical. Highly inbred lines, in which the members are genetically alike, but genetically different between lines, may be reared in identical environments and compared in respect of given behaviours. Observed differences between lines reared in identical environments will be genetic in origin. Many highly inbred lines of animals, particularly mice and fruitflies, have been produced and provide valuable material for behavioural study. Certain inbred strains of mice drink a solution of alcohol in preference to water when offered a choice, whereas other strains take only water. Crosses between such lines enable analyses of the genetic architecture to be undertaken.

(*iii*) *Mutations*. These offer a way of changing the genetic instructions at a single locus. Comparisons are made between normal genotypes and genotypes carrying the mutant gene. If the experimental and control animals are genetically identical except for the mutant gene, and if they are reared in identical environments then any differences will be a consequence of the mutation. The effects of gene mutation can sometimes be highly specific, but more often they are part of a cascade of developmental effects, some of which have consequences for an animal's behaviour. A number of single gene mutations which have behavioural consequences have been identified. In man the best known of these results in a condition called phenylketonuria (PKU). Individuals who carry two abnormal PKU genes are unable to metabolize the amino acid phenylalanine because they congenitally lack the necessary enzyme phenylalanine hydroxylase. Babies carrying two PKU genes are of low intelligence, though the extent of the disability can be reduced by rearing the children on a diet lacking phenylalanine. Mutations can also be used to create animals with various abnormalities of the nervous system which provide another means of examining the relationship between genes, nervous system, and behaviour.

By using, genetically, mosaic flies (individuals having male and female tissues where male tissues carry a mutant gene) and a technique called fate mapping, it is possible to locate sites in the nervous system for particular behavioural components.

(iv) *Family pedigree studies*. This approach provides the most direct way of studying the mode of inheritance of a character in man, and tracing the incidence of a trait down a family line provides a means of determining genetic dominance and recessiveness. Colourblindness is a phenotype which has been studied in this way.

(See COLOUR VISION: EYE MECHANISMS.)

(v) *Twin studies*. This is probably the bestknown method of studying the genetical basis of behaviour in man. Twins are either identical (monozygotic, MZ) or fraternal (dizygotic, DZ). MZ twins are derived from the splitting of a single fertilized egg, whereas DZ twins derive from the fertilization of two eggs by two sperm. DZ

twins are no more genetically alike than ordinary siblings, but since they share a common prenatal environment and usually grow up together they tend to be more alike than siblings born at different times. Differences within MZ pairs arise only from

Page 286

environmental origins, whereas withinpair differences between DZ pairs are a consequence of genetic and environmental factors. Observations on MZ twins reared apart and hence in dissimilar environments provide information on the differentiating effects of the environment. In general the results of such investigations show that family environments can vary greatly without obscuring the basic similarities between MZ twins, though the importance of genotype varies for different psychological characters.

A very wide range of behavioural and psychological phenotypes are subject to genetic variation. In man, data from investigations of MZ twins, reared together and apart, and from DZ twins shows that the higher the degree of relationship between individuals the higher the correlation of intelligence test scores. Thus the correlation for DZ twins reared together is 0.53, for MZ twins reared together 0.87, and for MZ twins reared apart 0.75. While this indicates that genetic factors play a major part in determining intelligence, there is also plainly an important environmental component. Studies with adopted children and their adopted and biological parents also provide support for this, since the correlation between children and their biological parents is higher and rises through early childhood. Measured intelligence is thought to be an aggregate of a number of primary mental abilities: verbal, spatial, number, reasoning, word fluency, and*memory. The available evidence indicates that genetic loadings on these vary, with verbal and spatial abilities having high loading, whereas memory has a lower loading. Many sensory and perceptual motor tasks show evidence of a substantial genetic component in man.

Evidence from multifactorial studies of twins indicates that the personality dimensions

of*extraversion and introversion are both influenced by polygenic systems. There is also evidence which indicates that many psychiatric conditions have a substantial genetic component. Manicdepressive illness, for example, shows a concordance (agreement) rate of 957 per cent in MZ twins and 263 per cent in DZ twins. For*schizophrenia, one model has been put forward for a major gene effect, but the case for a polygenic constellation that leads some individuals to be prone to the condition when subjected to too stressful an environment is stronger: thus both genes and environment contribute in a significant way to its manifestation.

GENIUS. The word comes from the Latin *genius*, the male spirit of a household existing, during his lifetime, in the head of the family and subsequently in the divine or spiritual part of each individual; the English word 'genial' has the same root since the spirit was thought to be propitiated by festivities.

The notion that special gifts run in families was explored by the nineteenthcentury polymath Sir Francis*Galton in *Hereditary Genius* (1896). Galton was a grandson of Erasmus*Darwin, and a cousin of Charles*Darwin. Extreme ability does run in some families—for example, the Bachs, the Darwins and their relations, including the Wedgwoods, the Huxleys, and the Barlows; and in a few political families, such as the Cecils (William, Lord Burghley, 152098; Robert, Earl of Salisbury, c. 15631612; and successive generations in high positions of government in England until the present day), though this might just be chance. It is of course extremely difficult to distinguish heredity from effects of family tradition and upbringing; yet there does seem some evidence for genetic transmission of special abilities.

The genius of, for example,*Newton (whose ancestry was undistinguished) seems in part to lie in the ability to concentrate on particular problems for very long periods of time. The genius of Mozart seems different, in that his music seemed to pour from him almost without effort, and, compared to Beethoven, with remarkably little correction or rethinking.

Since geniuses are rare and there are very marked differences between each, it is extremely difficult to make generalizations or to explain genius beyond saying that there are wide individual biological differences on almost all dimensions, including such obvious ones as height. An important question is whether genius is a fortunate *combination* of characteristics, or whether there are 'genius genes'.

GEOMETRY. Even the earliest history of geometry as a theoretical study of spatial relationships and spatial structures reveals that it had, in addition, a powerful symbolic role in both imaginative

and theoretically speculative thought. Thus, although the history of geometry can be told in purely mathematical terms, it is also, from another point of view, a history of forms of representation, of ways of thinking about the world and of views on the nature of thought itself.

We can never recapture the origins of geometry. Certainly there were in ancient cultures, such as those of the Babylonians and Egyptians, systematically codified empirical procedures relating to land measurement, the construction of temples, and astronomical observation which could be regarded as antecedents. But it is only with the Greeks that a sophisticated theoretical and demonstrative geometry of the kind we find in Euclid's *Elements* emerges. It would be difficult to overestimate the impact of the emergence of geometry as a deductively organized discipline, one in which it is shown that, for example, the internal angles of a triangle

must equal two right angles, given the apparently undeniable truth of the kind of propositions which Euclid adopts as axioms and postulates and the definition of a triangle. Such a demonstration provides knowledge not merely that something happens to be the case, but also an understanding of why it must be so, given the nature of the things concerned. Geometry thus provided, and to some extent continues to provide, the paradigm of what it is to have scientific knowledge or understanding, moulding, for example, Aristotle's discussion in *the Posterior Analytics* of the demonstration of causes.

But the very feature of geometry which singles it out as providing a conception of the ideal at which all other putative sciences should aim was also, from the outset, the source of philosophical problems concerning the status of geometrical knowledge and its relation to the everchanging physical world. Many sketches of the history of geometry suggest that the Greeks regarded geometry as a theory of physical space and that they thus thought they had found a way of discovering truths about the physical world by mere contemplation. But this is to project on to the Greeks a way of thinking about geometry, physical space, and their relation which is a product of the Renaissance and of the new scientific outlook which emerged from it. For while geometry did provide the Greeks and subsequent generations of Western thinkers with their ideal of what it is to have scientific understanding (theoretical knowledge involving demonstrations from accounts of essence), it is clear that geometry itself was not regarded as yielding a scientific understanding of the everchanging physical world even though it finds application in that world, especially in the applied mathematical disciplines of astronomy, optics, and harmony; geometry deals with a timeless, unchanging world of pure shapes and sizes (forms).

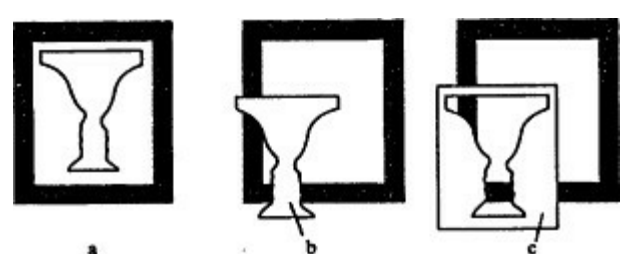

From this point of view the problems raised by geometry concern the relation between forms and items in the physical world, how knowledge of forms is possible, and how this knowledge can be so useful in everyday dealings with the physical world. To the Pythagoreans and to Plato the example of mathematics suggested that the knowable, intelligible reality must be an unchanging realm behind that of changing appearances. Aristotle, on the other hand, insisted that shapes and sizes have no existence except as aspects of physical, changeable things which are the things which have primary reality. The mathematician then deals with the possible shapes and sizes of physical things but *qua* measurable, not *qua* changeable, whereas the physicist, being primarily concerned with change and its explanation, seeks an understanding of natural objects *qua* changeable. Geometry is the science not

just of spatial magnitudes but of all continuous magnitudes which, being represented by lines, can then be handled geometrically. Arithmetic is the science of discrete magnitudes.

Thus, far from taking geometry to be the science of physical space, the Greeks tended to see it as the science of continuous magnitudes, essentially concerned with ratios and proportions and with methods of construction enabling these to be determined. The physical space of the Aristotelian universe is not the infinite, homogeneous space of Euclidean geometry, but is the highly structured bounded set of nested spheres centred on the earth. It was the cumulative effect of a number of diverse factors operating from the beginning of the Renaissance that led, by the eighteenth century, to that identification of physical with geometric space which is most clearly apparent in the works of Isaac*Newton when he talks of absolute space. Perhaps the two most important of these factors were: (i) The coordinate development of geometrical theories of perspective and of geometrical optics in the work of Italian artists such as*Leonardo da Vinci, gave geometry a role in accounts of the mechanisms of visual perception. The geometrical treatment of problems of perspective, involving twodimensional representations of threedimensional spatial relationships, brings with it (a) a tendency to treat geometry as descriptive of both perceptual and physical space and (b) the development of the methods of projective geometry (needed to handle the various possible projections of threedimensional solids into two dimensions). In projective geometry there is a shift of emphasis away from figures and their fixed shapes and sizes toward descriptions of the possible types of projections, the behaviour of shapes under such transformations, and a move toward a consideration of the more global, structural properties of spaces. (ii) The adoption of the Copernican, suncentred view of the universe shattered once and for all the crystalline spheres, leaving the earth spinning through an infinite, homogeneous threedimensional Euclidean space.

But if geometry is to be a theory of physical space then its axioms must be true of this space, and there is a problem of just how it is that we can come to recognize truths about physical space, the space of the world of experience, as necessary truths. To account for this necessity it would seem that they must be knowable*a priori, but without proof, for they are first principles. But then how can any truths about the world of experience be knowable prior to or independently of experience? There are two problems to be separated here. First there is a psychological problem of how we come by our grasp of spatial relations and spatial concepts and of what exactly we do acquire simply by experience. Secondly there is a philosophical problem which concerns not how we in tile first instance come by our beliefs about space but how, if at all, these beliefs can be proved or justified.

So long as geometry was synonymous with Euclidean geometry it was possible to think that we have some innate knowledge, or a faculty of geometric intuition which makes it possible for us to recognize the Euclidean axioms as necessarily and selfevidently true. But Euclid's fifth postulate

(which says, in effect, that parallel lines never meet however far they are extended) had never seemed entirely selfevident, and there is a long history of unsuccessful attempts to prove this postulate from the other four. In a work published in 1733, the Italian mathematician Girolamo Saccheri adopted a new strategy which was that of combining the first four of Euclid's postulates with the negation of the fifth, with the aim of deriving a contradiction and thus showing indirectly that the fifth postulate is a logical consequence of the remaining four. Although he thought he had succeeded in doing this, his proofs were faulty, as was shown by Bolyai, Lobachevski, Riemann and others who almost simultaneously demonstrated the existence of nonEuclidean geometries, ones in which the fifth postulate is false. These were shown to be consistent if Euclidean geometry is consistent, by interpreting them as the geometries of curved surfaces of various kinds (e.g. the surface of a sphere). When Einstein made use of nonEuclidean geometries in his theories of Special and General Relativity, treating spacetime as a nonEuclidean fourdimensional space, it was no longer possible to regard the Euclidean axioms as selfevident, necessary truths concerning physical reality. This opened up once again questions concerning the nature and status of geometry and its role in physical theories. Some have argued that the choice of geometry is merely a matter of convention; it is just a question of the form of representation we want to use. Others argue that it is an empirical matter, a question of seeking empirically to determine a correct account of physical space.

It is possible, however, to articulate more sophisticated intermediate positions as a result of the work carded out in pursuit of Felix Klein's Erlangen programme (1872). Klein proposed that every geometry can be defined by specifying its group of transformations, and thereby its invariants. This leads to a hierarchy of geometrical theories of increasing generality: metrical geometry, affine geometry, projective geometry, topology (roughly speaking). Given these distinctions it is possible to ask more precise questions about which parts of the full metrical geometry we use could be regarded as factually constrained and which are a matter of convention.

GESTALT THEORY was developed in opposition to the classical theory of psychology best represented by J. S.*Mill and H. von*Helmholtz. In the classical account of*perception, our sensory receptors analyse the energies provided by the physical world into independent, simple, but *unnoticeable* sensations, and the world teaches us to perceive those objects and events that would, under normal conditions, most probably have produced any given set of sensations. Many perceptual

phenomena, however, seem at first to defy analysis in terms of such 'atomistic' independent sensations. As an object moves laterally or sagittally in the field of view, its apparent shape and size remain unchanged (i.e. they display perceptual *constancy*) even though its projected image stimulates a changing set of visual receptors; a melody sounds the same although transposed to a new key and therefore to different auditory receptors; and the form depicted by any pattern can be completely changed by changing its context.

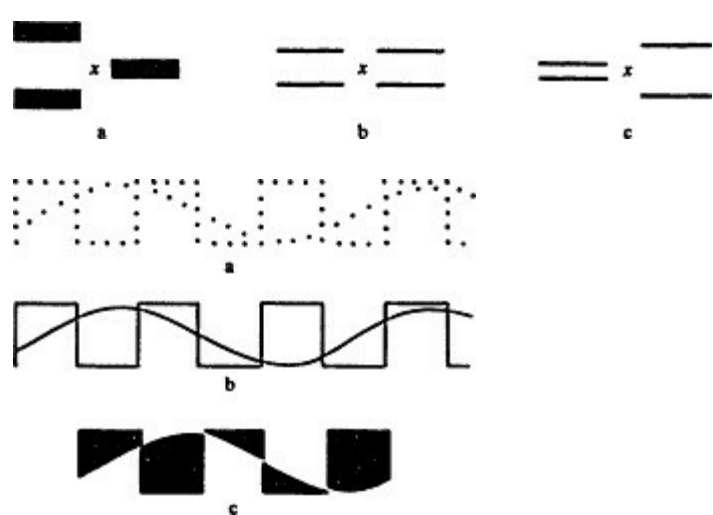

The most important example of this last point is the 'figureground phenomenon', i.e. that the same outline can be perceived as different alternative figures, with very different shapes. As E. J.*Rubin, a phenomenologist, noted in 1921, the region that is perceived as 'figure' appears to have hard surface, with a recognizable shape and definite boundaries; the 'ground' is usually less surfacelike, and without definite boundary, extending indefinitely behind the figure's contour. In Fig. 1a, either the vase (Fig. 1b) or the pair of faces (Fig. 1c) can readily be perceived as figure, with the other possibility then relegated to ground. For a shape to be perceived or recognized, it must be figure. The perception of objects, of depth, and of scenes rests, in each case, on shape perception (for instance, on the shapes that comprise the *depth* cues of linear perspective). Yet the classical theory seemed unable to account for the figureground phenomenon and, therefore, for shape perception.

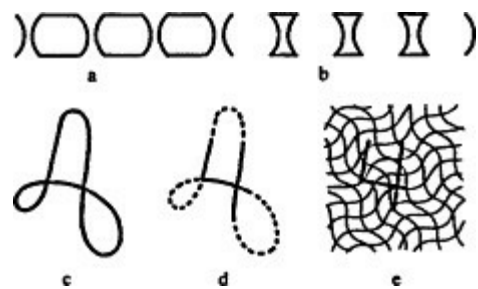

Such phenomena implicate a *Gestalt* (configurational) quality in addition to, or in place of, the individual elements composing the pattern of stimulating energies.

To Gestalt psychologists, notably Max*Wertheimer, Kurt*Koffka, and Wolfgang*Köhler,

Fig. 1.

Figure and ground. The figure perceived in a
can be either a vase (b) or a pair of faces (c).

Page 289

Fig. 2.

Figural aftereffects. a. Inspection figure. b. Test figure.

c. Exaggerated sketch of appearance of b after staring at point x in a.

form is the primitive unit of perception, taking its properties from underlying configured brain processes ('fields'). These brain processes were thought to be direct responses to the patterned energies acting on the sensory nervous system. The latter was variously conceived as an electrical network or a colloidal bioelectric medium. Brain fields might be studied indirectly by their effects on perceptual organization, an attempt pursued most concerted by Köhler and H. Wallach (1944) through the study of the '*figural aftereffect'. After staring at the fixation point, x , in an 'inspection figure' (Fig. 2a), a 'test figure' (Fig. 2b) appears distorted to subsequent viewing, as exaggerated in Fig. 2c; presumably the latter's contours are 'repelled' from regions previously 'satiated' by the brain fields (direct currents) involved in the perception of the inspection figure.

In point of fact, however, although there is ample evidence of organization in the nervous system (in that nerve fibres are arranged in patterns that constrain their function), there is no evidence for the directcurrent, steadystate, wholefigure process models of the Gestalt theories. Indeed, such steadystate brain fields seem inappropriate even as metaphors, because in order to perceive any extended object or scene, the eye must direct the very narrow region of detailed vision (the fovea) at different places, so that different parts of the object are seen in succession by the same part of the eye at a rate of about four discrete glances per second. This basic fact would result in a superimposition of different fragments of the stimulus configuration in rapid succession on any hypothesized brain field. It is hard to see how this process could be represented by the holistic steadystate models of the Gestalt psychologists.

With no viable physiological model, the Gestalt theory consists primarily of the so-called 'laws of organization'. The figureground method for studying these 'laws' uses ambiguous patterns of either dots (Fig. 3a) or lines (Figs. 3b, 4c) which can be perceived as forming one shape or another, reversible pictures in which the contour that separates two regions gives only one of them recognizable shape as figure at any moment in time (Figs. 1, 4a, b), or reversibleperspective outline drawings (such as 'wire' cubes) which can be perceived as either flat or threedimensional objects (Fig. 5). Configuration is varied to discover what factors lead one or another figureground organization to predominate.

One such factor is the 'law of good continuation', i.e. we perceive the organization that interrupts the fewest lines (for example, Fig. 3a, b is perceived as a square wave and a sine wave, not as

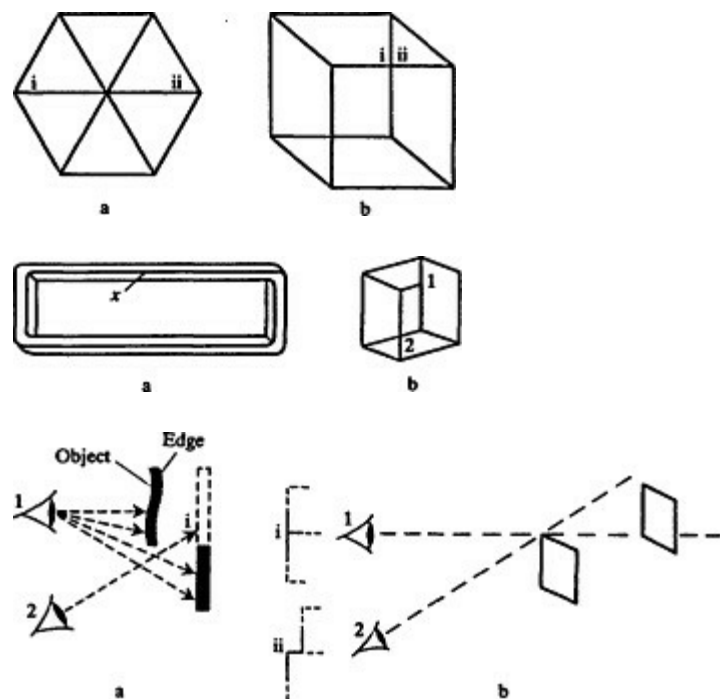

Fig. 3.

Laws of organization, I.

the set of truncated squares in Fig. 3c). Another is the 'law of enclosedness', i.e. the enclosed region tends to be figure (for example, Fig. 4a is perceived as a set of convex shapes, Fig. 4b as concave ones). It is not merely that we perceive familiar as opposed to unfamiliar shapes: letters and numbers (surely familiar) can be concealed by embedding them in a completely unfamiliar set of squiggles, if the latter provide good continuation, as they do in Fig. 4c but not in Fig. 4e.

Many such 'laws' were proposed. They are potentially of practical importance because they seem to determine whether any shape that is presented (by artist, photographer, cartographer, architect, or computer) will in fact be perceived. They seemed potentially of the greatest theoretical importance, because they were taken to show that we perceive objects and events not by learning to interpret our sensations, but because evolution has provided nervous systems that yield threedimensional perceptual organizations under appropriate conditions. In Fig. 5a the good continuation of the line iii would have to be broken in order to Fig. 4.

Laws of organization, II.

Page 290

Fig. 5.

Organization and tridimensionality.

perceive the pattern as a threedimensional cube; in Fig. 5b, the edge iii must be broken to see the figure as fiat.

For the most part, unfortunately, these 'laws' remain subjective demonstrations of unknown reliability. They can conflict: in Figs. 3a and 3b good continuation is in conflict with enclosedness. Because their relative strengths are unknown, they cannot be applied predictively. Many of them can, however, be subsumed under a single *minimum principle*, i.e. that we perceive the simplest or most homogeneous organization that will fit the pattern of sensory excitation. Fig. 5a, for example, is simpler (in terms of the number of different lines and angles that have to be specified) as a fiat figure than is Fig. 5b, whereas they are equally simple as cubes (cf. Hochberg and Brooks, 1960). This formulation offered a unifying thread to Gestalt theory that the 'laws' themselves did not. Because the Gestalt demonstrations seem visually compelling, as far as they go, and because of their potential importance, various objective and quantitative treatments of the minimum principle continued to be attempted (notably by F. Attneave, J. Hochberg, P. C. Vitz, and E. Leeuwenberg), all of them quite dissociated from the Gestalt theory and its brain fields.

What was new about Gestalt theory is almost surely not true: aside from the speculations about brain fields, the main Gestalt notion was that the whole of any perceptual organization determines the appearance of its parts. Although the limits of this principle were never fully spelt out, both the individual laws of organization and the minimum principle were clearly intended to be applied to an entire figure. Thus, whether any intersection in a reversibleperspective figure looks like a fiat pattern or like a solid corner in space is presumably a function of the whole configuration. Such antielementarism surely goes too far. This point is *suggested* by the

'impossible pictures' devised by Penrose and Penrose in 1958, in which inconsistently oriented parts of objects combine in a single picture that is physically impossible as a threedimensional organization yet nevertheless looks threedimensional. Fig. 6a is such a picture. The same point is *proven* by making a single intersection in the cube irreversible, and observing that the other intersection continues to reverse spontaneously (Hochberg, 1978). Overall sire. plicity simply will not serve as even a vague and unquantitative explanatory principle.

What is true about Gestalt theory was not new. Not only were the Gestalt 'laws' never systematized or quantified: they were never explained by Gestalt theory, nor were the perceptual constancies, nor was the figureground phenomenon itself. In fact, the figureground phenomenon is most plausibly explained within the Helmholtzian framework, i.e. that we fit our perceptual expectations about objects and their edges to the relatively unusual situation of viewing lines on paper. If an outline is taken as an object's edge, even slight changes in viewpoint (such as head movements) from 2 to 1 in Fig. 7a would be expected to cause parts of the further surface (such as point i) to disappear behind the nearer surface; so that the definite shape of figure and the indefinite shape of ground, described in connection with Fig.

1, are characteristic of the expectations associated with the edges of objects. In this view, as Fig. 6.

Relative independence of wholes and parts. Object

a looks three-dimensional even though the corners are inconsistently oriented and connected by an unbroken line (x). In cube b, the orientation is fixed at intersection 1, but perceived orientation reversals occur spontaneously at intersection 2 when the gaze is kept directed there.

Fig. 7.

Objects' edges, figural properties, and 'good continuation'.

Page 291

Brunswik implied in 1956, the 'laws of organization' are merely assumptions about what parts of the visual field are most likely to belong to what object, under normal conditions. For example, because it is very unlikely that the viewer would be standing at that one precise point in space (point 1 in Fig. 7b) from which the edges of objects at different distances would be aligned (i) rather than offset (ii), the 'law of good continuation' simply reflects the probability that aligned edges belong to the same object.

The classical theory—that we perceive whatever most probably would produce the stimulation we receive, and that psychological structure therefore generally reflects physical structure—not only still accounts best for the perceptual constancies and illusions (Gregory, 1974) but it may account as well for Gestalt organization. The fact that we perceive impossible figures as three-dimensional, however, and that figures which are made nonreversible at one corner are free to reverse elsewhere (Figs. 6a and 6b respectively) surely does not reflect the constraints of physical structure, and therefore is not accounted for by Helmholtzian principles without more specific amendments and extensions than have yet been undertaken.

GESTALT THERAPY is a noninterpretative psychotherapy which emphasizes awareness and personal responsibility and adopts a holistic approach, giving equal emphasis to mind and body. It began to achieve prominence towards the end of the 1960s. It is now one of the leading psychotherapies in the United States and is developing strongly in the United Kingdom. It is one of the several alternative therapies that comprise the Humanistic Psychologies of the Human Potential movement.

Existing more as a style of practice than as a theoretical framework, its ideas are drawn from many sources, the precise boundary between Gestalt therapy and its neighbours is not always clear, and many practitioners use it in conjunction with other approaches.

Gestalt is a German word taken from the psychology of perception. A Gestalt is a figure or pattern which can be distinguished against the background or field of perception (see GESTALT THEORY). But the term has a wider meaning than the nearest English equivalents, 'shape' and 'form', and carries stronger connotations of significance and meaning. Moreover, its use extends over the whole range of perception: shapes and tunes are *Gestalten*, and so are certain aesthetic and causal phenomena. The term applies whenever a significant pattern or construct (the 'figure') emerges against the background scene or noise (the 'ground').

Fritz Perls (1893-1970), the German-born psychoanalyst, was one of the main founders of Gestalt therapy. His inspiration was to give the concept relevance to psychotherapy and use it as a hook on which to hang a number of therapeutic concerns. He saw the task of psychotherapy as one of enhancing the figure-ground differentiation of those Gestalten which reflect the patient's needs. The needs of a healthy person organize the field of experience into well-differentiated Gestalten which command the appropriate response. So, for example, a fluid-depleted person experiences the complex of perceptions which emerge into awareness as the Gestalt of thirst, and he gets himself a drink. An affronted person who is aware of his anger has a choice of responses; a person who is unaware or incompletely aware, on the other hand, may repress his anger and get a headache instead. The neurotic is continually interfering with the process of Gestalt formation. He is unable to deal effectively with certain needs because he interrupts and avoids the formation of the relevant Gestalten.

Much of Gestalt therapy is a training in awareness, in improving the individual's contact with himself and his environment. A commonly used exercise is to produce a series of observations, starting with 'Now I am aware that ...'. Other exercises direct attention to specific experiences, and a distinction is drawn between observation and inference. 'I observe that you are smiling. I infer that you are happy.' Perls described Gestalt therapy as the psychology of the obvious, and he trained people to use what was immediately available by asking such basic questions as 'What are you feeling now?', 'What are you doing?' An important strategy is to increase the immediacy and completeness of any material used in therapy by bringing it into the hereandnow. This means that the patient describes his*dreams,*memories, and preoccupations in the present tense and, where possible, enacts them. 'Shuttling' is another method of increasing figureground differentiation. The subject moves his attention between different focuses. For example, if he shows confluence—i.e. lack of differentiation—between an emotion such as resentment and an associated symptom such as a headache, he might be asked to shuttle between his pain and his awareness of resentment.

A feature of Gestalt therapy is its ability to

Page 292

incorporate and use complex ideas which were quite remote from experience in their original form. For instance, Perls took the psychoanalytic concept of repetitioncompulsion and used it as 'unfinished business'. 'The patient feels compelled to repeat in daily life everything he cannot bring to a satisfactory conclusion.' In therapy, he is enabled to bring his unfinished business into awareness by acting out the meaning of selected aspects of his behaviour. The therapist may try to facilitate this, for example by getting him to repeat some characteristic behaviour, such as a gesture or statement, again and again until another level of meaning emerges.

Gestalt therapy explores the areas of conflict and confusion which result from failure to integrate aspects of the personality. 'Splits' occur when such aspects are in permanent and insoluble conflict. The attributes of a splitoff part may be projected on to other people or the environment; or, in retroflection, one aspect of the personality influences another—in depression, for instance, resentment against others is often retroflected against the self. In therapy, these elements are repeatedly expressed and enacted. They become transformed into an expression of self, i.e. the patient becomes aware of, and able to identify with, the component in these experiences which belongs to him. For example, someone who complains that everyone pushes him around may be asked to reverse the statement to 'I push everyone around', and may be invited to go round the group enacting this verbally and physically. 'Reowning projections' is a major theme in Gestalt therapy.

Clarifying the splits and polarities within the personality is another important area, and for this Perls used one of the most famous of Gestalt props, an empty chair. The subject may put feelings or a fantasy or a part of himself into the empty chair and begin a dialogue; in due course he moves into the empty chair and speaks as the other partner in the dialogue. It is a technique that illustrates a characteristic feature of much Gestalt work, which is to dramatize problems, thereby externalizing them and making them more accessible to the client.

In childhood, failure to cope effectively with certain kinds of experience may leave areas of impaired functioning which can be thought of as 'holes' in the personality.

The child develops various strategies to avoid being overwhelmed by the distressing feelings associated with them— strategies that involve the ego defence mechanisms described by Anna*Freud. The child also learns, and becomes identified with, roles designed to manipulate other people into providing the support which he cannot generate from his own resources. So the goal of therapy is to enable people to stop their neurotic avoidance and to become fully selfsupporting, in order that growth can take place. When the therapist succeeds in frustrating his client's defences and manipulations, the 'impasse point' is reached where the 'hole' in the personality is no longer protected and ordinary functioning breaks down. Movement in any direction seems impossible, and the subject may experience confusion and distress. Paradoxically this state, in which the feeling of being overwhelmed is again experienced, is also seen as 'the fertile void', offering the possibility of new growth through reexperiencing the old failure from an adult perspective.

According to one of its leading exponents, Irma Lee Shepherd, Gestalt is at its most effective with 'overly socialized, restrained, constricted individuals'; and she points out the dangers involved when inexperienced therapists use the powerfully confronting techniques of Gestalt to 'open up' unstable people with vulnerable personalities.

Such people need time, support, and longterm commitment from their therapists. This warning is necessary because much of the public image of Gestalt therapy derives from Perls's dramatic performances, many of which were filmed and videotaped. His clients must have been fairly tough and selfsecure to risk public exposure at the hands of a charismatic figure with an almost magical ability to penetrate defences.

Perls dominated Gestalt therapy during his lifetime. His years of experience and training and his extraordinary skill as a therapist made the work look deceptively easy;

and it is this that was probably responsible for the overselling of both the theory and his particular model of its application to people lacking in experience. His mistrust of authority matched the antiauthoritarian spirit prevailing in the 1960s. Thus Gestalt therapy has a great deal to say about the harmful effects of the superego but says little about the positive value of discipline, and there is little emphasis on the steady, unremitting work between sessions that must be maintained by patients wishing to make significant changes in their lives. The Gestalt view—which is that of humanistic psychology in general—is that the organism has an innate tendency towards health and wholeness and the full expression of its potential, but in Perls's work there is more emphasis on removing obstacles to growth than there is on working to acquire and strengthen desirable traits.

There are other features of Gestalt therapy which are helpful and productive in moderation but unfortunately lend themselves to exaggeration and abuse.

Intellectualization is rightly castigated as a major neurotic defence, but in the therapeutic process the intellect may be undervalued as a potential ally. In therapy, a challenging emphasis on personal

responsibility can be a powerful antidote to feelings of futility and helplessness—but selfcentredness and neglect of social realities may also be encouraged, together with insensitivity towards dependency needs in others. Emphasis on immediate experience, the hereandnow, can produce great therapeutic leverage—but it may lead to the discounting of historical perspective and to sidestepping round the issue of the unconscious in the developmental process.

Page 293

Gestalt therapy with its characteristics of directness and flexibility developed at a time when there was widespread dissatisfaction with the available psychotherapies.

Perls had the therapeutic skills and the charisma needed to sell the exciting new model, and he did so with courage and integrity. To him and his associates must go a lot of the credit for liberating psychotherapeutic practice from the dead weight of psychoanalytic technique. Gestalt therapy suggested new possibilities for the relationship between client, therapist, and symptoms. Traditional psychiatry and psychoanalysis take the patient's experiences and reinterpret them in terms of a system which remains the more or less exclusive property of the therapist. The patient's experiences become symptoms and instruments of diagnosis, something that only professionals can understand, and the process can increase his passivity and his sense of alienation from his inner experience. In this respect Gestalt therapy is radically different. The client works actively with his experiences under the therapist's guidance and there is a continual reference to what he is experiencing; therapist intervention is designed to clarify rather than interpret.

Research into psychotherapy has not yet reached a point where useful comparisons can be made between the effectiveness of different schools. It is therefore not possible to answer the question 'How effective is Gestalt therapy?' Even so, there are several indications of the worth of the Gestalt approach. (i) It has survived and expanded over a period which has seen the emergence, stasis, and collapse of many other therapies. (ii) It has survived the death of its charismatic founder. (iii) Most important, it is widely acceptable to many therapists, who apparently find Gestalt ideas valid and useful in their work.

GESTURES are movements of the body that signal intentions, commands, or comments—or suggestions, which may be rude or crude. Human gestures form a rich*body language. Some are innate, and probably derive from purely functional movements, such as picking something up, turning the head to look in a different direction, or hitting something hard. No doubt these functional movements were read by other members in a social group as indicating states and needs, and then they became developed as more or less conventional signs for conveying emotional states, intentions, commands, and so on. Although there is a genetic basis, the role of learning is clear because some gestures are specific to geographical regions, or to particular groups or families. People moving into a new area or marrying into a family will pick up some of their characteristic gestures.

The biological basis of gesture was pointed out in Charles*Darwin's masterpiece, *The Expression of the Emotions in Man and Animals* (1872), which suggests that many symbolic gestures are derived from functional behaviour. Their development may sometimes be traced through the use of individual or groups of muscles for purposes which changed in the evolution of species.

It is remarkable that artists, and especially cartoonists, can convey so much by recording a gesture even with just a few lines. It follows that gestures can be signalled and read from small changes of position of the limbs or body; some gestures may be recognized even at night or with the corner of the eye. Evidently we are well attuned in reading and responding to human gestures, which sometimes indicate vitally important intentions, sometimes a state of hope or fear, and sometimes doubt or confidence in those around us. It is necessary that it should be so, for the wellbeing and survival of any group.

Human gestures have been described and classified in considerable detail; for various regions, social classes and occupations, especially by Desmond Morris (1977, 1979). The range of social gestures is vast: 'the nose thumb', 'the eyelid pull', the vertical and horizontal 'horn sign', the 'palmback Vsign' and many more. It has also been shown how some of them have spread geographically, sometimes over several centuries.

GHOST. A manifestation of a dead person in human form, usually partially transparent and sometimes speaking (like Banquo's ghost in *Macbeth*). Ghosts, of various guises, are believed in to some degree in all societies.

Evidence from photography is dubious (if only because double exposures look remarkably as ghosts are supposed to appear), and there are plenty of possible explanations in terms of visual illusions. For example, afterimages of, say, candle flames or keyholes will appear very much larger when the gaze is transferred to a distant wall (see EMMERT'S LAW). There is a tendency to 'see' faces and human forms in even quite random shapes Page 294

(such as 'faces in the fire') which, indeed, is a very great help to artists, and especially cartoonists, who can represent the human face complete with expression with a very few lines. It is possible that perceptual creations of this kind are occasionally elicited in states of 'fear, and there do seem to be social factors determining to some degree the forms that ghosts take. There are, of course, less sceptical views; but lack of consistent evidence prevents general acceptance of ghosts.

GIBSON, JAMES JEROME (1904-79). A distinguished American experimental psychologist, whose work on visual perception was and remains unusually influential. Following an appointment at Smith College, Northampton, Massachusetts, where as a young professor he was considerably influenced by Kurt Koffka, who had recently emigrated from Germany, Gibson for many years ran a major department at Cornell University. His lifework was investigating visual perception of form and motion; his early work including the discovery that distorting lenses produce negative (reversed) adaptation to curvature even with free eye movements. But his main work was to challenge the approach of Helmholtz and suggest a very different account of perception.

Gibson first of all moved away from the traditional experiments with pictures, and what is seen with a single static eye, towards the observer moving around freely and viewing moving objects in natural conditions. He was led to this by considering pilots landing on fields, where the 'flow lines' of motion are important for seeing the landing point and estimating height and speed. From such considerations of 'visual flow', and texture gradients, he developed what he called 'Ecological Optics'. This almost ignored retinal images, and active brain processes, in favour of regarding perception as 'picking up information from the ambient array of light'. This is very different from the Helmholtzian notion of perceptions as Unconscious Inferences from sensory data and knowledge of objects. Gibson tried to explain object perception by supposing that some 'higher order' features are invariant with motion and rotation and are 'picked up' with no perceptual computing or processing being required. His search for such invariances, and for just what the visual system uses under various conditions (though this was not Gibson's intention) has proved useful for developing computer vision. His general philosophy, however, that perception is passive pick up of information, present in the world, is hard for Helmholtzians to follow. His important books are: *The Perception of the Visual World* (1950), and *The Senses Considered as Perceptual Systems* (1966). Much of his work was done with his wife, Eleanor, a distinguished developmental psychologist.

GNOSTIC. Relating to knowledge, from the Greek *gnosis* (knowledge or investigation), which is also the root for 'cognitive' and 'cognition'. Gnosticism in general is a variety of religious belief, assuming privileged knowledge of the spiritual world—knowledge considered superior to the science of the day—and bringing with it the promise of salvation. It has taken many forms, having its

origins in a variety of pagan sources, including Greek philosophy, Hellenistic mystery cults, and Babylonian and Egyptian mythology, and persisting into modern times in movements such as theosophy.

The bestknown adherents are the Christian Gnostics, active during the second century AD. They appeared first as schools of thought within the Church, eventually mostly becoming separate sects; indeed much of early Church doctrine was formulated to counteract their heresies. The various groups widely differed in their teachings and practices but in common made a distinction between a remote and unknowable Divine Being and an inferior deity (the Demiurge) who was the immediate source of creation which was necessarily imperfect since he was held to be antagonistic to the truly spiritual. Some men, however, were thought to contain a divine spark and, through gnosis and the (often secret) rites associated with it, this spiritual element could be rescued from its evil material environment. Gnosis came from the Divine Being through the medium of Christ bringing redemption.

GOALS IN LEARNING. A technical term in*learning theories and experiments in animal learning. Goals are set up by rewards (usually food) to establish learning through consistent (goal-directed) performance. In 'latent learning' (especially associated with the American psychologist Karl*Lashley) animals are allowed to explore mazes before goals are set up. It is then found, when food is provided at a particular place, that the goal is reached with fewer trials than for a control group which has not had previous access to the maze. It follows that learning can occur without goal-seeking (or drive reduction), but it is difficult to establish or measure this since specific goals for scoring the successes and failures of performance cannot be used. For further discussion, see PURPOSE.

GÖDEL, KURT (1906-78). A mathematical logician, born in Czechoslovakia, who emigrated to the United States and held a position at the Princeton Institute for Advanced Study from 1940 until retirement. In the 1930s he proved three major theorems. The first of these, presented in his doctoral dissertation to the University of Vienna in 1930, was a proof of the completeness of first order predicate calculus. The second, published in 1931, was a proof of the incompleteness of formal systems of arithmetic, and the third, presented in lectures given during 1938-9, was a proof of the consistency of the continuum hypothesis with the

Page 295
basic axioms of set theory. Each of these results had a profound influence on all subsequent work in the fields of formal logic, number theory, and set theory. But it is the second result which has had the greatest impact outside mathematical circles. This is often known simply as Gödel's theorem (more precisely his first incompleteness theorem) and states that, given any formal system S capable of expressing arithmetic, if S is consistent then there exists a proposition A of arithmetic which is not formally decidable within S, i.e. neither A nor its negation is provable in S.

There are two aspects of this result which mean that its implications extend well beyond the domain of pure mathematical logic. (i) The theorem concerns formal systems capable of expressing arithmetic, but the notion of a formal (logical) system is closely associated with the idea of reducing reasoning to a mechanical, computational process. In preparing the ground for the actual proof of his theorem, Gödel did much to clarify the relation between a formal logical system and the notion of a recursive, and hence effectively computable, function. He showed, loosely speaking, that the functions

representable in a formal system of arithmetic coincide with the recursively definable functions. This means that his result applies to all computer implementations of arithmetical reasoning based on recursive processes. Thus each such system will be incomplete in the sense that there will be sentences on which it can produce no decision. (ii) The proof works by providing a numerical coding (gödelnumbering) of formulae and sequences of formulae of the formal language which, since the sentences of the formal system were intended to be interpreted as statements about numbers, means that the system can also be interpreted as talking about its own formulae. This makes it possible to show that there must, for any such system S , be a sentence P of S which can be interpreted as saying ' P is not provable' or, more loosely, 'I am not provable'. It is then shown that if S

is consistent, neither P nor its negation can be provable in S . Thus, it is frequently argued, since P says 'P is not provable', P must be true. On the basis of this last step it has then been claimed that Gödel's theorem shows that the human capacity to recognize arithmetic truths can never be fully captured in a formal system and hence, in view of (i), that men are superior to machines in that given any machine there will be an arithmetical proposition which men can prove but which the machine cannot.

But this argument overlooks the fact that the proof of Gödel's theorem only allows one to conclude that *if S is consistent*, neither P nor its negation is provable in S . To go on to conclude that P is not provable, and hence is true, requires that one show S to be consistent. Because the proof methods Gödel used are, via gödelnumbering, themselves formalizable in S , one can argue that one machine T *could* prove of another machine, or even of itself, that *if* it is consistent there exists a sentence which it cannot decide. What a machine cannot do is prove its own consistency. To this extent the proof of Gödel's theorem does not of itself establish the superiority of minds over machines, but it shows that the issue here must be pushed back to the kinds of ground we have, or could have, for believing either a system of arithmetic or ourselves to be consistent.

GOETHE, JOHANN WOLFGANG VON (1749-1832). Germany's most distinguished poet and a scientist, Goethe was born in Frankfurt am Main. He made discoveries in comparative anatomy, especially on the skull, and in botany showing that leaves are the characteristic form of which all other parts of plants are variations. He vigorously attacked Newton's theory of light and colour, and although here he was incorrect he did point out important colour contrast effects—

'Goethe's shadows'. These are shadows cast by coloured lights, and they appear the complementary colour of the light. This is a startingpoint of Edwin Land's *retinex theory of colour vision.

Goethe is best known for his *Faust* (Part 1, 1808, Part 2, 1832). It is based on the medieval legend of

a man who sells his soul to the Devil. This became linked with the name and adventures of a sixteenth-century conjuror, Johann Faust. According to Goethe, Faust sold his soul to the Devil in exchange for superhuman powers of intellect and wisdom; and the Devil finally failed to claim his part of the bargain—Faust's soul. This story greatly affected Freud in his early years, and it has passed into psychoanalytical folklore.

Matthaei, R. (ed.) (1971). *Goethe's Colour Theory*. London.

GOLDSTEIN, KURT (1878-1965). German physician and psychiatrist, who was born at Kattowitz, Upper Silesia, of Jewish origins and educated at Breslau and Heidelberg. His interest in aphasia was kindled by Carl Wernicke and, like Wernicke, he considered himself a psychiatrist rather than a neurologist. His knowledge of neuropathology he acquired at the feet of Ludwig Edinger (1855-1918).

On the outbreak of the First World War, Goldstein joined the staff of an institute concerned with research on the aftereffects of brain injuries. Here he worked with Adhémar Gelb, a psychologist with strong Gestalt leanings which Goldstein largely shared. Their collaboration was highly fertile and resulted in the issue of sixteen papers published under the general title of *Psychologische Analyse Hirnpathologischer Fälle*. Among these was a remarkable case of visual agnosia ('mind blindness') which was attributed by the authors to a failure to experience compactly organized visual impressions, i.e. a breakdown in Gestalt formation with partial compensation by 'tracing' movements with the head or hand. (It has since been objected, however, that this case may well have been in part psychogenic.)

Page 296

In 1934, Goldstein published an important book expounding his mature views on the relations between general and localized brain functions and indeed the whole question of selective as opposed to global representation of psychological functions. An English translation of the book was published in 1939 as *The Organism: a holistic approach to biology*.

Goldstein delivered the William James lectures at Harvard in 1938-9, published in 1940 as *Human Nature in the Light of Psychopathology*. His short book on *The AfterEffects of Brain Injuries in War: their evaluation and treatment* (1944) was found exceptionally helpful by many concerned with the assessment and rehabilitation of those who had sustained war wounds of the brain in the Second World War.

O. L. Z.

GOLGI, CAMILLO (1843-1926). Born at Corteno, Lombardy, he became professor of pathology at Pavia. In 1873 he described his method of using chromate of silver to impregnate neural tissue, so that a proportion of neurones show up in high contrast, enabling microscopic examination. Golgi used this method on normal and pathological material. The method was developed by Santiago Ramon y Cajal (1852-1934) to study the fine structure of the brain. The two men were awarded the Nobel prize jointly in 1926. See NEUROANATOMICAL TECHNIQUES.

GREEK INVESTIGATIONS OF THE MIND AND SENSES. At what stage did the ancient Greek thinkers begin to realize the possibilities of carrying out empirical investigations in connection with their psychological theories, and at what stage did they actually do so?

Most of the terms used in Homer to refer to the seats of cognitive and emotional activity have strong concrete associations. Thus one of the words for a part of the body with which men think and feel is *phrenes*. Although this later came to be used of the diaphragm, it originally signified the lungs, as we can tell from a passage in the *Iliad* (xvi, 504) where, when a spear is withdrawn from a dead warrior's chest, his *phrenes* are described as prolapsing. But if we try to reconstruct in detail what was believed about the physical events corresponding to thoughts and feelings—about, for example, the movements of the blood and the breath and the changes taking place in parts of the body—much of the picture remains vague and unclear.

It has often been maintained that the first thinker who can be claimed to have undertaken dissections in connection with a theory of sensation is the preSocratic natural philosopher Alcmaeon (whose precise dates cannot be fixed but who appears to have been active some time around the middle of the fifth century BC). But that claim is probably unfounded. The chief evidence cited to support it is a reference to an investigation of the eye in the commentary on Plato's *Timaeus* written by Calcidius in the fourth century AD. But even if—as Calcidius may suggest—Alcmaeon used the knife in this connection, it was almost certainly not to carry out a dissection of the eye, let alone to cut open the skull to study the structures communicating with the eye within the skull itself, but merely to excise the eyeball to show that the back of the eye is linked to the brain.

The admittedly very meagre fragments of other natural philosophers of the fifth and early fourth centuries BC (see PRESOCRATIC PHILOSOPHERS) SHOW

THAT THEY WERE INTERESTED IN SUCH QUESTIONS AS THE CONSTITUTION OR SUBSTANCE OF THE SOUL (WHERE WE FIND SUCH

SUGGESTIONS AS THAT IT CONSISTS OF WATER OR AIR OR FIRE, OR OF ALL THE ELEMENTS OR OF ATOMS OF A PARTICULAR SHAPE), IN THE SEAT OF LIFE AND*consciousness (the heart and the brain were the favourite candidates), in whether sensation is by like apprehending like or by unlikes, and, sometimes, in the workings of the individual senses. They frequently cite analogies with objects outside the body to illustrate or suggest theories about its internal functioning, and some philosophers (Empedocles and Democritus especially) had some idea of the complexity of the structure of the eye, for instance. But our sources fail to yield clear and definite evidence that any of the natural philosophers employed dissection.

The possibility of opening the bodies of animals for investigative purposes is, however, occasionally mentioned in isolated texts from the fifth century. Herodotus (iv, 58) remarks that the fact that the grass in Scythia is exceptionally bilious may be judged by opening the bodies of cattle who have fed on it. Similarly the author of the Hippocratic treatise *On the Sacred Disease* (ch. 11) claims that his view that the sacred disease is due to the flooding of the brain with phlegm can be confirmed by inspecting the brains of goats who have suffered from the disease.

These texts establish that the idea of postmortem animal dissection had begun to be mooted long before Aristotle. Yet the occasions when this possibility was suggested were restricted, and the dissections that were actually carried out were cursory and confined to a narrow range of questions. Our chief evidence for this negative conclusion comes from the Hippocratic corpus, a collection of some seventy medical treatises dating mostly from the fifth and early fourth centuries BC. With the exception of one much later treatise (*On the Heart*, now generally thought to belong to the third century BC), these works mostly ignore the method entirely. Their anatomical and physiological theories, when not purely speculative or traditional, were based on the evidence obtainable from the observation of lesions, or on what their authors discovered in surgical operations, or on what they

Page 297

believed could be inferred from such clinical practices as venesection.

Passages in Aristotle indicate, however, that some dissections had been undertaken by his predecessors, although the contexts in which they did so were limited (they included, especially, the investigation of the courses of the blood vessels), and although even in those contexts the method was still far from being generally accepted or employed. We have, in fact, to wait until Aristotle himself for good evidence of more than merely occasional use of dissection. His zoological treatises refer frequently to the method, and sometimes do so in sufficient circumstantial detail to make it clear that what is reported is, in part at least, the result of firsthand observation.

It may, therefore, reasonably be claimed that Aristotle and his associates were the first to begin to exploit the possibilities of animal (though not of human) dissection for the purposes of research—with beneficial results in many areas of anatomy especially. The extent to which he did so in connection with his complex and intricate doctrines concerning the soul and the activities 'common to soul and body' is, however, problematic. His view that the heart is the seat of life is supported by what he claims to have observed in embryos, notably in his comparatively detailed researches on the growth of the embryo chick, namely that the heart is the first part to develop and become distinct. On the other hand on many topics in psychology his discussion is, in parts, quite imprecise. Thus, although he claims (for example in *De Juventute*, 469 a 12 ff.) that the senses of touch and taste 'clearly' extend to the heart, he makes no attempt to identify and trace the connections. The various descriptions of the anatomy of the pores or channels leading off from the back of the eye to the brain are vague, and are evidently based in part on inferences from lesions. His account of the movement of substances between the brain and the heart (on which depends his explanation of the mechanisms of sleeping and waking) is also largely unclear, as also is his description of the structure of the brain. His anatomical and some of his physiological theories are supported by much more systematic empirical research than those of his predecessors had been. Yet in the particular context of psychology, where the startingpoint of many of his speculations lies in certain traditional ideas and problems, it is often the case that his empirical investigations are not pursued beyond the point where he has satisfied himself that he has cited some evidence in favour of his own doctrine, or *some* to undermine those of his opponents.

The limitations of Aristotle's work in this area are evident when we compare it with what we know

of that of the major Alexandrian biologists of the third century BC, Herophilus and Erasistratus. Although the evidence that they dissected—and indeed vivisected—humans as well as animals has often been doubted, there is no good reason to reject it. The results they obtained, in so far as these can be judged from the reports in Rufus and *Galen especially, were, in any event, impressive. They were responsible for the first detailed accounts of the structure of the brain (including its ventricles) and of the heart (including its valves); and they distinguished four main membranes in the eye, corresponding to (i) the cornea and sclera, (ii) the choroid, (iii) the retina, and (iv) the capsular sheath of the lens. Most importantly, from the point of view of psychology, they discovered the nervous system. Whereas earlier theorists had spoken vaguely of channels or pores as the routes by which sensation and movement were transmitted, and the term *neuron* itself had been applied indiscriminately to what we should call sinews and tendons as well as to the nerves, Herophilus and Erasistratus identified the nerves as such and began to classify them, distinguishing, for example, between the sensory and the motor nerves.

By the second century AD, as we learn from Rufus and Galen, human dissection had almost entirely ceased, and even the value of animal dissection was contested by different medical schools. Nevertheless, that did not stop Galen himself from engaging in extensive animal dissections and vivisections in connection with his physiological and psychological doctrines. Disclaiming any definite theory concerning the substance of the soul, he concentrated his efforts on an account of its faculties, and his work on the nervous system, particularly, goes appreciably beyond that of Herophilus and Erasistratus. Apart from many specific discoveries (such as that of the recurrent laryngeal nerves), he undertook a masterly series of investigations of the nerves of the spinal column. In *On Anatomical Procedures* (book ix, chs. 13 f.) he reports the results of systematic animal vivisections, where he made incisions either right through the spinal cord or through one side of it beginning with the vertebra next to the sacrum and working his way up the spinal column in order to reveal the effect that incision at each level had on the animal's faculties—the gradually increasing loss of movement, sensation, respiration, and voice. Although many of his own physiological theories, such as the doctrine of the various kinds of breath or *pneuma*, are highly speculative, these sustained investigations of the nervous system are the supreme example from the ancient world of the application of empirical methods to the understanding of vital functions. Although many of the disputes on the nature of the soul were not susceptible to resolution by such methods, from the Hellenistic period Greek theorists had available quite detailed information concerning many aspects of the functioning of the nervous system.

H

HABITUATION (ADAPTATION). In general, an aspect of learning, whereby an animal becomes accustomed to a situation that persists. In a narrower sense, habituation is the gradual loss of a*reflex behaviour by repetition of a stimulus without reinforcement—for example, continual tapping on the shell of a snail; after a few taps, it ceases to emerge from its shell. Habituation, or adaptation, allows animals to disregard irrelevant stimuli. (If the snail came out every time its shell got tapped, it would get worn out!) Some reflexes are highly resistant to habituation—such as blinking at loud sounds, or at air blown on the eye. This may be because these reflexes are particularly necessary to the survival of the organism, disregard of the stimuli being highly dangerous. See also INVERTEBRATE LEARNING AND

INTELLIGENCE.

Humphrey, G. (1933). *The Nature of Learning in its Relation to the Living System*. New York.

HALL, GRANVILLE STANLEY (1844-1924). American psychologist who became Wilhelm*Wundt's first American student—and eventually president of Clark University, Worcester, Massachusetts. He was born at Ashfield, Massachusetts, and educated in New York and at Harvard. He obtained his doctorate under William*James with a dissertation on space perception. As president of Clark University, he was largely instrumental in inviting Sigmund*Freud and Carl*Jung to visit it in 1909 and deliver a course of lectures. His best known book is *Adolescence* (1904).

HALLUCINATION. Briefly defined as sensory perception in the absence of external stimuli, hallucination has three characteristics: thoughts or memory images, perhaps when they are as vivid and immediate as perceptions, are experienced as if they were perceptions; they are externalized, or projected, being experienced as if they came from outside the person; and the mistaking of imagery

for perception is not corrected in the light of the other information available. The term *pseudohallucination has been used to describe imagery as vivid and immediate as perception but not mistaken as such. Pseudohallucinations are more likely to be perceived in response to isolation or an intense emotional need: for example, shipwrecked sailors may visualize boats coming to their rescue well before this actually occurs. The fanciful elaboration of perception of external stimuli—for example, faces seen in the fire—is *illusion. The imagery of a vision is experienced as if it came from outside, although not from ordinary reality as perception does. These distinctions have little theoretical importance and are often difficult to make because they depend on evaluations of what a person says about what he has experienced.

Young children often fail to distinguish between imagery and perception and suppose that what they imagine is external and perceptible to others; but, as they grow older, they become better at making the distinction. Adults sometimes fail to make the distinction, especially at a time of high expectation or *arousal. A widow mourning her husband may see him or hear his voice or footsteps repeatedly after his death, resulting in a 'sense of presence', which fades with the passage of time. In a wood at night, dark shadows are seen as lurking beasts. Waking from a frightening dream, a person feels that what he has experienced has happened in reality.

Mistakes like these are corrected when the person recognizes that they conflict with other information or the views of others. Normally imagery is continually reappraised in the light of the further information becoming available; and further information is sought by testing reality. Hearing a noise, a person makes a small head movement and tests whether the change in the strength and character of the noise conforms to his expectation. Perceiving someone in a crowd as an acquaintance, a person looks again or asks a companion for confirmation. Macbeth in Shakespeare's play, while planning to murder Duncan, hallucinates a dagger, and asks: 'Art thou not, fatal vision, sensible to feeling as to sight? Or art thou but a dagger of the mind, a false creation, proceeding from the heatoppressed brain?'

After a long period of wakefulness or busyness, attention tends to be withdrawn from the outside world, and the testing of reality to be impaired and reduced.

Hallucination is relatively common under these conditions and remains uncorrected for longer. Sufficient information is available but is not used. On the other hand, the subjects of experiments on the effects of sensory deprivation, who are put into a darkened and soundproofed room, do not get sufficient information to enable them to test reality and to reappraise their hallucinatory experiences. (See ISOLATION EXPERIMENTS.) Also, a person on his own is less able to test reality and to reappraise what he has experienced.

Hallucinations tend to be disowned, the person feeling that he has no control over the imagery, Page 300

which he feels is imposed on him by an outside agency. They are often reported as distressing, threatening, or tormenting, only occasionally, for example by a widow, as reassuring; they may sometimes be accepted without any feeling being attached to them. There are other distressing

phenomena, which are not hallucinations, although akin to them in some respects. Thus, some recurring images obtrude and cannot be stopped, but are accepted as belonging to the individual. Such images are termed*obsessions. Ringing in the ear ('tinnitus'), resulting, for instance, from disease of the ear, is sometimes described by a fanciful simile, e.g. as being like sea flowing over shingle, or as if there were nearby a machine crushing stones. What is being described may be thought mistakenly to be hallucination if the explicit comparison of the 'like' or the 'as if' fails to be noted.

Hallucination is common in patients who have suffered damage to the brain as a result of trauma, infection, or intoxication by drugs or alcohol. The association of hallucination, fearfulness, and agitation in these cases may be described as*delirium. A patient who suffers from delirium tremens as a result of alcoholism may see such frightening things as red spiders or pink elephants, or he may feel that lice are crawling over his skin, because hallucination although usually visual may be experienced through any of the senses. Indeed, hallucinations in functional psychoses are more often auditory than visual.*Schizophrenic patients may hear the voices of their persecutors, conversations about themselves between third parties, or their own thoughts spoken aloud (*echo de pensée*). Severely depressed patients may hear voices making derogatory remarks or threatening them with punishment or torture. Some schizophrenic patients even experience tactile hallucinations which give rise to delusional beliefs that they are being sexually assaulted. Olfactory hallucinations are sometimes perceived by severely melancholic patients who come to believe that they are giving off revolting odours from their bowels causing people to avoid them. Patients mistake hallucinations of all these kinds for perceptions coming from outside themselves, and attribute to others what they experience, usually without any testing of reality.

Explanations of hallucination refer to several processes. In delirium there tends to be a high level of arousal and at the same time a lowering of vigilance, impairment of perception, and impairment and reduction of realitytesting. Enhancement of imagery as a direct effect of drugs or toxins on nervous tissue is similar to that of electrical stimulation of the temporal lobes of the brain when it produces, in a conscious patient whose brain has been exposed during surgery, intense visual, auditory, or other imagery as 'strips' of experience. Poisoning by drugs may also, more importantly, increase the random activity of nervous tissue. Sensations then become blurred, to produce background noise, which is then elaborated into illusion. A person poisoned by LSD may see visual patterns like lace curtains, usually coloured. In some illnesses in which there is hallucination, the functioning of peripheral nerves is affected by neuritis, and as a result the patient may experience numbness, pins and needles, or itching, which is elaborated into the illusion of lice. Similarly, the result of neuritis of the retina may be spiders dangling in front of the eyes, the elaborations of phosphenes. In schizophrenia, the patient has typically disengaged from social activities, and the testing of reality is reduced as a result, but this does not account for his disowning of what he experiences. It has to be supposed that thoughts and feelings have been dissociated as a psychological defence in order to reduce the*anxiety which would otherwise arise. The patient positively resists any reappraisal of what he has experienced.

HALO EFFECT. A powerful social phenomenon, that reputation or belief affects judgement. For example, we may regard people wearing spectacles as especially intelligent. People distinguished in one field are often regarded—by the halo effect, and sometimes dangerously—as wise and learned in others. For example, the great inventor Thomas Alva Edison was consulted on political and philosophical matters. Wealth and fashionable clothes, and even opinions, can similarly confer unjustified prestige. The converse phenomenon is 'Give a dog a bad name ...'.

HAND. The anatomist Wood Jones (1879-1954) proposed that 'man's place in nature is largely writ upon the hand'. There is a great deal of evidence that human perception and the way in which we classify objects are very much determined by how we handle them, not only in infancy but also in the later development of perceptual and motor skills. So mind may depend as much upon the hands as it depends upon the senses for gaining knowledge, and so developing.

See BLINDNESS, RECOVERY FROM; HANDEDNESS; SPATIAL COORDINATION OF THE SENSES; TOUCH.

HANDEDNESS is a characteristic peculiar to man. Only in man do individuals have a consistently preferred (and more skilful) hand for manual actions, and only man is predominantly righthanded. Other animals show paw preferences when freely picking things up, reaching into small spaces, pressing bars, or opening boxes, but they are less consistent within and across these activities, and are easily influenced by environmental variables such as training and object position. Moreover, in subhuman species tested (including mice, rats, cats, dogs, monkeys, and apes), one

Page 301

usually finds an even distribution of left and right preferences, without the typically human tendency to righthandedness. Man, by contrast, is predominantly dextral in all races and cultures, with most individuals' preferences remaining constant from an early age.

The inconsistency and lability of preferences in lower animals probably reflects their lack of an upperlimb dexterity comparable to man's. That is, the range of actions available to them—pushing, reaching for, or picking things up—usually involve wholelimb movements which require an accompanying postural body adjustment. Such movements are often stereotyped and appear to be controlled by lower centres in the brain. In man and the higher Primates, an individual's handedness becomes more marked the greater the manipulative skill required in an action, where movements independent of bodily position are controlled by higher cortical brain circuits.

Human handedness, therefore, appears to have developed along with, and to be a feature of, man's uniquely high level of finger dexterity and capacity to make and use tools. Anthropological evidence, although necessarily indirect, suggests that handedness first appeared in the lower Stone Age when toolmaking became common.

Some tools, for example, appear to have been made by righthanders for righthand use.

By historical times the predominance of righthandedness was well enough known for its origin to be discussed and for sinistrality to be noted as exceptional.*Aristotle discusses ambidexterity as a problem for contemporary ideas of the inherent superiority of the right side of the body. The Old Testament notes two cases of lefthandedness: a group of 700 sinistral slingshooters in the tribe of Benjamin, and Ehud the Benjamite who stabbed an enemy king with his left hand.

Once established, manual asymmetry quickly attracted a potent mythology associating the right side of the body and the right hand with things that are good, strong, pure, and honourable, while the left in contrast was equated with evil of all kinds. This symbolism has pervaded nearly all cultures (except the Chinese) throughout the ages. Ancient Greeks and Romans regarded the left side as inferior and profane, and in medieval times use of the left hand was associated with witchcraft. Arabs still regard the left as the 'unclean' hand and forbid its use in normal human contact. The odium of the left remains today in terms such as sinister, gauche, and cackhanded.

Righthandedness is of interest to psychology and neurology in that the development of a consistent hand preference in relation to fine motor skills may be linked to the development of hemispheric specialization in the human brain for certain cognitive functions (see NERVOUS SYSTEM). It is known that in 95 per cent of dextrals language is mediated exclusively by the left hemisphere, that is, by the hemisphere controlling the right side of the body, including the preferred hand. Originally this

'cerebral dominance' for speech was thought to imply that the left hemisphere was the vehicle for all man's highest mental functions. Subsequently, however, it was established that the right hemisphere plays its own dominant role in tasks requiring spatial perception, reasoning, or memory, as in mapreading and the recognition of faces, patterns, and melodies. This complementary specialization of the two sides of the brain is, like strong righthandedness, peculiar to man, so they may have evolved together.

Handedness may, however, reflect more directly the cerebral basis of sensorimotor function. Clinical and physiological evidence suggests that in righthanders the left hemisphere has sensory and motor connections to both sides of the body, whereas the right hemisphere is almost exclusively unilaterally connected. The former may thus have a dominant role in integrating activity of the two sides of the body to make a coordinated behavioural unit. If so, voluntary control of the right hand may be easier, and a preference for its use in delicate manipulative skills may emerge as a result.

In accordance with this idea, although it is not yet known exactly what the difference is between the hands in terms of skill, the evidence to date suggests that it centres on timing and the coordination of movements into sequences. Singlefinger contractions can be made as precisely or as fast with the left as with the right hand, and with practice either hand may run off preprogrammed sequences of movement (as in typing or pianoplaying) equally well, provided they do not require adjustment during their execution. But tasks involving visual aiming (such as pegplating or threading a needle) or serial adjustment (as in turning a crank handle or threading a nut on to a bolt) yield consistent differences in performance between the hands. Current theories of the basis of handedness include: (i) increased variability in the left arm's execution of movements, so that they require more frequent correction; (ii)

longer timelag in the correction of inaccurate movements when they occur, especially using vision; (iii) greater irregularity in timing of movements by the left hand; and (iv) a greater repertoire of movements available to the right hand because it has had more practice (this last being a rather circular argument).

Another explanation of dextrality is based on the predominant use of the right hand for gesturing, that is, for movements of communication rather than manipulation.

This again links it with the development of speech, itself seen as man's most sophisticated form of communication. Certainly the neural motor systems of speech and the right hand are adjacent, and motor activity in the latter is strongly associated with speech generation. Talking in dextrals is accompanied by gestures mainly of the right hand and arm (whereas arm movements in other situations are not specifically dextral), and talking interferes with a concurrent

motor activity in the right hand, such as balancing a rod on one finger, more than in the left. Musicians report that conducting rather than fingerwork is the most difficult action to perform with the nonpreferred hand, implying that handedness consists of a 'closer, more immediate availability of the right hand as the instrument of the individual's conceptions and intentions' (Oldfield 1969).

Any theory of handedness has to account for the minority of lefthanders found in all human societies, a proportion variously reported as from 4 to 36 per cent. The classification of subjects is itself a problem, because most sinistrals are less well lateralized than dextrals. Their preferences and usage are weaker and more changeable both within and across tasks, that is, they may prefer to use the right hand for any actions occasionally or for some tasks regularly. There seems, moreover, to be no hierarchy of preferences, nor any activity common to all sinistrals suitable for selecting them as such (although writing, throwing, shooting, and using scissors have been used for the purpose).

Nor is it clear whether handedness is a continuum (albeit an unusual Jshaped one) ranging from total dextrality to total sinistrality or comprises discrete categories and, if so, whether there are two groups (left and right) or a third 'ambilateral' (mixedhanded) group as well. Much variability in results between different studies of handedness stems from this ambiguity. The great variety of laterality measures used—including grip strength, touch sensitivity, eyedness, and writing hand—also adds to the confusion, especially as many have little relation to dexterity and do not intercorrelate.

On tests of manual speed, accuracy, and steadiness, the performance of pure sinistrals mirrors and equals that of dextrals, both showing a distinct superiority of the preferred hand. In ambilaterals of all kinds (including most selfprofessed left and some righthanders) the two hands are more equal in skill, and neither perform quite as well as the preferred hand of the strongly lateralized.

Cerebral specialization and dominance in sinistrals is less clear cut than in dextrals. Speech is still represented in the left hemisphere in 70 per cent of left* and mixedhanders, but 15 per cent have righthemisphere language and 15 per cent bilateral representation. Sinistrals may suffer*aphasia from damage to either hemisphere, but recover from it better than do dextrals. Similarly equivocal results are found for other skills, suggesting a bilateral brain involvement in all mental functions. Some

investigators claim pure lefthanders are the mirror opposites of dextrals while ambilaterals are a separate group. Others distinguish 'familial' lefthanders (with sinistral relatives) from 'nonfamilials'. Others again classify all sinistral brains as 'imperfectly developed' or 'undifferentiated'.

Theories of the origins and distribution of handedness are of three kinds. (i) learningcultural theories claim that it is produced by social pressures or early experience, especially of tools designed for righthand use. These (mostly older) theories are too imprecise to predict accurately the handedness of any individual or the distribution of handedness in any group. (ii) Genetic models (see GENETICS OF BEHAVIOUR) suggest handedness is inherited, although the exact mechanism is as yet unknown. Current theories include a twogene model (levy and Nagylaki, 1972) and a rightshift model in which pure righthandedness may be inherited from a dominant gene but, if not, the degree of laterality to either side is determined randomly by environmental factors (Annett). (iii) Braindamage theories hold that neonatal injury shifts cerebral dominance and handedness or prevents normal hemispheric specialization. They explain thereby the higher incidence of sinistrality found in such pathological states as subnormality and epilepsy. Whether they account for lefthandedness in the population generally is debatable.

HANDICAP. A term now commonly applied to a person suffering from a physical or mental disability (as opposed to illness). The word probably comes from the phrase 'hand i' (in) cap', referring to a seventeenth-century sporting lottery in which the contestants deposited forfeit money in a cap or hat. Later, in horseracing, it referred to the extra weight which various horses were required by the umpire to carry in order to penalize the superior animals and so even out the contest. Since the nineteenth century the term has been applied to any disability in a contest.

See also MENTAL HANDICAP; SUBNORMALITY.

HAPTIC TOUCH. Touching by active exploration, especially with the fingers. It is in contrast with 'passive' touch, in which structures are sig

Page 303

nailed by patterns impressed on the skin. Haptic touch has the advantage that large objects (much larger than any region of skin) can be discerned and identified, but is seldom used, except in the dark, or by blind people, when it is extremely useful. It is essentially *singlechannel* scanning in time, whereas passive touch uses simultaneous *parallel* neural*channels. Since the sensitive nerve endings of the skin adapt with constant stimulation, movement and active touch are important for renewing their signals. See also TOUCH.

Iggo, A. (1982). Cutaneous Sensory Mechanisms. In Barlow, H. B. and Mollon, J. D. (eds.), *The Senses*. Cambridge Texts in the Physiological Sciences, 3.

HARTLEY, DAVID (1705-57). British philosopher and physician, born in Halifax and educated at Jesus College, Cambridge. While a medical practitioner in Newark, London, and Bath he developed an account of mind based on soundlike vibrations, which he used not only to explain transmission of messages in the nervous system but also association of ideas by a kind of resonance, as when one vibrating string activates another by sympathy. His associationism is highly important in the history of psychology. *Observations on Man* appeared in 1749.

HAWTHORNE EFFECT. A kind of experimenter effect which has been found in industrial research. There may be changes in productivity, etc., simply in response to attention from the investigators, rather than as the effect of any particular experimental treatments. It is so named because of a study at the Hawthorne plant of the Western Electric Company in Chicago in 1927-9 in which five girls were moved into a test room and subjected to various changes in rest periods and refreshments; it was found that output increased by about 30 per cent, this being unrelated to any particular experimental conditions. It was generally concluded that the increase was due to social factors within the group, although it could be accounted for by the change in group piecework which was shared among a group of five instead of a larger group, the smaller variety of work done, the replacement of two of the girls by faster ones, the enthusiasm of the penurious operative number two, and the general

expectation throughout the works that the experiment would be a 'success'.

Whether the result was correctly interpreted or not, this study had a profound effect on the subsequent development of research in industrial*social psychology. It was concluded that physical conditions of work might be less important than factors like the structure of groups and the style of supervision, and the study thus led to the

'human relations' movement.

It also led to greater care in later work to avoid errors of this kind. Sometimes it is possible to work from records, for example when studying the effect of group size on absenteeism. The Tavistock Institute of Human Relations has cultivated a strict neutrality and kept its distance both from managers and from workers. The effects of administering interviews or tests can be eliminated by means of elaborate designs with extra control groups. Industrial social psychology is still subject to various errors, nevertheless. For example, in followup studies of training it is rarely possible to keep raters 'blind' as to who has been trained.

M. A.

HEAD, SIR HENRY (1861-1940). British neurologist, born in London and educated at Charterhouse School and Trinity College, Cambridge. As a young man, he studied with Ewald*Hering in Prague. Later he joined the London Hospital, becoming consulting physician. He is best known for his work with W. H. R.*Rivers, Gordon*Holmes, and others on sensation and the cerebral cortex and for his studies on*aphasia, in which he cast doubt on the prevailing ideas regarding the cortical localization of speech. His concept of the*schema—a flexible representation of past experience in memory—greatly influenced the British psychologist F. C.*Bartlett.

His books include *Studies in Neurology*, 2 vols. (1920) and *Aphasia and Kindred Disorders of Speech*, 2 vols. (1926).

HEAD INJURY. See CONCUSSION.

HEARING. When an object vibrates, pressure changes are set up in the surrounding medium, usually air, and these pressure changes are transmitted through the medium and may be perceived as sound. Sounds can be categorized into two main classes. Those for which the pressure changes have a random or irregular quality are perceived as noiselike: examples are the sound of a waterfall, or the consonants 's' or 'f'. Those which repeat regularly as a function of time are called periodic sounds, and generally have a welldefined tone or pitch: for example, a note played on a musical instrument. The size of the pressure change is related to the perceived loudness of a sound; the greater the pressure variation the greater the loudness. However, it is inconvenient to express the magnitude of sounds in terms of pressure changes, because the ear can perceive sounds over a huge range of pressures. Hence a logarithmic measure called the decibel (abbreviated dB) is used to express sound magnitude, or level; 0 dB corresponds roughly to the quietest sound which can be heard by a healthy young adult, normal conversation has a level of 60-70 dB, while sounds above about 100 dB tend to

be uncomfortably loud and can damage our ears if heard for a long time. Sounds with a level above 120 dB can damage our ears within quite a short time, perhaps only a few minutes. When the level of a sound is increased by 10 dB, the subjective loudness roughly doubles, whereas the sound power actually increases by a factor of 10. The smallest detectable change in level is about 1 dB.

Periodic sounds can also be described in terms of

Page 304

their repetition rate and the complexity of the pressure variation. The repetition rate is related to the subjective pitch; the higher the rate the higher the pitch. Complexity is related to the subjective timbre or tone quality; differences in timbre distinguish between the same note played on, say, the violin and the organ. One of the simplest pressure waves has the form of a sinusoid: pressure plotted against time varies as the sine of time (see the lower part of Fig. 3). A sine wave may also be called a pure tone or simple tone, since it has a very 'pure' or 'clean' quality, like that of a tuning fork or the Greenwich timesignal. For a pure tone the repetition rate, the number of complete cycles per second, is called the frequency. The unit of one cycle per second is called the hertz (abbreviated Hz). The Greenwich timesignal has a frequency of 1,000 Hz. The highest frequency we can hear varies from 16,000 to 20,000 Hz in young adults, but tends to decrease with increasing age. The lowest frequency which is heard as sound is about 20 Hz. Below that the pressure changes are felt as a vibration rather than heard as sound. We are most sensitive to frequencies around 1,800 Hz.

Sine waves, or pure tones, are particularly/ important in the study of hearing. Joseph Fourier showed that any periodic complex sound can be considered as composed of a sum of sine waves with different frequencies and levels. Conversely, any periodic sound can be synthesized by adding together sine waves with appropriate frequencies and levels. This can be very useful, since if we are investigating how some part of the auditory system works, it is often sufficient to measure only the way it responds to sine waves of different frequencies. The response to any complex sound can then be predicted from the response to the sine waves. The same philosophy lies behind the specification of amplifiers or loudspeakers in terms of their frequency response. It is assumed that if an amplifier faithfully reproduces any sine wave within the audible range, and amplifies each sine wave by the same amount, then it will also faithfully reproduce any complex sound composed of those sine waves.

A further reason why sine waves are important in the study of hearing is that the ear behaves as though it carries out a Fourier analysis, although it does not do this analysis perfectly, and is therefore said to have limited resolution. Thus when we are presented with two sine waves which are sufficiently separated in frequency, we are able to hear two separate tones, each with its own pitch. This contrasts with the eye, where a mixture of two different colours (frequencies of light) is perceived as a single colour. The process by which the different frequencies in a complex sound are separated in the ear is known as frequency analysis or frequency resolution.

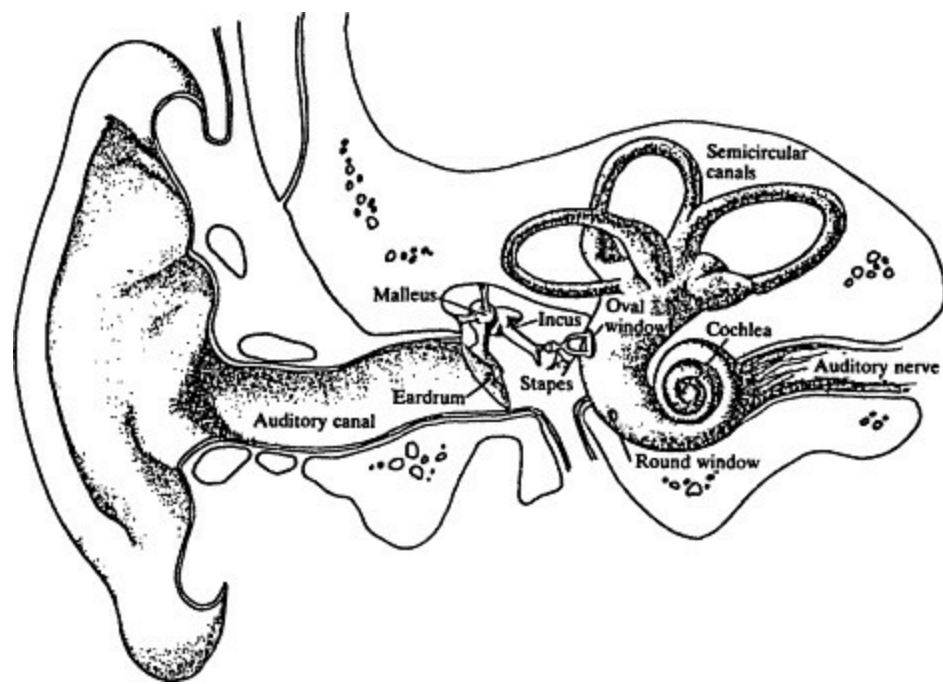

If we subject a complex sound to Fourier analysis, and then plot the level of each sinewave component as a function of frequency, the resulting plot is known as the spectrum of the sound. The spectrum is related to the complexity of the pressure variation: the simple sine wave has a spectrum

composed of a single point, or vertical line, whereas musical instrument tones generally contain many sinusoidal components, and have a spectrum composed of many lines. The subjective timbre of sounds is more easily explained in terms of the spectrum than in terms of the pressure variation as a function of time. Sounds with many highfrequency components will seem sharp or strident, while those with mainly lowfrequency components will seem dull or mellow. This correspondence between spectrum and timbre provides another example of the action of the ear as a frequency analyser. In the following sections we will discuss the physiological basis of this frequency analysis, and some of its perceptual consequences. We will also discuss the perception of pitch. Finally we will describe the major types of hearing impairments, and their perceptual consequences.

The anatomy and physiology of the ear. Fig. 1 illustrates the basic structure of the outer, middle, and inner ear. The outer ear consists of the pinna and the ear canal. The pinna is thought to play an important role in our ability to locate complex sounds. The spectrum of such sounds is modified by the pinna in a way which depends upon the direction of the sound source relative to the head. These spectral modifications are not perceived as changes in timbre, but rather determine the perceived direction of the sound source. They are particularly important in allowing us to distinguish whether a sound comes from behind or in front, and above or below.

Sounds impinging upon the eardrum are transferred by means of three small bones in the middle ear (the smallest bones in the body, called the malleus, the incus, and the stapes) to a membranecovered opening (the oval window) in the inner ear or cochlea. The main function of the middle ear is to improve the efficiency of transfer of energy from the air to the fluids inside the cochlea. Small muscles attached to the bones contract when we are exposed to intense sounds, reducing sound transmission to the cochlea, particularly at low frequencies. This may serve to protect the cochlea, and it may also help to stop intense low frequencies, occurring in the environment or in our own voices, making higher frequencies inaudible.

The cochlea is filled with fluids, and running along its length is a membrane called the basilar membrane. This membrane is stiff and narrow close to the oval window (called the base), while at the other end (the apex) it is wider and less stiff. In response to sinewave stimulation a wave appears on the basilar membrane travelling from the base towards the apex, at first increasing in amplitude and then decreasing. The position of the maximum in the pattern of vibration along the basilar membrane varies with frequency; high frequencies produce peaks towards the base, and low frequencies towards the apex. This is illustrated in Fig. 2. Thus the basilar membrane acts as a

Page 305

Fig. 1.

The structure of the peripheral auditory system, showing the outer, middle, and inner ear.

frequency analyser, different frequencies producing activity at different places along the basilar membrane.

The patterns shown in Fig. 2 are rather broad to account for the frequency resolution which is actually observed in human subjects (see below). However, recent work has indicated that many of the early measurements may have been in error. The basilar membrane appears to be extremely vulnerable, so that even small impairments in the physiological condition of the animal being studied alter the responses and produce broader 'tuning'. It has recently been shown that the 'tuning' on the basilar membrane, i.e. its frequency resolution, can be extremely sharp if the animal and its cochlea are in good condition.

The information which is contained in the patterns of vibration on the basilar membrane has to be transmitted to the brain in some way in order for us to perceive sound. This transmission is achieved by an electrical 'code' carried in the auditory nerve. Each auditory nerve contains the axons or 'fibres' of about 30,000 individual nerves, or neurones, and information is transmitted in each of these in the form of brief electrical impulses, called spikes or action potentials. Thus transmission takes place in an all-or-none fashion; the size of the spikes does not vary, and only the presence or absence of a spike is important.

The vibrations on the basilar membrane are transformed to spikes by rows of special cells, called hair cells, which rest on the basilar membrane. The hair cells are among the most delicate structures in the cochlea, and they can be destroyed by intense sound, lack of oxygen, metabolic disturbance, infection, or drugs. They also tend to be lost with increasing age. Once lost they do not regenerate,

and loss of hair cells is a common cause of hearing impairment.

The exact way in which information is 'coded' in the auditory nerve is not clear. However, we know that any single neurone is activated only by vibration on a limited part of the basilar membrane. Each neurone is 'tuned' and responds to only a limited range of frequencies. Thus information about frequency can be coded in terms of which neurones are active or 'firing' with spikes. This form of coding is called 'place' coding. Information about sound level may be carried both in the rate of firing (i.e.

the number of spikes per second) and in terms of the number of neurones which are firing. Finally, information may also be carried in the exact timing of the spikes.

For stimulating frequencies below about 5 kHz (1 kHz = 1,000 Hz), the time pattern of neural spikes reflects the time structure of the stimulus. Nerve spikes tend to occur at a particular point or phase of the stimulating waveform, a process called phaselocking, although a spike will not necessarily occur on every cycle. This is illustrated in Fig. 3. For a sinewave stimulus with a frequency of, say, 1 kHz, the time for one complete cycle will be 1 millisecond (ms), and the time intervals between successive nerve impulses will be integral multiples of this, namely

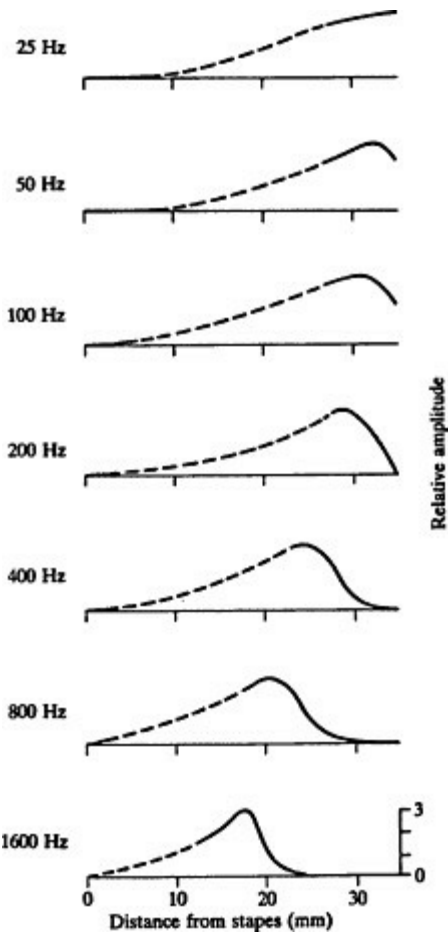

Fig. 2.

Envelopes or outlines of patterns of vibration on the basilar membrane for low frequency sine waves of different frequencies. Solid lines indicate the results of actual experiments, whereas the dashed lines are extrapolations.

Fig. 3.

The lower trace shows the waveform of a sine wave with frequency 300 Hz. The upper trace shows the response of a single auditory nerve fibre. Note that each impulse occurs at the same phase of the waveform, although an impulse does not occur on every cycle.

1, 2, 3, 4, 5, ... ms. Thus phaselocking provides another way in which the frequency of a sound may be coded. Notice that a given neurone cannot 'fire' more than a few hundred times per second. It used to be thought that the frequency of the stimulus at higher frequencies could be coded by cooperation between groups of neurones firing in volleys, the so-called 'volley' theory. In fact, the time pattern of response in a single neurone is sufficient to define the frequency of the input, provided that time *intervals* between firings are analysed, rather than overall firing rate.

Theories of pitch perception. The pitch of a sound is defined as that attribute of sensation in terms of which sounds may be ordered on a musical scale; variations in pitch give rise to the percept of a melody. For sinewave stimuli the pitch is related to the frequency, and for other periodic sounds it is usually related to the overall repetition rate. Classically there have been two theories of how pitch is determined. The *place* theory suggests that pitch is related to the distribution of activity across nerve fibres. A pure tone will produce maximum activity in a small group of neurones connected to the place on the basilar membrane which is vibrating most strongly, and the 'position' of this maximum is assumed to determine pitch. The *temporal* theory suggests that pitch is determined from the time pattern of neural impulses, specifically from the time intervals between successive impulses (this used to be called the volley theory, but as discussed above, volleying is no longer considered necessary).

It is generally agreed that the place theory works best at high frequencies, where the timing information is lost, and the temporal theory works best at low frequencies, where resolution on the

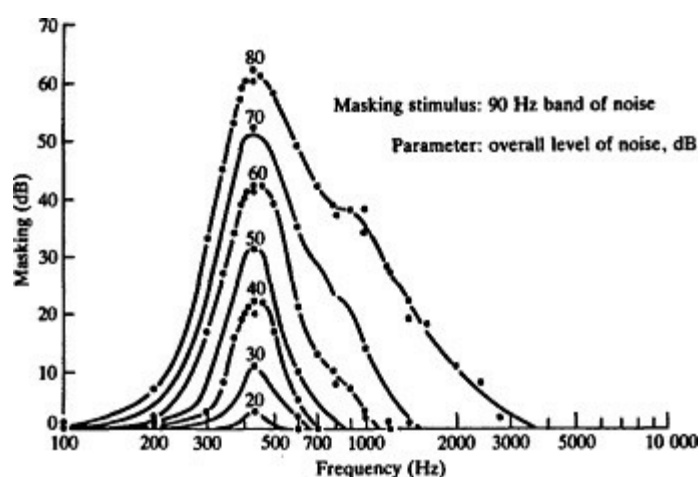

basilar membrane is poorest (see Fig. 2). However, the frequency at which the change from one to the other occurs is still a matter of debate.

We can get some clues from studies of frequency discrimination, the ability to detect a small difference in frequency between two successive tones. For low and middle frequencies a change of about 0.3 per cent is detectable, but above about 5 kHz the smallest detectable change increases markedly. Furthermore, above 5

kHz our sense of musical pitch appears to be lost, so that a sequence of different frequencies does not produce a clear sense of melody. Since 5 kHz is the highest frequency at which phaselocking occurs, these results suggest that our sense of musical pitch and our ability to detect small changes in frequency depend upon the use of temporal information. Place information allows the detection of relatively large frequency changes, but it does not give rise to a sense of musical pitch.

We do not have space to deal with the pitch of complex sounds, but it is thought that relatively complex pattern recognition processes are involved which depend upon both place and temporal information. For a review see Moore (1982).

The ear as a frequency analyser. We initially described how the auditory system functions as a

Page 307

Fig. 4.

Masking patterns for a narrowband noise masker

centred at 410 Hz. The threshold elevation of

the sinewave signal is plotted as a function of

signal frequency, with masker level as parameter.

limited resolution frequency analyser, splitting complex sounds into their sinewave components. Although we have argued that place information is not the most important determinant of pitch, it

seems almost certain that the place analysis which takes place on the basilar membrane provides the initial basis for the cat's frequency analysing abilities. We will now describe briefly some perceptual consequences of this analysis.

We are all familiar with the fact that sounds we wish to hear are sometimes rendered inaudible by other sounds, a process known as masking. Fig. 4 shows masking patterns produced by a masker containing only a small range of frequencies: a narrowband noise. The threshold elevation of the sinusoidal signal (the amount by which the masker raises the threshold) is plotted as a function of signal frequency for several different masker levels. The figure illustrates two basic points. First, the greater the masker level, the more masking there is. Secondly, more masking occurs for signal frequencies close to the masker frequency than for those farther away.

This makes sense if we assume that masking will be most effective when the pattern of vibration evoked by the masker on the basilar membrane overlaps that of the signal. If the place analysis on the basilar membrane is sufficient to separate completely masker and signal, then no masking will occur. (See also AUDITORY

ILLUSIONS.)

As was described earlier, the subjective timbre of a sound depends primarily on the spectrum of the sound; the level of sound at each frequency. Presumably timbre is perceived in this way because the different frequencies excite different places on the basilar membrane. The distribution of activity as a function of place determines the timbre. Obviously, this distribution can be quite complex, but each different complex tone will produce its own distribution, and hence will have its own tone colour.

This helps us to distinguish between different musical instruments, and to distinguish between the different vowel sounds in human speech.

Hearing impairments. Hearing impairments can be classified into two broad types. *Conductive* hearing loss occurs when the passage of sound through to the inner ear is impeded in some way, for example by wax in the ears, or by some problem with the bones in the middle ear. It can often be cured by simple medical treatment, or by surgery, and when this is not possible a simple hearingaid can effectively alleviate the problem. *Sensorineural* hearing losses arise in the inner ear, or at some point 'higher up' in the auditory system. Cochlear hearing losses are often produced by damage to the hair cells and they are common in the elderly. Sensorineural hearing losses are not usually helped by surgery, and simple hearingaids are of only limited use, since the percepts of the listener are 'distorted' in various ways.

One common problem in cochlear hearing loss is *recruitment*, an abnormally rapid growth of loudness with increasing sound level. Faint sounds may be inaudible to the sufferer, but high level sounds are as loud to him or her as to a normal listener. A hearingaid which amplifies all sounds will overamplify intense sounds, and these will be uncomfortably loud. One way round this problem is to use hearingaids which 'compress' the dynamic range of sounds, by amplifying low level sounds more than high level sounds. Such aids are currently being evaluated, and have met with some success.

A second common problem in cases of cochlear hearing loss is an impairment in frequency selectivity. This has a number of consequences. First, the sufferer will be more susceptible to the effects of masking. Secondly, the ability to identify the timbre of different sounds, including speech, will be impaired. These two effects mean that the sufferer will have great difficulty in understanding speech whenever there is more than one person talking at once, or when there is background noise.

Page 308

Present hearingaids cannot compensate for this problem, and as a result many people with cochlear hearing losses never go to pubs or to parties.

Further research may clarify the nature of the defects in impaired ears, and suggest ways in which those problems can be alleviated. In the meantime we should remember that for most impaired people a hearingaid does not restore normal hearing; it may make sounds louder but it does not bring them into focus.

HEDONISM. Name for (i) the ethical doctrine that pleasure is the only good, and (ii) the psychological thesis that all actions are in fact directed towards the pursuit of pleasure in some form or another. Hedonism in both its forms has a long philosophical ancestry, but was especially prominent in the work of the utilitarians of the late eighteenth and the nineteenth centuries. Jeremy*Bentham argued that 'nature has placed mankind under the governance of two sovereign masters, *pain and pleasure*. It is for them alone to determine what we ought to do as well as what we shall do' (*Introduction to the Principles of Morals and Legislation*, 1789). For Bentham, pleasure was a purely quantitative notion, and the utility of an act could be calculated by measuring the amount of pleasure it produced in terms of intensity, duration, etc. J. S.*Mill, by contrast, distinguished between higher and lower pleasures, and argued that certain types of pleasure (notably those of the intellect) are qualitatively superior, irrespective of the actual amount of pleasure they produce (*Utilitarianism*, 1861). It seems, however, that this manœuvre involves a radical departure from hedonism, since it suggests that the value of an activity is not solely a function of the pleasure involved.

The psychological thesis that people only pursue pleasure seems false. It is a matter of common sense that people pursue a wide variety of goals in life (e.g. scientific truth, justice, religious enlightenment); and it does not appear that the pursuit of these differing goals can be exhibited as being 'really' the pursuit of pleasure—unless the concept of pleasure is defined so widely that the claim that only pleasure is pursued becomes trivially true. Ethical hedonism also seems untenable. The value of goods such as liberty and autonomy cannot, it seems, be explained solely in terms of the amount of pleasure which may be produced by securing them.

HEGEL, GEORG WILHELM FRIEDRICH (1770-1831). German philosopher born at Stuttgart. He studied theology at Tübingen, and became *privatdocent* at Jena and then headmaster of a school at Nuremberg, where he instructed the boys in his own, highly obscure, philosophy, which is a modification of Kant's. He became professor of philosophy at Heidelberg in 1816 and finally at Berlin in 1818, where he dominated German philosophy.

Hegel is essentially mystical; he rejects the reality of separate objects, and of minds in space and time, and holds, rather, an all-embracing unity: the *absolute* which is rational, real, and true. To draw attention to a particular is to separate this from the whole; and so the particular is only partially true. Greater unity and truth are achieved by the dialectic of positing something (*thesis*), denying it (*antithesis*), and combining the two half-truths in a *synthesis*. It has been said that Karl Marx 'stood Hegel on his head' by making matter, and not reason, the ultimate reality. Hegel is the contrary of an empiricist, for he held that the whole has a greater claim to reality than the parts that may be observed; and (in societies) that the group has more reality than the individuals composing it. This came to justify extreme authoritarian political philosophies, from Fascism to Communism. It is also the mainspring of idealist philosophies such as Bradley's, which were finally abandoned with the impact of pragmatism and logical positivism, and the linguistic analysis and emphasis on 'atomic statements' of G. E. Moore, Bertrand Russell, and Ludwig Wittgenstein.

Hegel's main philosophical work is *Phänomenologie des Geistes* (1807; English trans. *The Phenomenology of the Mind*, 1844).

R. L. G.

HELMHOLTZ, HERMANN LUDWIG FERDINAND VON (1821-1894). German physiologist and physicist, born at Potsdam. He was the son of Ferdinand Helmholtz, a teacher of philology and philosophy in the gymnasium. His mother's maiden name was Penne; she was descended from the Quaker founder of Philadelphia, William Penn. Hermann Helmholtz became the founder of the science of perceptual physiology. He carried out a vast number of observational experiments, often with himself as observer, as well as physiological experiments for explanations. He also formulated psychological concepts which have lasting significance. His immense range—he was one of the greatest physicists of the nineteenth century—even includes ideas on aesthetics and art. He was also a director of research, and with his *Popular Lectures* a lucid presenter of science: by following a suggestion of his, his student Heinrich Hertz (1857-1894) discovered how to confirm James Clerk Maxwell's theoretical prediction of radio waves. Helmholtz was professor of physiology at Königsberg (1849), Bonn (1855), and Heidelberg (1858). Then in 1871 he became professor of physics at Berlin, and from 1888 to 1894 was president of the Physikalisch-Technische Reichsanstalt, which he designed as 'an institute for the experimental promotion of exact science and the *technique* of precision'. It is, however, for his earlier work on the nervous system and especially on vision and hearing, and as the founder of the

experimental study of perception, that he concerns us here.

His first great achievement, in 1850, was to measure the rate of conduction of signals in nerves. It had been thought that sensory signals arrive at the brain immediately.

Indeed, the founder of modern physiology, Johannes Müller (1801-58) considered it to be beyond experimental possibility to measure the neural conduction rate, because nerves are so short, in comparison with the astronomical distances over which the velocity of light had been estimated, that no instrument could measure the very short time differences. But Helmholtz's friend Emil du Bois-Reymond (1818-96), the originator of electrophysiology, suggested that there might be a molecular basis for neural conduction, so it could be a great deal slower than the velocity of light. Further, a new instrument, the chronograph, was invented in 1849, making it possible to record short durations and rapid changes with an electrically operated pen on a revolving drum. Helmholtz used this with frog preparations, and then on humans. The method with humans was to find the difference between reaction times to a stimulus at, say, the ankle and the calf of the leg. Since the muscle action time (which he also succeeded in measuring) would be the same in either case, a longer reaction time from the ankle must be due to conduction time in the nerve of the leg.

Helmholtz found it to be comparable to the speed of sound, rather than of light. His father commented in a letter to him: 'the results at first appeared to me surprising, since I regard the idea and its bodily expression not as successive, but as simultaneous, a single living act, that only becomes bodily and mental on reflection; and I could as little reconcile myself to your view, as I could admit that a star had disappeared in Abraham's time should still be visible'. This was, however, a misunderstanding which was for some time shared by the older physiologists; for as Helmholtz immediately pointed out to his father: 'the interaction of mental and physical processes is initiated in the brain, and consciousness, intellectual activity, has nothing to do with the transmission of the message from the skin, from the retina, or from the ear, to the brain. In relation to intelligence this transmission within the body is as external as the propagation of sound from the place at which it takes origin, to the ear.' The measurements did however lead Helmholtz to appreciate that the brain is quite slow, for reaction times are much longer than they should be from the speed of signals in peripheral nerves, and so he came to appreciate that a great deal of routing and switching of signals must be going on during perception, and for decisions for muscle movement. This led to analogies between brain function and telephone exchange switching, and then computers.

Helmholtz was philosophically a thoroughgoing empiricist, believing that sensory signals only have significance as the result of associations built up by learning. We are essentially separate from the world of objects, and isolated from external physical events, except for neural signals which, somewhat like language, must be learned and read according to various assumptions, which may or may not be appropriate. This is the basis of Helmholtz's interest in perceptual and especially visual illusions.

More generally, it is the basis also of his notion, at that time disturbing, that perceptions are 'unconscious inferences'. This challenged the prevailing view that responsibility, and just blame and praise, depend on consciously held reasons and motivations. Sigmund Freud's slightly later notion of

an active unconscious mind is a rather different idea, though equally shocking to the Victorians. For Helmholtz it was simply that most of what goes on in the nervous system is not represented in consciousness. Physiological and psychological experiments are important, and often surprising in their findings, because we cannot experience or discover by introspection how we see or think, or even know on what data our perceptions and beliefs are based. Thus Helmholtz wrote of visual illusions, in his last paper on perception (1894):

Knowledge gained through daily experience, with all its accidents, does not usually have the range and completeness which it is possible to obtain with experiments.... We usually refer to incorrect inductive inferences concerning the meaning of our perceptions as *illusions of the senses*. For the most part they are the result of incomplete inductive inferences. Their occurrence is largely related to the fact that we tend to favour certain ways of using our sense organs—those ways which provide us with the most reliable and most consistent judgements about the forms, spatial relations, and properties of the objects we observe. ... Unusual perceptions, concerning whose meaning we have no trained knowledge, occur with unusual positions and movements of our sense organs, and incorrect interpretations of these perceptions may result. We can, in fact, lay down the general rule that with abnormal positions and movements of the eyes, the intuitions which occur are those of the objects which would naturally have to exist in order to produce the same perceptions under the conditions of normal vision.

Then, after pointing out that ordinary plane mirrors produce illusions of this kind, though we are seldom actually misled, he adds: 'most observers know how to change an unusual kind of observation into one that is common and normal, thus causing the illusion to be recognized and to disappear'. Thus*afterimages impressed on the retina by a flash of light are seen as external objects, even though we may realize they are illusory, as we move our eyes and find part of the visual world moving with them. The illusion persists but we are not fooled by it.

Helmholtz was remarkable in combining shrewd psychological accounts with extraordinarily powerful physical insights, as in his work on the conservation of energy.

His experimental and inventive skills were also remarkable. They led to the ophthalmoscope (1851) for examining the retina; the ophthalmometer for measuring the curvature of the optical surface of the eye; and the Young

Page 310

Helmholtz trichromatic theory of*colour vision, which is the basis of current theories. In*hearing, he introduced the resonance theory of pitch discrimination. That he achieved his results before there were stable sources of light, or electronic instruments for producing and measuring sound waves, humbles the present-day investigator.

Helmholtz's *Treatise on Physiological Optics* (3 vols., 1856-67; trans. 1924-5 reprinted New York 1962) is the foundation of the science of visual perception and well worth reading today. His *On the Sensations of Tone* (1863; 4th edn. 1877 trans. New York 1954) was his main work on perception in

hearing, and his *Popular Lectures* (1881; New York 1962) range from painting through perception to physics and the basis of geometry.

Warren, R. M. and Warren, R. P. (1968). *Helmholtz on Perception: its physiology and development*. New York. A selection of Helmholtz's writings on perception, with a short life and excellent comments on his work and ideas.

HELVÉTIUS, CLAUDE ADRIEN (1715-1771). French encyclopaedist philosopher. In *De l'esprit* (1758) he set out to prove that sensation is the source of all intellectual activity. This work was denounced by the Sorbonne and condemned by the French parliament to be publicly burned. It was, however, translated into several European languages. His posthumous *De l'homme* (1772) is supposed to have influenced Jeremy Bentham.

HERACLITUS (c. 540 c. 480 BC). Greek PreSocratic philosopher, born at Ephesus; he founded a school in the Ionian tradition. Fragments exist of his *On Nature*, which is divided into 'On the Universe', 'Politics', and 'Theology'. It was placed in the Temple of Artemis, and it has been suggested that it was deliberately written so obscurely as to be intelligible only to aristocrats and scholars. Heraclitus's philosophy is based on unity in change; hence the famous remark of his follower Cratylus that 'you cannot step twice into the same river'. Apparent permanence of objects is attributed to conflicting movements or flows; the essential element is fire, out of which all else comes and perishes. In modern times this emphasis on change, and on permanence as illusion, is expounded by A. N. Whitehead.

HERBART, JOHANN FRIEDRICH (1776-1841), German philosopher and educator, born at Oldenburg. He was professor of philosophy at Königsberg and Göttingen. His account of mind essentially followed the philosophy of Leibniz. For Herbart the universe consisted of independent elements, called reals; though these were different from the Leibnizian monads, as the reals were not necessarily conscious. They were, rather, units of a causally interacting machine—which is very different from Leibniz's conception of preestablished harmony. Herbart defined psychology as the 'mechanics of the mind'; but at the same time he emphasized the importance of consciousness, explaining mental states and thinking as interactions of ideas. They were supposed to interact

somewhat as physical particles obey and represent or manifest the laws of physics.

Herbart believed that experimentation is impossible for psychology. He maintained that for psychology to be a science it must be mathematical. To this end he set up equations: for example, for how ideas are suppressed. He attempted to show how the mind could be atomic—with ideas as atoms, displaying attraction and repulsion as in Newtonian physics. Some ideas (such as a musical tone and a visible colour) would, however, not interact, except presumably in special cases of synaesthesia.

For Herbart ideas were in themselves active, and could struggle with one another to cross the threshold into consciousness, rather as the most active molecules of water escape through the boundary of surface tension. His philosophy of mind may appear absurd, in giving ideas independent vitality, but it did introduce concepts of suppression which reappear in Freud's account of the unconscious, and also, if more mundanely, in current theories of memory and forgetting by interactive inhibition.

His *Textbook in Psychology* was translated into English by M. K. Smith (2nd edn., 1891) and *The Science of Education* by H. M. and E. Felkin (1892).

HERING, EWALD (1834-1918). German physiologist, born and raised near the Bohemian border; the son of a pastor. He studied medicine in Leipzig in the 1850s.

His contributions to sensory physiology contrast distinctly with the main current of German science of his time. The outstanding representative of the latter was Hermann von Helmholtz, a thorough physicalist and empiricist. By careful attention to the findings in more basic sciences, coupled with thoughtful but still simple experiments, and rigorous application of mathematics, Helmholtz managed to place physiological optics and acoustics as well as thermodynamics on the solid foundations so magnificently utilized by twentieth-century science. But Helmholtz had

Page 311

strayed a long distance from the two giants of the German intellectual scene, Goethe and Kant. Their much more direct descendant was the physiologist Ewald Hering, who claimed also to have been influenced, as a student, by Schopenhauer and Fechner.

After gaining his MD, Hering stayed in Leipzig for several years, and before he was 30 had written a series of short monographs on visual space and eye movement.

They are slightly querulous in tone and do not now make the same impact as his contribution during

the following decades, but they obviously marked the author as a rising young scientist of significance. His first major academic post, as physiology lecturer in the Vienna military medical academy (the Josephinum), brought him into contact with Josef Breuer, who was later to work with Sigmund*Freud on the foundation of psychoanalysis. Together Hering and Breuer showed that respiration was in part controlled by receptors in the lung, which signal excessive distension and cause cessation of inspiration: the HeringBreuer reflex. The Josephinum was about to be dissolved, and in 1870 Hering accepted a call to be professor of physiology at the Charles University in Prague, where he stayed for twentyfive years, until returning to Leipzig as head of the physiology department in 1895.

In his physiological researches Hering sought a synthesis of physics and psychology. He epitomized his attitude to purely physical analysis in sensory physiology in his analogy of those who might understand a timepiece by dissecting it into component gears; would not a glance at its face and hands yield an indispensable insight into its function? Accordingly, Hering made the subjective phenomena of sensation fullfledged ingredients when assembling the bases for a physiological theory, most successfully in his theories of*brightness perception and*colour vision. In this he broke ranks with almost the entire materialist natural philosophy of his time, except indeed with*Mach, a colleague in Prague. Hering did not follow Fechner, who stressed a rather simple form of psychophysical parallelism. Nor was he entirely in the tradition of Goethe and Schopenhauer, who, while sponsoring opponent theories of colour vision, placed almost all the emphasis on the subjective elements. Hering's theories of light and colour postulated substances and neural processes that could go in two directions from their neutral point—anabolic and catabolic. To arrive at these formulations, he used not only the available data on colour mixture that had been basic to previous theories, but also the observations that subjectively yellow did not *appear to* be a mixture of green and red, that yellow was a stable hue with changes in intensity, and that*afterimages and complementary colours fitted best into an opponentcolour scheme. It took seventyfive years before electrophysiologists demonstrated the existence at the cellular level of Hering's mechanisms: centresurround organization of retinal ganglion cells; and opponent, i.e. excitatory *and* inhibitory, coding of colour. However, Hering was still very much a creature of the science of the middle of the nineteenth century. His postulated sensory and neural processing may have been more advanced and more encompassing than that of his contemporaries, yet he also believed it to reside in the cells of the organism. Its universality and presence at an early stage of development (in the case of perfect conjugacy of the eye movements even at or shortly after birth) led him to conclude that the mechanism for this kind of processing (i.e. of eye movements, of colour and brightness detection) was inborn.

In his most widely read essay (1870), Hering dealt with 'Memory as a general function of organized matter'. Because memory survives periods of unconsciousness (see MEMORY: EXPERIMENTAL APPROACHES) and*sleep, it cannot be merely associated with our*consciousness but must be regarded as a capacity inherent in brain substance and hence must follow the rules of purely material processes.

Hering's acceptance of compelling perceptual impressions as pointers of how the organism processes sensory inputs, and his willingness to postulate for them physiological, i.e. to him material, channels, at one time had great influence. A whole generation of researchers in perception followed Hering's

lead by basing their theories on rules derived from (to them) persuasive sensory judgements: *Gestalt psychology was a major force until well into the 1930s. While never popular with the physicalist researchers who have dominated sensory physiology and psychology from the 1930s to this day, Hering's theories had more unity of design and less of a dualistic component than those of, say, Helmholtz. The latter relegated certain visual phenomena, such as apparent contrast, to 'errors of judgement', whereas Hering looked at them as inevitable concomitants of the physiological organization that gives us good discrimination of colour or contrast or space. As the diversity and richness of neural connectivity of the mammalian brain is being displayed by modern neuroanatomy and neurophysiology, and the untold variety of possible pathways becomes evident, many scientists are turning again to Hering and his characteristically synthetic way of making theories.

G. W.

HERMETIC. Associated with alchemy, from the Greek god Hermes. This is the origin of 'hermetically sealed' jars, etc.

HEROPHILUS (*fl.* 300 BC). Greek anatomist, and founder of the medical school of Alexandria. He was the first person who is known to have dissected a human body and compared it with other animals. He described many bodily organs and was the first to distinguish between sensory (afferent) and motor (efferent) nerves.

See GREEK INVESTIGATIONS OF THE MIND AND SENSES.

Page 312

HEURISTICS. Serving to discover or solve problems, even when no *algorithms or rules exist, using rules which involve essentially a process of trial and error. An item of information or a rule used in the process is sometimes known as a heuristic for that problem. The term is especially important in *artificial intelligence and *cybernetics.

HIPPOCAMPUS. A region of the brain, in the lower part of the cerebrum. The old anatomists thought it looked like a seahorse, hence its name. There are two parts: hippocampus major (or horn of Ammon), and hippocampus minor. It is especially associated with memory. See NERVOUS SYSTEM.

HIPPOCRATES (*c.* 470 *c.* 370 BC). Greek physician born on the island of Cos. He practised medicine in Thrace, Thessaly, and Macedonia, before returning to Cos, where a school of medicine gathered around him. It is not known how much of the Hippocratic collection, consisting of some seventy books in the form of notes, is his own work. Some is known to be much later and indeed the collection may have been the library of Cos. Like his contemporaries, Hippocrates believed that disease was the result of an imbalance of the humours (see for example, INSANITY: EARLY THEORIES), but his emphasis on objective observation and critical deductive reasoning was enormously influential in separating medicine from superstition. He and his followers were the first to record case histories—some of the descriptions of disease contained in their writings are so vivid

that a modern diagnosis can be made. Of particular interest among the works is the treatise entitled 'On Wounds of the Head', which describes trephining—making holes in the skull. This is known to have been a prehistoric practice, probably usually intended as a means of releasing evil spirits from the heads of the afflicted, though Hippocrates describes trephining for what we would regard as rational medical usage. His ethical standards, largely embodied in the much later Hippocratic oath, have offered inspiration to the medical profession over the centuries and largely account for his reputation as the 'father of medicine'.

Singer, C. and Underwood, E. A. (1962). *A Short History of Medicine*, 2nd edn. Oxford.

HOBBS, THOMAS (1588-1679). British philosopher, born prematurely at Malmesbury, Wiltshire, when his mother 'fell into labour upon the fright of the invasion of the Spaniards'; Hobbes was later to say that his life was dominated by a constitutional timorousness. Foreseeing the impending civil war he went over to France in 1640—the 'first of all that fled'; in Paris he met Mersenne, friend and principal correspondent of Descartes, who persuaded him to contribute the Third Set of Objections to Descartes' forthcoming *Meditations* (published 1641). Hobbes's masterpiece, the *Leviathan*, appeared in 1651. This work is famous for its investigation of the basis of political authority. The authority of the sovereign (whether an assembly, or, as Hobbes preferred, a monarch) depends on the fact that supreme power is used to provide for the citizens that stability and physical security without which life would be 'a war of every man against every man' and the condition of humanity 'nasty brutish and short'. Hobbes's other works include the *De Cive* (1642), *De Corpore* (1655) and *De Homine* (1658), dealing respectively with political theory, the nature of matter, and human nature.

Though Hobbes is best known as a political theorist, he made a major contribution to the philosophy of mind. He may be regarded as an early exponent of a physicalist or materialist approach to mental phenomena. First, the universe is purely material, and contains none but physical things: 'the universe, that is the whole mass of things that are, is corporeal, that is to say body' (*Leviathan*, ch. 46). Second, talk of the soul as an independent substance that could be separated from the body is absurd: to say that something possesses a 'soul' is simply to say that it is alive (ch. 42). Third, statements about mental or psychological properties can ultimately refer only to the motions of matter in the body: 'all qualities called sensible are in the object that causeth them but so many motions of the matter that presseth our organs diversely. Neither in us that are pressed are they anything else but diverse motions, for motion produceth nothing but motion' (ch. 1).

J. G. C.

HOLMES, SIR GORDON MORGAN (1876-1965), Irish neurologist, was born in Dublin and studied medicine there at Trinity College. He was awarded a scholarship which gave him two years' study abroad after qualifying and went to Germany to work under Karl Weigert and Ludwig Edinger, the neuroanatomist. In 1901 he was appointed housephysician at the National Hospital for Nervous Diseases in London, where he stayed until his retirement in 1941, and later in his career also held consultancies at the Royal London Ophthalmic and Charing Cross hospitals. In 1914 he became

consulting neurologist to the British Army, and from 1922 to 1937 was editor of *Brain*.

For about ten years from 1901, Holmes was concerned mainly with improving the accuracy of neurological examination, and this he accomplished through research and stringent clinical observation. It led him to investigate the neurophysiology of sensory perception in the cerebral cortex and the location of sensations with (later Sir) Henry*Head. During the First World War, especially, his work on spinal and head injuries was of great importance.

Holmes was revered as a teacher and he inspired

Page 313

the many postgraduates who came to work under him. His *Selected Papers* (edited by Sir F. M. R. Walshe) were published in 1956.

D. D. H.

HOLT, EDWIN BISSELL (1873-1946). American philosopher and psychologist, who was a strong supporter of the behaviourism of J. B.*Watson. He is best known as the author of a book entitled *The Freudian Wish and its Place in Ethics* (1915) which attracted considerable interest in its day. Holt was essentially a philosopher by temperament and training, and reflected the close links between philosophy and psychology which were virtually taken for granted in the later decades of the nineteenth century but scarcely exist today.

HOME, DANIEL DUNGLAS (1833-1886). British*spiritualist medium, who was born near Edinburgh and went to America as a child. The phenomena for which he was to become famous there, and later in Britain and Europe (he was expelled from Rome as a sorcerer in 1864), included rappings, 'messages' from the dead, tables and chairs which apparently rose or tipped, musical instruments which seemed to play by themselves, and*levitation. He held many seances, some rigorously tested by scientists, for which he never accepted money, and while a few people who attended them remained unconvinced, none could find any evidence of dishonesty. See his *Incidents of My Life* (1863-72).

HOMEOSTASIS. The main concept of homeostasis is the principle of negative*feedback control, which was developed for military purposes in the Second World War. It is the basis of*cybernetics, whose founding fathers were Norbert*Wiener, Ross Ashby, and Grey*Walter. Producing stability in dynamic systems by negative feedback has, however, a history back to James Watt's governor for the automatic regulation of steam engines as their load varies, and the still earlier governor for windmills. There are even hints of the notion of feeding the output of a system back to its input for maintaining stability in some ancient Greek devices, described by Hero in the first century AD, especially for maintaining constant supply for waterclocks by a float and needle valve, as in modern

carburettors.

The term 'homeostasis' was coined some years before cybernetics, by the American physician Walter B.*Cannon, in his germinal book *Wisdom of the Body*, 1932. It is interesting that Cannon stated the basic idea of feedback as a fundamental physiological principle before it was properly recognized by engineers, though it had been used as it were implicitly, without recognition or understanding. Cannon explained the regulation of body temperature by mechanisms such as perspiring when the body is too hot and shivering when it is too cold, as maintaining the body's equilibrium by feedback signals from *what* is needed to *how* what is needed can be attained. It is now clear that this is an extremely important principle for almost all physiological processes, and also for the guiding of skilled behaviour.

HOMUNCULUS. Literally a 'manikin' or 'little man'. The term 'homunculus fallacy' is often used to condemn accounts of psychological processes which are vacuous or circular, because they ascribe to some internal device the very psychological properties which were being investigated in the first place. Consider, for example, a theory of vision which says that there is within the brain a 'soul' or 'sensorium' or whatever, that 'scans', 'views' or 'inspects' images on the retina: such a theory is vacuous, since 'viewing', 'scanning' and 'inspecting' are all instances of the very visual processes that the theory was supposed to be illuminating in the first place. At the crudest level such explanations invite us to imagine a 'little man' sitting inside the skull inspecting some neurological equivalent of a television screen on which images of the outside world are displayed. Such theories arguably commit the 'category mistake' of trying to locate, within the structure of the brain, events and processes that belong to a higher level of description.

The term 'homunculus' is also commonly used in artificial intelligence theory to refer to a subsystem which executes functions specified entirely in formal terms.

Whether reference to such homunculi is fallacious or circular hinges on the complexity of the functions they are supposed to perform. If the operations involved can be specified ultimately in terms of very elementary devices (e.g. very simple switching devices), then the role of homunculi in this context seems relatively benign. Thus D.

Dennett: 'homunculi are only bogeymen if they duplicate entirely the talents they are rung in to explain.... If one can get a team of relatively ignorant, narrowminded, blind homunculi to produce the intelligent behaviour of the whole, this is progress' (*Brain Storms*, p. 123).

HUBEL AND WIESEL: JOINT WORK. Their work on the visual cortex opened a new chapter in our understanding of the mechanisms of the brain. It started when David Hubel joined Torsten Wiesel in Steve Kuffler's laboratory at Johns Hopkins in 1958, and continued for twenty years after Kuffler moved his laboratory to the neurobiology department of the Harvard Medical School. Their outstandingly successful collaboration produced a

flow of important new discoveries year after year, and these will here be summarized under four headings: the pattern selectivity of single cortical neurones, their binocular connections, their anatomical arrangement, and their normal and abnormal development in early life.

Pattern selectivity. The striate cortex (area 17, or the primary visual area) contains some 10^8 cells, and in 1960 many people felt that recording from them just one at a time would not reveal much about how it all worked. But Hubel and Wiesel claimed that for each cell there was a specific pattern of excitation that would reliably excite it, and this obviously had a major impact. They discovered that the most important characteristics of the stimulus were its orientation, size, contrast (darker or brighter than the background), and which eye it was delivered to. The idea of 'feature detectors' was already a familiar one at that time and examples were known in the frog retina and arthropod visual systems, but theirs were the first examples in the mammalian nervous system, and the implications were revolutionary. Instead of thinking of the striate cortex as a structure with myriads of cells, each taking part in the representation of every visual image, one was forced to recognize that each cell had its own specific stimulus requirements, and that consequently when it became active it 'said' something specific about the nature of the image in its own particular part of the visual field. Not all their ideas about the hierarchical connections of cells or the mechanisms whereby pattern selectivity was achieved have stood the test of time, but theirs were the results that put the idea of feature detectors into the psychological literature.

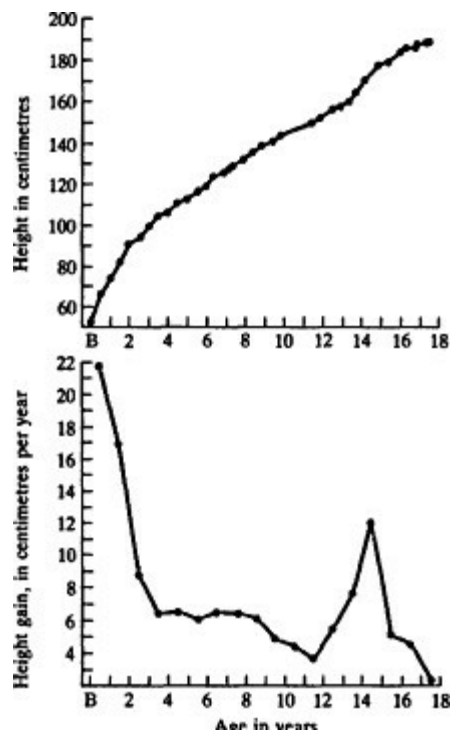

Binocularity. Cortical neurones are the first cells in the visual pathway that have access to information from both eyes. Hubel and Wiesel found that many of them could be activated through either eye or both together, and that in such cases the stimulus requirements were nearly the same, regardless of which eye was used. In other cases the cell could be activated only through one eye and not through the other, and there were yet other cells that could be strongly activated by one eye but only weakly by the other. They plotted the numbers of cells of each type as the 'ocular dominance histogram', and this turned out to be a sensitive tool for showing the influence of factors that disturb the normal development of cortical connections. It is, however, a potentially misleading tool, for we now realize that the main significance of the binocular connections of cortical neurones lies in the small differences of alignment of the connections from each eye; this is what makes different cells responsive to different disparities and hence gives information about the distance of objects from the

eyes. The ocular dominance histogram tells one nothing about this aspect, and it is therefore wrong to deduce from a normal histogram that the cortex is in a normal functional state. Hubel and Wiesel may possibly have been misled by this when assessing the role of experience in formulating the properties of the mature cortex.

Anatomical arrangement of cortical cells. This is the area of their greatest success, for they revealed an orderly arrangement of cortical neurones, constituting a microstructure, that was previously unsuspected. They were fortunate in that many new anatomical methods became available while they were engaged in the task of mapping this microstructure, but they were in the forefront in developing these methods and demonstrating their usefulness. The existence of a map of the visual field on the striate cortex was well known before their work, but this map is only accurate to distances of about one millimetre on the cortical surface. Each square millimetre contains some quarter million cells, and Hubel and Wiesel found first that neurones were grouped according to ocular dominance, each eye supplying irregular, alternating strips of cortex about half a millimetre wide. Orientation was also organized, for the preferred orientation of successively recorded cells tended to shift regularly through a small angle as the recording electrode moved across the cortex, a complete cycle occurring every 1 to 1 mm. It has subsequently been shown that cells preferring a particular spatial frequency (or size) are also clustered, as are those preferring particular colours. The final details of the arrangement of the cells according to their selective properties is not yet (1983) known, but there seems little doubt that Hubel and Wiesel have sketched the skeleton of this microanatomy.

Development. The clinical facts of amblyopia (poor sight not caused by defects in the visual system) have long suggested that visual experience has an important effect on the neural development of the visual system. As early as 1963 Hubel and Wiesel published their first results on this problem, showing that depriving a kitten of the use of one eye by closing its eyelids has the effect of permanently disrupting the connections that eye makes to the cortical neurones. This was shown by the bias of the ocular dominance histogram towards the eye that continued in use, and they were also able to modify the histogram by surgically induced strabismus (squint), and by occluding each eye on alternate days; both of these procedures leave many cells connected to each individual eye, but cause a marked reduction in the number of cells that receive connections from both of them, thus showing that these connections require associated use of both eyes to become firmly established. They later showed that these effects of deprivation only occur up to about 6 weeks of age in the cat, or 6 months in the monkey.

This was the first demonstration of a critical or sensitive period that has physiologically demonstrable consequences and is caused by changes to

Page 315

normal sensory messages. The results have been obtained consistently by many others and they are among the most robust and wellconfirmed findings in a field where not all claims have been substantiated. It is interesting that Hubel and Wiesel have consistently argued that experience does no more than preserve innately formed connections, basing this on the apparently normal responses and ocular dominance histograms found in young, visually inexperienced animals. Later results have shown, however, that immature and inexperienced cortical neurones lack the disparity selectivity and fine spatial resolution of adult cells, and that the cortex is therefore far from normal. Hubel and Wiesel have thus provided some of the best evidence for the effects of experience on the cortex, while making some of the most dogmatic statements on the predominance of ontogenetic factors in determining its properties. (See also VISUAL SYSTEM: ENVIRONMENTAL INFLUENCES.) Hubel and Wiesel's interpretations of their results have often been replaced by others which they, the pioneers, have vigorously resisted; even so, their results themselves have an enviable record of reliability. Furthermore, they led the field over a twentyyear period during which exceptionally rapid progress was made. It must be added, however, that their contribution cannot be finally assessed, for there is as yet no confident understanding of how the striate cortex helps us to see the world around us. David Hubel, Torsten Wiesel, and Roger Sperry received the Nobel prize for their work in neurophysiology, in 1981.

H. B. B.

HULL, CLARK LEONARD (1884-1952). American psychologist, born at Akron, New York. He originally intended to become an engineer but contracted poliomyelitis, and this obliged him to pursue a less taxing career. In consequence, he turned to psychology, obtaining his doctorate at the University of Wisconsin and eventually becoming a professor at Yale. His early work was concerned with the

measurement of attitudes and with an important study of hypnosis—almost certainly the first in which the experimental procedures were fully controlled and the results submitted to statistical analysis (see HYPNOSIS, EXPERIMENTAL). His major work, however, lay in the field of systematic*behaviour theory, in which he won considerable renown, though his attempt to evolve a hypotheticodeductive model of the learning process in animals and man has not stood the test of time (see BEHAVIOURISM and REASONING: DEVELOPMENT IN CHILDREN). None the less, he brought muchneeded rigour and control into research in experimental psychology. His books include *Hypnosis and Suggestibility* (1933), *Mathematico*

Deductive Theory of Rote Learning (1940), *Principles of Behaviour* (1943), and *A Behaviour System* (1952).

HUMAN GROWTH. A term which covers both the increase in size of individuals with increasing age, and change in shape during the same time. In considering either aspect it is fundamental to recognize the effects of sexual dimorphism in determining both change in size and differential change in shape between the sexes. See also SEX DIFFERENCES IN CHILDHOOD.

Growth in size. It is convenient to use growth in height as an example. Our knowledge of the pattern of growth can come only from repeated measurements on individual children as they grow. Fig. 1 shows the growth in height of a boy from 0 to 18 years of age, measured by his father every six months (see Tanner, 1978).

The upper panel shows the actual height measurements at each age, the lower panel shows the rate of growth at the various ages. Growth is a form of motion, and the former can be considered as distance travelled while the latter shows velocity. Two principal facts are shown by this figure: firstly the marked regularity of growth, and secondly the existence of three important epochs. From birth to about 4 years of age the child is growing very rapidly, but slowing steadily from growth rates of 20 cm per year to nearer 6 cm per year. Over the next six to eight

Fig. 1.

Growth in height of a boy (son of De Montbeillard, during the years 175977): (above) distance curve, height attained at each age; (below) velocity curve, increments in height from year to year.

Page 316

years the growth rate slows still further, but gently, so that the average velocity is about 5 cm per year. At 10 to 12 years of age the rate increases rapidly before finally slowing down to cessation of growth between 17 and 19 years. This general pattern holds for all muscular and skeletal measurements and for the more composite variables such as weight, but not for all body organs. Growth of the

reproductive organs is quiescent for many years and does not start properly until the onset of puberty. Then there is very rapid growth to adult size over five or six years. Growth of the lymphatic organs, such as the tonsils and lymph nodes, is considerable in early childhood, so that between 8 and 12 their size is actually greater than in the adult, although at puberty these organs regress to adult size. Lastly, braingrowth occurs very much earlier than general body growth, achieving some 95 per cent of mature size by the age of 6 years. (The growth and development of the human brain is discussed separately, under BRAIN DEVELOPMENT.)

Sex differences. On average, growth in height is little different between boys and girls until the onset of adolescence in girls, on average at about 10 years of age. Then the average girl starts her adolescent growth spurt and for one or two years she is taller than the average boy, who is still continuing to grow at a prepubertal rate. At about 12 years of age, by which time the average girl is at the peak of her growth spurt and starting to slow down again, the average boy starts his adolescent growth spurt. This is greater in intensity than in the average girl, so that not only does he reach equal height again but he goes further, to attain a greater adult height by some 12 cm. The excess of adult height in the male has two components. First there is the extra two years of growth at the preadolescent rate, and secondly there is the more intense growth spurt once adolescence begins.

A similar pattern is seen in other body dimensions, such as leg length, trunk length, and shoulder width. There are, however, some interesting sexual differences in timing and intensity. The growth spurt in shoulder width is more intense in the male than in the female, whereas that of pelvic breadth is rather similar between the sexes. The net effect of this is the greater shoulder breadth relative to pelvic width of the male. Thus the differential growth of these few simple dimensions is already beginning to produce differences in the *characteristic* shapes of the average male and female adult. Added to this are differences in the growth of subcutaneous fat.

During adolescence the average male actually loses subcutaneous fat and increases muscle bulk under the influence of male sex hormones. In contrast, although the rate of gain of subcutaneous fat slows down in girls, they do not actually lose it. The effects of female hormones on the distribution of body fat produce the softer female profile, compared with that of the male.

Differences between individuals of the same sex. There are two principal differences: first, in size at a given age, and, secondly, in tempo—the timing with which each individual reaches the various stages of physical growth.

The range of variation in size at any age is surprisingly large. The height of a perfectly normal 10yearold boy at the lower end of the range might be 124 cm, which is the same as that of an equally normal 6yearold at the upper end of his range. This variation increases with age, so that the normal range of height for 2yearold boys is about 14 cm, whereas for 10yearold boys it is about 26 cm.

With tempo—the differences in speed with which a child passes through the various stages of development—it is slightly more complicated. Thus a child with a fast tempo, who is always advanced in his growth, seems large compared with his peers, goes through an early adolescence, and finishes growing early. This is in contrast with the so-called 'late developer', who passes each of the

stages late compared with the average, and finishes growing much later. Such differences are most apparent in adolescence, and so are important when assessing individuals or groups of individuals at or after the onset of puberty: it is possible to find among boys of identical chronological age one who is preadolescent and another who is nearly mature. Clearly in such cases comparison is invidious and to be avoided; usually it is possible to relate growth to a maturity index, such as the stage of pubertal development.

Size at birth is generally related to maternal size; large women tend to have large babies. The size of the father is relatively unimportant, except in so far as, due to assortative mating, there is a tendency for large mothers also to have large husbands. It is believed that the dominant maternal influence is due to the environment within the uterus determining the intrauterine growth of the child. After birth, the influence of the father's size gradually increases, until, from about the age of 2, the child's growth is related principally to the average of its parents' heights, both exerting an equal influence. This association between the child's and the parents' heights remains fairly constant from then until maturity, although during adolescence it becomes distorted unless the child matures at an absolutely average rate.

Prediction of adult height. Without knowledge of a child's tempo, it is very difficult to make any sort of prediction of his final height from heights at earlier ages.

Given a measure of his skeletal maturity obtained from studies of Xrays, the possibility of prediction improves considerably, though there is still room for quite considerable error. For example, a prediction of the final height of a child of 9, with known skeletal maturity, is subject to a range of 14 cm in possible error. This range becomes progressively smaller the older the child is at the time of the prediction, but unless he is very near maturity it is always quite significant. A Page 317

large par of scope for error arises from the great unpredictability of the size and the timing of the adolescent growth spurt.

Environmental factors. Thus far, genetic factors have been our main consideration. Chronic illness of any sort may affect growth, usually to reduce and very rarely to increase it, and there are some diseases, such as deficiency of growth hormone, which have highly specific effects. Disease apart, nutrition is the most obvious environmental influence, and it varies from extreme, starvation situations, where children's growth may be grossly stunted, to less severe, suboptimal situations. With suboptimal nutrition there is a tendency for growth in size to be reduced overall, but relative to reduced weight and reduced body fat. Tempo is usually affected first.

Minor differences in diet, as between a child who is just rather 'faddy' about his food and one who eats heartily, do not produce significant effects on growth.

Socioeconomic class has long been considered to be a significant determinant of physical size. Generally, children from families of higher socioeconomic groups are taller than others. Part of the reason is nutrition, but it is probably due also to the general circumstance of the environment: children from betteroff families are, for example, less exposed to recurrent infection. The fact that in

the West such differences between socioeconomic groups are getting smaller, and in Scandinavia have almost disappeared, presumably relates to family income and size. The more children there are in a family, in general, the smaller they are, but again these differences are tending to decrease.

Allied to the socioeconomic effects are certain psychological problems. Without doubt, severe psychological stress may affect a child's growth. The condition may mimic organic disease, and severe growth failure may be apparent before it becomes clear that there are emotional difficulties. In such a situation resolution of the emotional problems leads to a prompt improvement in growth and usually to complete, or near complete, normality.

Although in general children appear to grow evenly over a span of years, in some cases there are quite marked variations within any one year. In about one-third of children there is a seasonal variation, most commonly with fast growth in the spring, and slower growth during the rest of the year. In a rather larger number there are less regular cycles, with the fast time not necessarily occurring at a fixed time of year; while in some children there is no variation at all. A child's growth should be considered over a whole period of one year; indeed, all growth standards are constructed on this criterion.

The most striking environmental effect of the last 150 years, called the secular trend, is the tendency for all children to grow to greater adult height and to mature earlier. Adult height has increased by approximately 1 cm per decade, while the first menstrual period has advanced from an average age in Norway of about 16 ½ in 1840 to about 13 at the present time. The cause of this secular trend is still obscure, but certainly includes improved nutrition (perhaps especially in infancy) and social circumstances.

Growth is the result of a continuing interaction between environmental and hereditary factors. It is a matter not of a simple additive effect of environment upon heredity, but of a complex interaction between the two that determines the timing of events and the degree to which various changes occur at different ages. The timing and degree vary between groups of individuals—between sexes, for example, or between ethnic groups—and in turn determine the final size and physical characteristics of the adult. But they do not materially alter the fundamental physique of an individual from that seen at a very early age. Thus it is that a child's ultimate adult appearance can largely be predicted from about the age of 5.

M. A. P.

Falkner, F. and Tanner, J. M. (1985). *Human Growth*, 2nd edn. New York.

Tanner, J. M. (1978). *Foetus into Man*. London.

HUMANISM. How does *humanism connect* with *humanity*? The dictionary doesn't help, both words have a cluster of meanings. The Renaissance humanists (for example, Petrarch and Erasmus) were so called because they felt that Christianity should be as much concerned with human affairs here on earth as with the afterlife in heaven and hell, and also because they were learned in the newly

discovered literature of classical Greece and Rome, which was rated as 'the humanities' because it was the secular work of man whereas the Bible and the patristic commentaries were treated as the divinely inspired works of God.

Contemporary humanism is a morally concerned style of intellectual atheism openly avowed by only a small minority of individuals (for example, those who are members of the British Humanist Association) but tacitly accepted by a wide spectrum of educated people in all parts of the Western world. The essence of this modern humanism is summed up in the following quotation from Vico, who was an eighteenthcentury Italian, though he wrote in the manner of the Renaissance humanists: '[it is] a truth beyond all question that the world of civil society has certainly been made by man and that its principles are therefore to be rediscovered within the modifications of our own human mind'.

Vico considered himself a Christian, but twentiethcentury humanists have no use for God either as an external force which interferes in the processes of nature and the affairs of men or as an arbiter of moral judgements. Many things that happen are the consequence of pure chance, but there is no point in deifying chance and treating it as a disembodied mind which might respond intentionally to prayer. The only intentional force in the world is our own human mind.

Page 318

But although modern humanists reject supernaturalism, they are not*behaviourists in any simple sense. They do not claim that all human action can be explained in terms of triggered responses to external stimuli. Humanists believe that we are capable of making choices, changing our minds, and telling lies. Men are therefore responsible for what they do. But this formula is less straightforward than it seems. Where is this 'I' located that can assume responsibility for what I do?

Let us go back to Vico, who was a thinker of great subtlety. Vico contrasted certainty (*certum*), which is what we learn from empirical observation, and truth (*verum*), which he thought of as a kind of structural model in the mind which we use to interpret the 'certainties' of our sensory experience. Hence history, that which we know as certain, is constantly transformed by the developing modifications of the mind through which alone we come to know what is true. Putting the same argument in a different way, Vico insisted that an external observer can never understand a product of human craft in the way that the craftsman himself understands it.

Comparably we can understand human history not only because men made it but because our understanding comes from the truths which we hold in our mind rather than from the certainties which we obtain as external observers.

The relevance of all this to humanism is that it bears on what we might mean by the concept *humanity*. In what sense is this creature 'man', who makes his own history as a carpenter makes a chair, 'other than' just an animal caught up in the accidents of fate? How is man different? What makes him a human being?

The religious answer to this question is that man has a soul; the atheisthumanist answer is that man has

a mind. But what do we mean by that? Significantly, both in German (*Geist*) and in French (*esprit*) soul and mind are covered by the same word.

Let us try to be more specific. Humanity is that which differentiates man from other animals. Where does that get us to? What can we do that they cannot do?

All animals have a limited capacity to discriminate and categorize other animals. They can recognize members of their own species and discriminate as to sex; they can distinguish food from notfood; they can recognize potential predators; some highly social species (for example, various insects, birds, rodents, baboons) can learn to discriminate neighbours from strangers. In man this last capability has been greatly elaborated. In the human case the development of a selfconscious 'I' which is contrasted with 'other' is closely linked with the formation of verbal concepts. The structure of speech, which is linear and segmented, encourages us to perceive our environment as consisting of separable 'things' and 'events' and 'categories' each of which can be described by a name. The discriminations which are indicated by such contrasts as 'I'/'other', 'we'/'they' are a part of this very general process.

But our thinking is not limited to this linear form in which we distinguish polarities, one thing after another. We also think by analogy (*metaphor), one thing superimposed upon another. Thus, while polarity may lead us to distinguish 'I'/'other', 'we'/'they', 'man'/'animal', 'tame'/'wild', 'cultivated'/'natural', analogy may lead us to feel that these pairs somehow resemble one another, so that 'we' are to 'they' as 'man' is to 'animal', as 'tame' is to 'wild', and as 'culture' is to 'nature'.

The way we make discriminations and the way we make metaphoric associations seems to be largely arbitrary so that, overall, there are many degrees of freedom built into the way we perceive the environment in which we live. A great deal of this 'freedom' (arbitrariness) derives from our use of language in category formation;

hence we may infer that other animals, which do not possess language, have a much more constricted perception of the world. To put it differently, because we have language we are able to convert sensory inputs into 'concepts in the mind' and we can play with these concepts in the imagination without reference to operations in the external world. We have persuaded ourselves that this is a human characteristic which is not shared by other animals.

The concepts which have been listed above all represent categories which derive from our experience of the external world, but language allows us to form other concepts which are wholly products of the imagination and which have no objective counterpart in the world out there. We can then use polarity to distinguish things in the world from products of the imagination, thus: 'man'/'God', 'mortal'/'immortal', 'imperfection'/'perfection', 'impotence'/'omnipotence'—and then, by the use of analogy, we may come to polarize 'impotentimperfectmortalman' against 'omnipotentperfectimmortalGod'. But this is precisely the dichotomy which modern humanists reject as superstition!

In some ways this is paradoxical since it is one of the peculiarities of our humanity that we should be capable of inventing such religious concepts at all. The point is however that whereas religion insists

that God created man in his own image, humanist scepticism maintains that man created God in his own (mirror) image and that it is only selfdeception which leads us to credit this mirror image with a potency which we ourselves lack. Humanists hold that religious faith is undesirable firstly because it encourages belief in what is false, namely that the human individual survives after death, and secondly because, by attributing omnipotence to God, it undervalues both the limited potency of man and the final responsibility that goes with it.

But God is more than a magnified nonnatural man; he is also the source of moral judgement and here the humanists run into difficulty.

During the nineteenth century atheistical moral

Page 319

ists believed that they could dispense with God the Moral Arbiter and substitute an equally metaphysical concept, Human Reason. At this stage in its development rationalist humanism was simply a variation of eighteenthcentury deism and was itself a form of religion which even developed a church hierarchy. Modern humanism has largely abandoned ideas of this sort, though the central humanist thesis that human beings are what they are because of their education rather than because they were created to be that way by God has persisted right through. But 'education' must here be understood in the broad sense of socialization. The individual is created by the whole social milieu into which he was born; my consciousness of myself is coloured by my class consciousness, by my community consciousness, and by my national consciousness of what 'we' are as against the 'others'.

When it comes to morality, humanists now recognize that each individual's conceptions of what is right and wrong will depend upon the circumstances of his upbringing. And since humanists reject the idea that there can be any absolute criteria for making such distinctions they are led to put an unusually high valuation on the virtue of tolerance.

Many religions preach tolerance, but they do not practise it. The divine commandment 'Love thy neighbour as thyself' has never inhibited Christians from inflicting every imaginable barbarity upon their neighbours in the name of true religion. But it was a sixteenthcentury humanist, Montaigne, who first complained that the contemporary treatment of heretics was far more horrible than anything that had been reliably reported of South American cannibals.

In this context the unique feature of humanism is that not only does it proclaim the virtue of tolerance but at the same time it denounces all forms of religious zeal, including zeal for humanism itself. In short, humanism is an intellectual attitude rather than the creed of a religious sect or political party; it provides us with a sceptical base from which to criticize the prejudiced certainties with which other people are prepared to proclaim the Will of God and the Destiny of Mankind, but it is not in itself a guidebook to any new kind of Utopia.

E. R. L.

HUME, DAVID (1711-1766). Scottish empiricist philosopher, born in Edinburgh. He studied law at

Edinburgh University, though he did not graduate, and took up commerce in Bristol, but without success. Indeed he came close to a nervous breakdown. In 1734 he moved to La Flèche in Anjou and there he wrote, while in his midtwenties, *A Treatise of Human Nature*, his masterpiece. As Bertrand*Russell (1946) points out, in the later shortened version, *An Enquiry concerning Human Understanding* (1748)—which became much better known—Hume left out the best parts and most of the reasons for his conclusions. Even so, it was the later *Enquiry* that awakened*Kant from his 'dogmatic slumbers': he does not seem to have known the *Treatise*. Hume also wrote *Dialogues concerning Natural Religion* (written in 1750, published posthumously in 1779), in which he discusses, with scepticism, proofs for the existence of God; on *Morals* (1751); and on politics and the history of England.

Hume is important for his systematic development of*Locke's and*Berkeley's empiricism; and for his critical discussions of*cause, and of the status of the self as no more than a 'bundle of sensations'. For Hume, the self is not an entity, for it is not an object of perception since there is no specific impression corresponding to 'I'. He somewhat similarly denies cause as usually considered, on the grounds that there are no logical connections between events.

Just as Berkeley banished *substance* from physics, as having no properties, so Hume banned *substance* from psychology. This follows in part from his view that there is no 'impression' of self, and so no 'idea' of self. In the *Treatise* (Book 1, Part iv, Sect. 6) he writes: For my part, when I enter most intimately into what I call myself, I always stumble on some particular perception or other, of heat or cold, light or shade, love or hatred, pain or pleasure. I never catch *myself* at any time without a perception, and never can observe anything but the perception.

Hume's graded distinction between *impressions* and *ideas* is fundamental to his philosophy. Thus (the opening sentences of Book 1, Part i): All the perceptions of the human Mind resolve themselves into two distinct kinds, which I shall call Impressions and Ideas. *The difference betwixt these consists in the degree and force and liveness with which they strike upon the mind, and make their way into our thought or consciousness.*

This leads to his treatment of belief (in Part iii): the 'force and liveness of the perception' is belief—and not inference, or the conclusions of inference. He argues this mainly from the example of causal beliefs; but he considers also belief in perceptions of objects. He accepts immediate experience of objects as absolutely certain.

This is indeed a feature of all empiricists, for perceptions are taken as the basis of all knowledge, and some knowledge is supposed to be unquestionably true in order to give a basis for certain knowledge—although empiricist philosophers seldom agree as to what knowledge is certain. For*Aristotle, and the later Scholastics, the causal relation, *A causes B*, is a logical relation to be discovered by understanding the*essences of *A* and *B*. This, for Aristotle, is explanation. But Hume realized that it would not do as an account of cause, or as a theory of explanation. He writes: 'There is no object, which implies the existence of any other if we consider these objects in themselves, and never look beyond the ideas which we form of them.' He thus argues that cause is not a logical relation; and also that we do not experience causal relations, though we may perceive events and objects. He suggests

infer cause from experiences of successions, of following *A* in time. This takes cause—and inductive inference—outside logic and into psychology. Hume raised problems here which are still not fully resolved. One of the difficulties is that *A* and *B* may occur in regular sequence, or occur together through some other factor, *C*.

It seems absurd to say, for example, that day causes night (or vice versa); or that winter causes summer, and yet they occur in regular succession. We would put the cause into our conceptual model of the solar system—the earth rotating With respect to the sun, and so on. But it remains a problem just why cause is supposed from some features of cognitive models—especially scientific accounts—and not from others.

Hume was disappointed by what he saw as his failure to justify knowledge as rational by showing that cause is not a logical relation, and that, *induction is suspect. This

'failure' is the basis of all modern sceptical philosophy. Although Kant said he was awakened from his dogmatic slumbers by reading Hume, he did not succeed in countering Hume's scepticism as to whether knowledge based on induction from observed instances could be rational knowledge. Ultimately, Kant's a priori categories of perceived space and time are not justifiable, either on rational or on empirical grounds. Even more generally, there is no justification of any principle of uniformity of nature for giving logical status to induction and prediction, except by inductions such as 'predictions have worked in the past, so they will go on working in future'. But this use of induction to support induction is clearly circular, and so cannot provide rational grounds for empirical knowledge.

The appalling consequence of Hume's sceptical arguments is that, strictly speaking, any belief is as justified as any other. So, strictly, there are no grounds for distinguishing madness from sanity.

This conclusion has led to retreat from demands for rational. certainty for empirical knowledge and belief, and towards essentially *relative* accounts of knowledge, in which even observations are accepted as being dependent upon assumptions, not all of which can be justified. This is well argued by the American philosophers Norwood Russell Hanson (1958) and Thomas Kuhn (1962; 1970). An alternative and very different approach is taken by Sir Karl Popper (1959, 1972). Popper takes the radical step of trying altogether to deny that there is any induction, in human or animal learning or in scientific discovery. He attempts this by suggesting their knowledge can only be gained by putting up and testing (by match or mismatch against the observed world) hypotheses, which must be framed so as to be testable.

For further discussion, see FALSIFICATION.

HUMOUR. Most popular dictionaries when defining 'humour' include the psychologist's three usages—stimulus, response, and disposition. Hence, for example, the *Concise Oxford Dictionary of Current English* refers to 'comicality', the 'faculty of perceiving', and 'state of mind'. It is extraordinary, therefore, that Dreyer's *Penguin Dictionary of Psychology* (the bestknown specialist dictionary for psychologists) provides a much narrower definition of humour and a provocative definition of laughter. Humour is defined as the 'character of a complex situation exciting joyful, and in the main quiet, laughter, either directly, through sympathy, or through empathy'; and laughter is said to be an 'emotional response, expressive normally of joy, in the child and the unsophisticated adult'. Dreyer's dictionary was published by Penguin in 1952, and it was revised in 1964. Today few psychologists, and perhaps no one currently researching humour and laughter, would endorse his definitions without substantial qualification. The psychological literature has burgeoned since the early 1970s, and we now know considerably more about humour, that ubiquitous phenomenon which most of us cherish so dearly.

Dreyer's reference to the 'unsophisticated adult' might startle many of us. Some would find it quaint, even amusing. It reflects a long period of history, finishing not so far back, when laughing was not so universally prized. In the eighteenth century, Lord Chesterfield, writing to his son, said '... there is nothing so illiberal, and so illbred, as audible laughter'; and others have said of laughter that it is 'the mind sneezing' (Wyndham Lewis), 'the hiccup of a fool' (John Ray), and that it '(speaks) the vacant mind' (Oliver Goldsmith). In the 1930s Ludovici argued that humour was a principal cause of the decadence of the times; and, for him, laughter was a sinister behaviour. More recently a number of writers have inferred from systematic analysis that it is only in contemporary times that humour and laughter have been regarded as important; and they point, for example, to the Bible, where there is scant mention of laughter, and such laughter as there is tends to be of a scornful kind.

Surveys indicate that these days nearly all of us believe that we have an above average sense of humour. That statistical impossibility might merely illustrate that 'sense of humour' has many shades of meaning, but in part at least it stems from the high value that society now places on humour. The possession of a good 'sense of humour', or the capacity to laugh frequently at pleasurable and amusing events, is regarded as thoroughly desir

able by almost all of us. Far from being base and degenerate, fit solely for the trivial and ignorant, the appreciation of humour is now taken as a sign of health and wellbeing. Humour is valued as a way of preserving order, changing group esteem and cohesion, expressing allegiances and revealing attitudes with relative impunity, testing the standing of a relationship, maintaining or undermining a status hierarchy, and so forth. The quality of our exchanges with other people can be greatly enhanced by the use of humour, whether or not it is injected as a deliberate play. Across a wide variety of everyday encounters, humour can be a crucial tool in our serial armoury, conscripted for attack and defence. Humour can be used by protagonists to precipitate an absorbing and pacifying digression: with little danger of rebuke, they can use it to defuse the threats of others by engendering a debilitating discomfort; and through it they can easily make light, or pretend to make light, of their own misfortunes and predicaments.

Beginning with Plato's *Philebus* in 355 BC, philosophers, essayists and others have provided a broad array of earnest and challenging statements concerning the nature of humour and laughter. Plato saw the weak as a justifiably prime target for humour. For Aristotle (in *Poetics*) the ludicrous was based in deformities, defects, and ugliness which are neither destructive nor painful. Notions such as these were revived in Hobbes's (1651) superiority theory: in *Leviathan* and *Human Nature* Hobbes presented laughter as a selfglorifying, triumphant gesture emanating from comparisons made with inferiors. The origins of incongruity theories can be traced back through Schopenhauer (1819) and beyond to Kant (1790), who talked of 'an affection arising from the sudden transformation of strained expectation into nothing'. According to Schopenhauer, laughter is the expression of our recognizing an incongruity, and Spencer (1860) limited it to descending incongruity: laughter naturally occurs when 'the conscious is unawares transferred from great things to small'.

There are various other forms of theory, the most influential of which has been Freud's (1905, 1928). His was a synthesis of incongruity, relief and conflict theories. A sharp distinction was drawn between 'the comic', 'wit', and 'humour'; and humour was said to grant relief through diverting energy from unpleasant emotion. In 'jokework' (i.e. making jokes) there is said to be a number of techniques each of which is also to be found in 'dreamwork', and the principal two of which are

'condensation' and 'displacement'. Both of these *techniques* require deviations from normal thought and representation, and both entail an economy of thought and expression. It was Freud's contention that the ludicrous always results in a saving in the expenditure of psychic energy: not only is the joke expressed with brevity, but amusement is taken to be the most economical response to the joke. Freud also maintained that both forms of economy could be false: energy can be liberated unnecessarily and then dissipated in expressing amusement. However, through techniques analogous to those of dreaming, humour can lift repressions; and in Freudian theory humour is amongst the most implant defences.

The pervasive view of the classic Greek and Roman scholars that humour and laughter are rooted in shabbiness and deformity persisted in various guises for many centuries, but it has been largely discarded in recent years as empirical researchers, particularly psychologists, have begun to

contribute significantly to knowledge.

There has been a genesis and development Of substantial strands of experimentation, and at the same time the quest for a grand theory has been generally abandoned.

No one seems sanguine about there ever being a grand theory of humour which is capable of embracing adequately all aspects of creation, imitation, and reaction.

Instead the new literature abounds with 'minitheories' which, typically, address stimulus issues (e.g. content, structure, complexity), *or* individual differences (e.g.

personality, cognitions, physiology), *or* overt expression (e.g. verbal and nonverbal reactions), *or* social influences (e.g. effects of companions and audiences), etc.

The minitheories differ from the older, global theories in a number of salient respects (cf. Keith Spiegel, 1972). For example, the older accounts, with few exceptions, were in effect statements of function or properties; they were little more than taxonomies of laughterprovoking stimuli, or descriptions of conditions under which laughter is sometimes evoked. The modernday accounts draw more on general principles in psychology, and most of them tacitly or explicitly acknowledge that laughter can find expression when there is a total absence of humour. They recognize that it may not be possible to delineate any set of circumstances under which laughter is never to be found. It can prosper under conditions of deprivation, pain and oppression: seemingly it can be observed in persons experiencing any of mankind's diverse emotional states. In his book *The Sere of Humour* (1954) the English humourist Stephen Potter summed up laughter's ubiquity as follows: We laugh when the sea touches our navel.... We laugh at something because it is familiar and something else because it is unfamiliar.... We laugh at misfortunes if they do not incur danger.... We laugh because other people are laughing.... Then there is the laugh which fills up a blank in the conversation.... The laugh of the older man talking to a girl, which can suggest: 'You are charming, but I am charming too.' The laugh to attract attention. ... The laugh ... which we hear in the hall from the new arrival not sure of himself, who wishes to appear sure of himself, and it makes us sure we are not sure of him. The laugh of the lone man at the theatre, who wishes to show that he understands the play or understands the resign language which is being spoken, or gets the point of the joke quickest, or has seen the play. The laugh of creative pleasure.... The laugh of relief from physical danger.... We laugh at funny hats ... we laugh at sex jokes. We do

not laugh at sex jokes if they are not funny unless other people are present.

While it is important to be aware that any particular instance of laughter need not have been triggered by humour, it is disturbing to find that the vast majority of humour researchers opt to exclude laughter and other behavioural measures from their indices of humour appreciation. It seems that humour loses much of its splendour, infectiousness and power under laboratory scrutiny, to such an extent that exuberant laughter is rarely elicited from experimental subjects. There is a need for more trenchant empirical work, and particularly research in 'the field', rather than for any continuation in the escalation of asocial, laboratory studies. As far as theoretical progress is concerned, no one has made noticeable headway in answering questions of the sort, 'Why does humour produce laughter, rather than, say, a more quiescent form of behaviour?' and 'Why should the enjoyment of humour climax in any overt response whatsoever?' Then there are other questions, barely more tractable, to do with the conditions necessary for laughter to feature in the repertoire of behavioural responses. The label 'humorous laughter' is to some extent a misnomer because research indicates that the quality and quantity of laughter which, temporally, follows a joke is primarily governed by social aspects of the prevailing situation in which the joke is presented.

It is generally thought that in the early stages of an individual's development a 'safe' or 'playful' mood has to be generated for the infant to engage in 'humorous laughter'.

Laughter maturationally precedes humour appreciation and first appears at about four months of age. An inevitable consequence of definitional disagreements is that distinguished scientific scholars (e.g. McGhee, 1979; Rothbart, 1980) dispute when humour is first experienced. Those who say that symbolism is an essential ingredient in humour (e.g. McGhee, 1979) report that humour does not occur until the second year of the child's life: only then does the child have sufficient capacity for fantasy and pretend activities. Others report that humour is experienced by children as young as four months (e.g. Pien and Rothbart, 1980). At that age they laugh when incongruous events are presented in safe situations, but then the cognitive resolution does not entail symbolic capacities. Rothbart (1976) observes that, for children this young, incongruity is limited as an explanatory principle: while the perception of an unexpected event may lead to laughter, it may instead lead to curiosity, fear, problemsolving or conceptlearning. For laughter, the incongruous event must be safe or playful, and resolution, or partial resolution, of the incongruity must be feasible.

Incongruity is defined in terms of a disparity between what was perceived and what was expected, and such a disparity is usually taken to be a necessary but not a sufficient condition for humour. Resolution refers to the rendering of the disparity as meaningful or appropriate, or to the discovery of a rule which renders the incongruity explicable within the context of the joke. We still have no model which satisfactorily embraces both the perception and resolution aspects of incongruities.

However, we do know from empirical work as well as from everyday experiences that incongruities can be too trivial or they can be too complex for humour to be experienced; and, independent of complexity, some themes (e.g. sex and aggression) are generally more comic than others.

A notable exception to the modernday brand of minitheory is that propounded by D. E. Berlyne. His

was an 'arousal' theory which enjoyed considerable support in the 1970s. Like Freudian theory, however, it has been gradually discarded by empirical researchers as they have increasingly dedicated their investigations to cognitive dimensions of humour. Berlyne's analysis was founded upon the view that moderate levels of arousal ('nonspecific drive') and changes in arousal are pleasurable, whereas high and low levels of arousal are not pleasurable. Humour was said to boost the individual's arousal to an unusual level until resolution of incongruity caused a sharp decline. Hence pleasure can result from the change *per se* and from the raising of arousal from an uncomfortably low level. It is not clear from Berlyne's writings whether arousal changes and humour appreciation are related in a linear, inverted U, or Ushaped fashion. Since it is possible to argue for any of these three possibilities, the theory is inherently untestable.

The superiority theories of yesterday were precursors of contemporary disposition theory (Zillmann, 1983), and that theory posits that humour emanating from disparagement depends upon a balance of affective dispositions towards the disparaged and nondisparaged parties. The theory predicts that humour appreciation will be strong when one is negatively disposed towards the disparaged party, and it will also be strong when one is positively disposed to the person purveying the disparagement. A principal difference between disposition theory and superiority theories (e.g. La Fave, 1977) is that the latter highlight both the debasement of an inferior and the enhancement of a superior, whereas in disposition theory the enhancement of the superior is a byproduct and is not essential to humour appreciation.

Disposition theory is especially useful when accounting for the success of jokes aimed at minority groups, such as the physically handicapped and psychiatrically disturbed. It is similarly useful when accounting for the pervasiveness of jokes aimed at demographic, political and ethnic minorities.

It has been claimed that women find jokes funnier when heard by the left ear, with the suggestion that this ear routes to the right hemisphere of the brain, which processes information more holistically than the left hemisphere, which is analytical. Could this be the basis for a biological explanation

Page 323
of sex differences in humour appreciation? Unfortunately, each ear is represented in both hemispheres (though with some contralateral preference) so this is hardly a serious suggestion. Clinical studies of patients with damage to the right hemisphere have identified correlated deficits in humour comprehension and appreciation.

However, it cannot be assumed that a cerebral 'centre for humour' is located in the right hemisphere. The operation of the left hemisphere is crucial in providing and organizing relevant information necessary to resolve perceived incongruity.

The bias of psychological theory and investigation has been towards a characterization of *responses* to humour. We know little about factors bearing on the creation and initiation of humour. Also, researchers tend to neglect fundamental conceptual and measurement questions, and they are too often insular in their approaches and objectives. None the less there is now much evidence to the effect that humour reflects basic underlying trends in emotional, social, and cognitive development.

HUMOURS, CLASSICAL. See INSANITY, EARLY THEORIES FOR.

HUMPHREY, GEORGE (1889-1966). British psychologist, born at Westgate-on-Sea, Kent, and educated at All Souls College, Oxford, where he was one of the last of the 'Bible clerks'—as the four undergraduates admitted yearly to the College were then known. After graduating in classical studies, Humphrey moved into psychology, then nonexistent in Oxford as a subject for undergraduate study. He studied first in Leipzig and subsequently at Harvard, where he obtained his doctorate in 1924. He was appointed to the Charlton professorship of psychology at Queen's University, Kingston, Ontario, where he built up a laboratory in which most of his own best work was done. Humphrey, whose special interest lay in the nature of conditioning and learning, did much to narrow the gap between German and American conventions in the approach to experimental psychology.

He returned to Oxford in 1947 as the foundation professor of psychology charged with setting up a new Honours school of psychology, philosophy, and physiology and with developing the then tiny institute of experimental psychology, which he took over on the resignation of the then director, Dr William Stephenson. From the start, therefore, psychology in Oxford evolved along clearcut experimental lines. While there can be no doubt that Humphrey's contribution to its birth was indeed substantial, the task of establishing and guiding the new psychology school imposed a severe stress upon his health and vitality, and appreciably limited his output in research. None the less, it is largely due to him that a major department of psychology came into being in Britain's senior collegiate university.

Humphrey's most important books are *The Nature of Learning* (1935) and *Thinking: its experimental psychology* (1951).

O. L. Z.

HUNGER AND FOOD INTAKE REGULATION. That organisms need to ingest nutrient is obvious; but what the mechanism is that controls such ingestion is not, and that is a question of more than academic interest. Disorders of the hunger mechanism, of which obesity is the most common, are cosmetically disfiguring and pose a very considerable danger to health, curtailing the life span significantly. Because of the threat that obesity poses, a large dieting industry has sprung up, which, as a result of misconceptions and ignorance of the normal hunger mechanism, is almost totally ineffective.

Normal humans and normal rats (and we know much more about rats) regulate their caloric intake so as to maintain their weight within close limits. Further, they are able to select various dietary constituents so as to maintain themselves in good health. Infants given a choice of a variety of foodstuffs at each meal thrive better than those whose diet is prescribed by a dietician, and so do rats. There are two questions posed by these observations. The first is how do organisms manage to regulate the amount of food eaten, and the second is how do they know which dietary constituents to choose. Let us start with the first question. To regulate the amount eaten there must be an internal signal which initiates eating, the introspectible counterpart of which we call hunger, and another signal which terminates eating, which we call

satiety. It is sad to report that we do not know what these signals are.

We have found that it is possible to induce eating through various interventions. Peripheral injections of insulin produce hunger, and injections of noradrenaline (norepinephrine) into the brain ventricles produce some increase in food intake. However, rats and people that do not secrete insulin still feel hungry and eat, and noradrenaline produces a drop in body temperature which itself will increase food intake. Secondly we have believed that we know where the biochemical change that produces hunger acts in the brain. Small lesions in the lateral hypothalamus in rats produce an animal that starves in the midst of plenty; and electric stimulation of the same area through chronically implanted electrodes induces vigorous eating in an already satiated animal. These experiments might seem fairly conclusive, but there are problems. A rat with a lateral hypothalamic lesion is a very sick animal, and

a number of peripheral mechanisms are disrupted by the operation: the effect on eating might therefore be indirect. Similarly, stimulation of the lateral hypothalamic area may stimulate other mechanisms which then induce eating. But the most devastating

objection is that it is also possible to induce eating simply by a sustained pinching of the rat's tail!

Although the exact identity of satiety signals still eludes us, some progress has been made in their discovery. The simplest idea was that termination of eating occurs when the changes that produce hunger are reversed. But such an idea must be incorrect because eating stops when the digestion of a meal has barely begun. Another idea has been that we learn to eat a certain amount of a particular food because such an amount has in the past eventually led to the reduction of hunger. Though there is some evidence that this can be a minor factor under some circumstances, it cannot by any means be the whole story, because when an animal eats and the food does not either reach or stay in the stomach, the animal may continue to eat until exhausted. This suggests that satiety signals are generated somewhere in the upper gastrointestinal tract, either in the stomach or in the upper part of the gut. Such a conclusion is supported by experiments in which food is placed directly in the stomach: great reductions in subsequent feeding are observed. Unfortunately, however, the reason for this result could be wholly artefactual, for it has been recently found that placement of food in the stomach causes nausea, which by itself could produce a reduction in eating.

As we have just seen, when food is not allowed to stay in the stomach, animals eat abnormally large amounts. One popular hypothesis for this has been that the nutrient does not reach the duodenum; and experiment has shown that if food is pumped into the duodenum and not allowed to stay in the stomach, then overeating does not take place. But this experiment also is not conclusive, for it has subsequently been shown that pumping of food into the duodenum causes discomfort or nausea. Secondly, the duodenum is sometimes considered to be the origin of satiety messages because it secretes the gastrointestinal hormone cholecystokinin, injections of which have been shown to reduce eating. But although this has been taken to indicate that cholecystokinin is a satiety hormone, subsequent research has shown that the same dose also causes nausea. Thus there is no compelling evidence that the duodenum or its hormones are involved in satiety.

There is now clear evidence, however, that satiety signals emanate from the stomach. It is possible to implant a pyloric cuff round the exit from the stomach of a rat, a cuff which, when inflated, prevents the escape of stomach contents into the duodenum, without causing distress to the rat. (The gut may be squeezed, cut or cauterized without producing pain or distress, while distension is aversive.) Also implanted in the stomach is a tube for the overflow when pressure in the stomach reaches the normal limit. Under these circumstances rats do not overeat, as they would if it was signals from the duodenum that produced satiety. A further experiment makes the same point in another way. A rat is allowed to drink nutrient to satiety and, after the pyloric cuff has been inflated, a certain amount of nutrient is drawn off through the stomach tube. The rat then begins to drink again, even though the content of the duodenum is unchanged. Moreover, if a rat drinks nutrient to satiety while the pylorus is occluded, and then nutrient is allowed to escape from the stomach to the duodenum, the rat will drink more nutrient, when it is presented, even though the cuff is inflated.

These experiments demonstrate that signals of satiety emanate from the stomach. However, we are not yet sure what such signals are. There are various possibilities. It may be that satiety arises when the stomach has been distended past a certain point. Or it could be that the stomach senses the total amount of nutrient in the volume ingested, and that it is this that signals satiety. We now have evidence that both may be true. Rats are allowed to drink under two conditions: in the first they simply drink nutrient to satiety; in the second they also drink to satiety but as the nutrient is drunk the same volume of saline is pumped into the stomach. If the stomach distension hypothesis is correct, the rats in the second condition should on average drink only one-half the volume of nutrient. If the theory of absolute amount of nutrient is correct, on the other hand, the same volume should be drunk in both conditions. The truth is complex. Rats that drink very large volumes to satiety support the distension hypothesis, but those that drink small amounts behave as if the absolute amount of nutrient theory is true. So it seems that satiety at small volumes is regulated by nutrient. However, past a certain point distension becomes an important cue in causing a rat to stop eating.

Page 325

There is other evidence that the stomach can sense nutrient when volume is kept constant. A hungry rat is given a choice between the contents of two tubes, each containing a different nonnutritive flavour. When it drinks from one of the tubes, nutrient made nonaversive by predigestion is placed in the stomach. When it drinks from the other, an equal volume of saline is placed in the stomach. Each training session lasts only ten minutes and a pyloric cuff is inflated during this period. The rat quickly learns to drink from the tube that produces nutrient in the stomach. We do not know as yet whether this sensitivity to nutrient is due to early absorption of small amounts of this nutrient or whether it is due to sense organs within the stomach. We do know, however, that the partial digestion is necessary for the nutrient to produce satiety signals. The rat secretes an enzyme at the back of its tongue which splits a portion of the fat or oil into its constituents. When a rat drinks oil and we place some of the same oil directly in the stomach, thus bypassing that part of the early digestive process due to the enzyme secreted by the tongue (lingual lipase), there is little or no reduction in the amount that the rat chooses to drink. On the other hand, an amount of predigested oil, drawn from the stomach of a donor rat, when placed in the stomach reduces the volume drunk by the same amount.

If, as seems likely, the sense organs are in the stomach, we do not know how they relay their messages to the brain. It is known that the stomach produces hormones which could affect the brain via the bloodstream, and it is also known that a large number of nerve fibres carry messages to the brain via the vagus and splanchnic nerves. But it has been found that sectioning of the vagus does not affect a rat's ability to monitor nutrients in the stomach: a rat with its vagus nerve cut still compensates accurately for any nutrient removed from the stomach during a meal. On the other hand, it no longer stops eating in response to overdistension of the stomach.

So far we have spoken of hunger as if it was a single phenomenon. However, in order to obtain an adequate diet most organisms must select a balanced mixture of foods, because they must satisfy not only their caloric needs, but their protein, vitamin, and mineral requirements as well. The mechanism of selection varies from one requirement to another. For instance, the appetite for common salt is 'wired in' or built in: when a shortage of sodium occurs, whether it be through dietary insufficiency or

malfunction of the adrenal cortex, the shortage is directly translated into a craving for a particular taste—the taste of salt—and the rat does not have to learn that the ingestion of salty tastes has beneficial consequences. There are other types of deficiency, on the other hand, where the rat has to learn what food will relieve the deficiency. The way this happens is rather curious. The deficient rat begins to prefer any novel foodstuff; it seems to develop an aversion to its normal diet. If the novel diet relieves the symptoms of deficiency the rat will then learn to consume it even if the relief is not immediate.

Generally learning occurs only if a few seconds at the most separate an act, or a signal, from its consequences; but this is not true in the case of eating. If a rat eats poison, it will learn to avoid its taste even if sickness due to the poison occurs between 10 and 24 hours later. Similar taste avoidance has been noted in children who have eaten icecream of a certain flavour before undergoing chemotherapy. Clearly organisms must learn what foods are good for them, although learning is not necessary in every case. In the same way as the example of salt, aversions can also be 'wired in'—and that is as true of sweet as of bitter substances.

'Wired in' aversions and preferences have consequences for weight control. It has been shown that rats fed palatable diets maintain much higher body weights than those whose diets are unattractive. Another finding is that rats fed diets low in calories compensate by eating more. Now the stockintrade of the diet food industry seems to consist of two main items. The first is the substitution of sugar as a sweetener by nonnutrient substances such as saccharin. The second is the sale of food that has a lower number of calories per unit weight or volume than normal food. Now, if calories per unit volume are reduced and there is no restriction on the volume that can be eaten we would expect from the results of research that the volume eaten would increase to compensate. And as for saccharin, when it was shown that it was carcinogenic, the major argument for its retention as a food additive was that it made dieting easier; but as we have seen above, making a food palatable, or less aversive, increases its intake. One of the major aims of food production and preparation is to make food more attractive both by the addition of substances which are palatable and by removing tastes and textures which are aversive. Such gastronomic practices have almost certainly led to much ill health and a curtailment of life span through a general increase in obesity and other disorders.

HUNTINGTON'S CHOREA. Several types of cerebral degeneration occur which lead to loss of mental powers in middle age. All are rare. One type is Huntington's chorea, which owes its name to George Huntington (1850-1916), an American physician, who first described the disease. Among its cardinal features Huntington mentioned 'a tendency to insanity and suicide'. In the early stages spontaneous movements give the impression of clumsiness and fidgetiness, but, as the disease progresses, the characteristic jerking and writhing movements become more prominent, particularly affecting the face, tongue, and upper limbs, although, ultimately, all parts of the body musculature may be involved. The disease runs in

families, and its pattern of distribution within families shows it to be due to a single autosomal dominant gene. It survives because the average age of onset is in the middle thirties, late enough for most carriers of the gene to have begotten children. The patients described by Huntington were said all to be descendants of a family of three brothers who had emigrated from England.

Two expectations have to be met before a disease is attributed to a dominant gene. One parent must have been affected, and the proportion of children affected must not depart significantly from onehalf. Cases of Huntington's chorea do occur occasionally in which neither parent seems to have been affected. In some of these, a parent has died young; in others, there is doubt about the identity of the father. The proportion of children affected has usually been found to be about one in three.

The probable reason why this falls short of onehalf is that a relatively high proportion of the sibship have died young; some of those affected die before birth.

The course is progressive, with increasing disability due to the loss of neurones leading to*dementia. The cerebrum atrophies and loses weight. The ventricles enlarge.

The caudate nucleus and putamen of the midbrain are especially affected. Severe*depression is a common complication which may end in suicide attempts or actual suicide, which is the cause of death of 7 per cent of nonhospitalized patients.

Numerous attempts have been made to identify carriers of the gene before they enter the reproductive period of life but, so far, none has been of proven validity. In any case, predicting a progressive, incapacitating neuropsychiatric illness in somebody who may at the time be relatively healthy raises ethical problems which may outweigh the potential eugenic advantages.

HUSSERL, EDMUND GUSTAV ALBERT (18591938). The name of the German philosopher Edmund Husserl is associated with one of the most important philosophical revolutions of recent times. If one had to name the major changes which occurred in philosophy at the end of the nineteenth century, Husserl's*phenomenology would doubtless be mentioned, together with the developments of Marxist thought and of early*logical positivism. The case of Husserl calls for special attention in view of his deep influence on the overall field of disciplines which we label today human sciences and which include psychology, sociology, and philosophical anthropology, as well as classical humanistic sciences such as history and philology. Linguistics, which also contributed to the transformation of human sciences, evolved autonomously and became important much later, as testified by the relatively recent developments of structuralism and semiotics. The striking fact in Husserl's case is that, starting from the philosophy of mathematics, he succeeded in elaborating a radical philosophy of*consciousness, from which a general epistemology as well as a new kind of psychology developed in the course of time. For these reasons, it is impermissible to consider

Husserl's phenomenology just as one philosophical system among others.

Husserl's investigations began with his *Philosophy of Arithmetic* (1891), which was intended to lay the foundations of a philosophy of mathematics. In this initial phase, Husserl analyses the concept of number from both the psychological and the logical points of view. From the psychological point of view, numbers do not only correspond to sets of elements liable to be counted, they constitute wholes beyond the capacities of immediate perception as soon as they include a large quantity of units. From this moment on, they only exist for consciousness as wholes expressed by symbols. This theory of symbolic wholes foreshadowed the basic principle which was to be fully developed by Gestalt theorists in later years.

The second phase of Husserl's work began with the *Logical Investigations* (1901). His main concern was then to establish the foundations of logic outside psychology, namely against the empiricists' contention that the basic principles of logic could be ultimately referred to psychological laws. As a result, the main effort of Husserl's philosophy centred for many years on a fundamental criticism of *psychologism*, i.e. the conviction that not only logic, but every field of knowledge would be rooted in psychology, being the science dealing with consciousness. The reasons for rejecting psychology as *the* fundamental science are twofold. First, from the point of view of logic and of mathematics, the psychologistic postulate leads to internal contradictions within the theoretical systems because it can be established that psychology, *as a science*, is necessarily a subsystem of a more extensive one comprising at the outset the minimal postulates which psychology needs to proceed as an organized field of knowledge. Secondly, in Husserl's time, scientific psychology, then mainly represented by early psychophysics and experimental psychology, was not in a position to furnish sufficiently rigorous proofs of its supposed founding role within the general framework of the theory of knowledge.

Consequently, the *Logical Investigations* stressed the fact that the logical structures exist independently of their psychological correlates and that the search for the psychological aspects of the logical acts as subjective experiences must itself be conducted beyond the realm of psychological science. In other words, if we want to study adequately such experiences, we are bound to turn to a descriptive science of psychic acts. Such an enterprise needs a science of phenomena, i.e. a *phenomenology*. It is, however, clear that if phenomenology is to be such a basic 'descriptive psychology' it has to cope with the *essences* of our subjective experience and not with the concrete

Page 327

scientific facts as evidenced in experimental psychology.

We see, thus, that in his attempt to situate the phenomena of experience in their proper subjective perspective, Husserl broadens Brentano's theory of intentionality up to a general epistemology, amounting finally to a radical theory of subjectivity. This implies that the descriptive dimension of phenomenology should evolve towards a *transcendental* mode of analysis, in which the point of view of natural science is 'bracketed', i.e. left out of consideration, but not eliminated because every act of consciousness is intentionally directed towards some object. This is the sense of his so-called

'reduction'.

Husserl's search for an adequate science of phenomena, as outlined in the second part of his *Logical Investigations*, was further developed in his *Ideas* (1913). In the period between 1901 and 1913 he produced two major works: *Die Idee der Phänomenologie* (1907), and *Die Philosophie als strenge Wissenschaft* (1911), in which the philosophical dimension of his epistemological strivings is thoroughly developed.

Because of its radical standpoint, Husserl's phenomenology is in a sense an attempt at founding the philosophy of all possible philosophies, which amounts to raising the basic question of the ontology implied by every act of knowledge. At the beginning of his career, Husserl believed he could locate the science of phenomena by drawing a fundamental distinction between the natural standpoint and that of pure transcendental phenomenology, the latter being freed from psychologism by the process of 'reduction' ('bracketing' of the natural). Towards the end of his life, he left aside his first idea of founding pure phenomenology on a descriptive (or phenomenological) psychology and expected to find a more suitable startingpoint in an analysis of man's lifeworld (*Lebenswelt*).

This last phase of his research is represented by his work entitled *The Crisis of the European Sciences and Transcendental Phenomenology* (German edn. 19357; English trans. 1970). The main thesis developed in this important book deals with the historical consequences of Western science for everyday experience. Husserl contends that in striving to build up an objective picture of reality, scientific practice has progressively cut off subjective experience from the lifeworld to such an extent that Western man is in a permanent state of crisis, i.e. he feels that science is the only source of facts and loses consequently his lived relation to the historical and social reality of life. In brief, Western man is deprived of the immediate evidence of his world considered as the realm of significant relations to objects and to his fellow men, and is condemned to rely only on intermediate abstract constructs: the lifeworld is concealed by the transcendental act of scientific elaboration. *The Crisis* shows with a wealth of detailed analyses how *objectivism* (i.e. the belief in the exclusivity of science in reaching wellestablished truths) has replaced actual *objectivity*. Once again, if objectivity is to be established as the intentional result of the activity of consciousness, we need an a priori epistemological theory of phenomena. This brings us back to the necessity of phenomenology as the startingpoint of every rigorous mancentred philosophy.

In attempting to appreciate Husserl's undertaking, we must not forget that his theory of transcendence was rooted in a basic analysis of logic, aiming at a radical refutation of psychologism and of the mistaken attempts of individual sciences to present themselves as the fundamental discipline governing the development of other fields of knowledge. It must also be pointed out that though Husserl stresses the necessity of an a priori theory of phenomena in order to lay the foundations of any human science, his philosophy calls for a 'return to things themselves', i.e. to the primary experience of the subject in his world. The meaning of experience as the founding fact of Husserl's philosophy is therefore radically opposed to the positivistic outlook, according to which the scientific constructs as such are the only basic facts.

Considering the specific case of psychology, it is certain that phenomenology has profoundly

modified its epistemological situation as a potential rigorous science. As a consequence, scientific psychology is now evolving towards a mancentred discipline under the heading of *phenomenological psychology*, an expression which should not be confused with Husserl's own attempt at elaborating the preparatory phase of his critical analyses. Presentday phenomenological psychology is in search of a new kind of empiricism, in which the subject, the observer, and the methodology which allows them to communicate are situated within a new functional framework. This framework allows a more adequate formulation of experimental, clinical, and social problems, and avoids a mere transposition of naturalistic postulates to a field of research in which subjectivity must be considered as a founding fact of the human lifeworld.

HUXLEY, THOMAS HENRY (1825-95). English biologist and palaeontologist, born in London. He studied medicine but failed to complete his degree. He served on the four-year cruise of HMS *Rattlesnake* (1846-50) and undertook detailed studies of marine life, for which he was elected a Fellow of the Royal Society. In 1854 he was appointed lecturer of natural history at the Royal School of

Page 328

Mines (now Imperial College) in London. Huxley explicitly rejected the possibility of evolution until he read Charles Darwin's *Origin of Species* (1859), upon which he became 'Darwin's bulldog', propounding the theory in public on many critically important occasions and thus protecting Darwin from the public appearances which he found onerous and tiring. Huxley was in his own right a first-rate scientist, and he also supported popular education. His essays *Man's Place in Nature* (1863) contain his philosophy. He coined the term 'agnostic', following Hume in his theological questioning.

HYPERAESTHESIA. Extreme sensitivity to touch and a low pain threshold.

HYPEROPIA. See EYE DEFECTS AND THEIR CORRECTION.

HYPNAGOGIC HALLUCINATION. An extremely vivid image, usually visual, which is often experienced when one is dropping off to sleep, or, less commonly, immediately on awakening. Unlike fully fledged dreams, hypnagogic states are to a large extent under the control of the will and can be described to a second person on, or immediately after, their occurrence. Hypnagogic images are often said to possess an overwhelming sense of reality, with much detail and supersaturated colour.

An interpretation of hypnagogic phenomena along the lines of Freud's celebrated theory of dreams (see FREUD ON DREAMS) has been put forward by a Belgian psychologist, J. Varendonck, to whose book on *The Psychology of Day Dreams* Freud himself contributed an introduction. Varendonck places much emphasis on the role of preconscious thought and wishful thinking in hypnagogic phenomena, but it might seem more probable that these possess a physiological basis related to the incipient onset of sleep or partial awakening.

O. L. Z.

HYPNOSIS, EXPERIMENTAL. In the course of the twentieth century, interest in hypnosis has largely passed from the physician to the experimental psychologist, whose concern is with its nature and mechanisms rather than with its therapeutic efficacy. While a few scattered experiments, such as those of D. R. L. Delboeuf, were reported towards the end of the nineteenth century, the modern era in the study of hypnotism may be said to have been ushered in by the work of Clark L.*Hull and his coworkers at Yale University in the early 1930s. While militantly disowning hypnotism's murky past, Hull insisted that hypnosis is an essentially normal phenomenon that can be studied in precisely the same way as any other mental capacity which varies from one individual to another. His book published in 1933

represents the first systematic attempt to apply the experimental and statistical methods of modern psychology to the study of hypnosis and suggestibility.

Hull's work was to a considerable extent designed to cast doubt on the extravagant claims current in some quarters that individual capacity in the hypnotic state might transcend the limits of the normal. Thus it has been argued that exceptional feats of sensory discrimination, of muscular strength, or of*memory might be performed in the hypnotic state, suggesting that hypnosis *per se* enhanced many aspects of human capacity. Hull and his coworkers were able to show that whereas hypnosis as such does not appear to confer any obvious advantages, it is none the less possible to influence human performance, sometimes dramatically, by hypnotic suggestion.

For example, he produced evidence of some increase in muscular capacity, more especially in sustained resistance to fatigue, and alterations in threshold of a variety of sensory stimuli, whereby the lower limits of intensity of stimulation necessary to produce a conscious sensation were appreciably raised. As regards memory, whereas no improvement in the reproduction of recently memorized material under hypnosis could be demonstrated, there was some evidence that memories of childhood might become more readily accessible. Hull's work, while producing no real evidence of the transcendence of normal capacity in hypnosis, did undoubtedly demonstrate the reality of many classical hypnotic phenomena (for example, hypnotic anaesthesia or analgesia and posthypnotic amnesia) under reasonably wellcontrolled experimental conditions. His work also served to bring out the essential continuity between the effects of suggestion in the waking and the hypnotic states.

Experimental hypnosis rapidly expanded in the 1950s and 1960s, some of its foremost representatives being F. X. Barber, E. R. Hilgard, M. T. Orne, and T. R.

Sarbin. One of the main preoccupations at this period was the construction of standardized scales of hypnotic susceptibility, of which the best known and most widely used were the Stanford scales devised by A. M. Weitzenhoffer and E. R. Hilgard in 1961. The rationale of their construction and use was well described by Hilgard (1965) and one need only comment here on some of the more interesting findings. In the first place, contrary to traditional belief, there is no real evidence that women are more readily hypnotizable than men, or are capable of greater depth of hypnosis. In the second place, a critical period seems to exist as regards hypnotic susceptibility. While it has long been known that children are in general more easily hypnotized than adults, it has been found that children between the ages of 8 and 12 are more easily hypnotized than either older or younger children. The advantage may lie in part in the fact that whereas children of 8 and below find sustained concentration difficult and are readily distracted, children above the age of 12 or so have developed greater powers of self-criticism and are

Page 329

consequently less suggestible. Although changes in hypnotic susceptibility over the adult life span do not appear to be striking, the natural history of hypnosis is certainly deserving of closer study.

From Hull onwards, experimental methods have been widely used to study such classical phenomena of hypnosis as hypnotic anaesthesia or analgesia (Hilgard and Hilgard, 1975) and sensory deceptions or hallucinations. In some ingenious experiments, Hilgard has shown that it is not difficult to induce selective deafness for sounds of weak intensity—for example, the ticking of a watch—without interfering with the subject's perception of the experimenter's voice. In susceptible subjects, it may even prove possible to effect profound attenuation of sensation within a particular sensory modality, such as touch or pain. Experiments by A. M. Halliday and A.

A. Mason (1964) have, however, shown that, in such cases, the nervous messages from the sense organs do in fact reach the relevant areas of the cerebral cortex, where they give rise to electrical responses ('evoked potentials') of normal amplitude. It therefore seems that the conscious sensory responses with which these electrical activities are ordinarily correlated must undergo some form of suppression or dissociation. That this is so is strongly indicated by a dramatic experiment of Hilgard's, in which he showed that a hypnotized subject in whom a profound loss of pain sense had been induced by suggestion, and who entirely denied feeling pain when appropriately stimulated, did in fact admit to doing so when tested by automatic writing, the content of which was ostensibly unknown to him. This is a classical example of hypnotic dissociation of the kind much discussed by Pierre Janet (see HYPNOTISM, HISTORY OF) and other early expositors of the relations between hypnosis and hysteria. It strongly suggests that hypnotic anaesthesia and analgesia are true dissociative phenomena rather than mere exaggerations of ordinary suggestibility.

Sensory deceptions (illusions) and even hallucinations induced by suggestion have also been demonstrated on occasion, using healthy, volunteer subjects in an experimental situation, but only in those whose susceptibility to hypnosis is unusually high (Hilgard, 1965, pp. 12949; Weitzenhoffer, 1947, pp. 1537, 28695). In such cases, a distinction should be made between the generation of behaviour appropriate to an imagined object, which is not difficult to induce, and the production of what is described by the subject as a true perceptual experience (hallucination proper). For example, Hilgard has shown that many subjects will react positively to the suggestion that a fly has alighted,

say, on their face, by grimacing or brushing it off. This might almost be regarded as playacting in the sense of T. R. Sarbin and others who stress the 'roleplaying' element in hypnosis. Even so, a few such subjects will say when asked that the experience was very real and lifelike, suggesting a true positive hallucination. Further experiments, in which it is suggested that the subject will perceive two dim lights, when only one is shown, likewise on occasion elicit surprisingly convincing reports of a hallucinated experience. It is possible in such cases that suggestion in alliance with the artificial hypnotic state has produced a condition akin to *dreaming, in which a visual image can assume the vividness and reality of an actual external object. At all events, such phenomena seem to magnify, if not transcend, the effects of suggestion in the ordinary waking state.

Similar considerations also arise in connection with so-called age regression, in which a subject aged perhaps 20 is told that he will experience himself as he was when, say, 10 years old (Hilgard, 1965, pp. 16775; Gill and Brenman, 1966). He will thereupon comport himself, superficially at least, in accordance with his suggested age. Without further or more specific suggestions being given, he will commonly write or draw in a strikingly more juvenile manner and may even develop an apparent disorientation, stating, for example, that he is in the school he attended at the age of 10 and that the experimenter is a schoolmaster at that time known to him.

In such cases it is often difficult to decide whether the patient is an accomplished, if unintentional, actor or whether there is a genuine reactivation of long superseded attitudes and modes of behaviour, i.e. a true regression to an earlier state of the person and genuine reenactment of the past. One simple test might be to suggest to him that he should progress rather than regress in age, and see to what extent he can duplicate the presumed behaviour of a very much older person. It is also entirely conjectural whether regression, as some believe, can be pursued into earliest infancy.

As might be expected, experimentalists have given much attention to the relationship between hypnosis and ordinary *sleep (see Hull, 1933, pp. 193243). Although subjects often refer to lethargy, drowsiness, and diminished contact with reality as characteristic of hypnosis, it seems clear that this state, whatever its nature, differs categorically from normal sleep, with or without dreaming. As James Braid observed in the nineteenth century, the muscles do not relax as in ordinary sleep and the subject does not drop an object held in the hand as he becomes hypnotized. Further, *reflexes which disappear in sleep can be elicited normally in the hypnotic state.

Finally, study of the electrical rhythms of the brain (*electroencephalography) shows that the electroencephalogram (EEG) in hypnosis in no way resembles that in any of the recognized states of sleep but is essentially identical with that of ordinary wakefulness. From the electrophysiological point of view, therefore, the hypnotized person is awake.

Let us now turn briefly to theories of hypnosis. William *James wrote in 1890 that the suggestion theory of hypnosis may be approved, provided that we regard the trance state as its essential prerequisite. Although the term 'hypnotic trance' is seldom used today, most people regard the hypnotic state as something *sui generis* with its own peculiar

properties. In addition to greatly enhanced suggestibility, these are commonly said to consist in voluntary suspension of initiative, restriction of attention to a narrow field, and marked reduction in selfconsciousness and critical appraisal. Some would add that the hypnotized person, much like the dreamer, is not fully in contact with reality and exhibits a facile mode of reasoning ('trance logic') in some respects characteristic of childhood. Although the state of hypnosis lacks definite physiological or biochemical criteria of an altered state of consciousness, it does not of course necessarily follow that no such criteria will ever be discovered. Indeed, it is only in comparatively recent years that firm physiological correlates of ordinary dreaming have been securely established.

None the less, this lack of physiological criteria of the hypnotic state, together with its resemblances to many phenomena in ordinary waking life involving the effects of suggestion, has induced some recent workers, in particular F. X. Barber, who has published much useful work in experimental hypnosis, to argue that the concept of a trance state is an unnecessary assumption (Barber, 1969). As he sees it, hypnosis is to be viewed as an essentially normal state of waking consciousness in which a voluntary compact between experimenter and subject enables each to exercise his respective role, which is, so to speak, enshrined in traditional expectation. Although such a view has the merits of parsimony, it fails to account for many features of the hypnotic state, such as spontaneous posthypnotic amnesia in highly susceptible subjects, loss or diminution of pain sense, and the operation of posthypnotic suggestion. Further, the production of sense deceptions and hallucinations is more reminiscent of the effects brought about in indisputably altered states of consciousness, such as may be produced by drugs or toxic agencies, than the ordinary operations of waking suggestibility.

To say this is not of course to deny that there are important psychogenic factors in hypnosis which are closely related to suggestion and fantasy in daily life. Josephine Hilgard, in particular, has emphasized the links between susceptibility to hypnosis and the propensity to become immersed in novels, plays, and films and to participate in the fictional existence of the characters. She likewise stresses the element of identification with parents or other emotionally significant figures in early life, and indeed calls attention to many aspects of hypnosis, among them the blurring of fantasy and reality, the ready involvement in games of pretence, and the tendency to believe uncritically in the pronouncement of others, which may be viewed as 'part and parcel of childhood' (Hilgard, 1965, pp. 343-74). But just as dreaming, in itself essentially psychogenic, presupposes the altered state of consciousness characteristic of a certain stage of sleep, so it may be argued that hypnosis, likewise essentially psychogenic, presupposes the less dramatic alteration of consciousness formerly known as the hypnotic trance.

In conclusion, one may ask whether experimental hypnosis presents any hazards. By and large, the procedure seems harmless enough, though medical men rightly warn that it can be dangerous if the subjects should happen to include emotionally disturbed individuals or those with a history of psychiatric illness. In such cases, the experimenter may well lack both the knowledge and the experience to handle the emotional relationships, positive or negative, which may unwittingly be generated in the process. A related question is whether experimental hypnosis calls for ethical guidelines. We know, for example, that certain types of psychological experiment involve calculated deceit, as in the work of Stanley Milgram on obedience. Milgram explained to his subjects that it was necessary for the purposes of his experiment to deliver shocks of potentially lethal intensity to other

human beings, and he found, somewhat to his surprise, that many subjects were prepared to undertake this in spite of their ignorance of the deceit which was being practised upon them. (See OBEDIENCE.) If such an experiment were repeated under conditions of hypnosis, it is entirely possible that even greater conformity with the instructions of the experimenter would be forthcoming. While it remains true that, in general, hypnotized subjects cannot be induced to perform actions that are morally repugnant to them, and that the danger of crimes being committed as a result of hypnotic suggestion appears to be extremely small, there is no doubt that any form of experiment on the effects of suggestion, with or without hypnosis, must be regarded as open to potential abuse. It is to be hoped that the psychological fraternity will take due notice of these hazards and introduce appropriate ethical guidelines for the conduct of human experiments, in particular those making use of hypnosis.

HYPNOTISM, HISTORY OF. The term 'hypnotism' was invented by a contemporary of John Elliotson (see MESMERISM), James Braid (1795-1860), who spent much of his life as a general physician and surgeon in Manchester. Like Elliotson, Braid was introduced to mesmerism by a visiting French magnetizer, but he seems from the

Page 331

start to have held no belief whatsoever in animal magnetism and was quite convinced that the phenomena he had witnessed at a mesmeric seance were attributable to natural causes. The so-called mesmeric trance (i.e. the altered state of consciousness into which the subject had passed) Braid attributed to prolonged fixation of the eyes on a bright object that the magnetizer had used to induce a sleeplike state. Indeed Braid repeated this induction procedure with a number of volunteer subjects—including his own wife—and became at once convinced that his explanation was in principle correct. He supposed that protracted ocular fixation brings about a state of fatigue in the relevant brain centres which eventually causes the subject to enter into a state which he called 'nervous sleep', allied to, but

not identical with, natural*sleep. The doctrine of 'nervous sleep' as a condition in which functional nervous disorders could be successfully treated he called *neurhypnology*, and the state itself *neurhypnotism*, later contracted to plain *hypnotism*. The latter he defined as 'a peculiar condition of the nervous system induced by artificial contrivance'.

Although Braid came later to specify 'contrivances' other than fixation which may be used to induce hypnosis—for example, sustained concentration on the hypnotist's words—his initial idea that the hypnotic state is similar to natural sleep and, like it, of physiological origin, was widely accepted at the time. Braid also attempted treatment of certain conditions which are nowadays recognized as purely organic—for example, speech disorders resulting from strokes. Any success that may have attended his efforts in such cases can almost certainly be ascribed to the effects of hypnosis in reducing the patient's anxiety or selfconsciousness in relation to his disabilities. There is no good evidence that any wholly organic nervous or mental illness responds favourably to hypnotic treatment.

With the passage of time, Braid's ideas about the nature of hypnotism underwent considerable modification. Although he never abandoned the concept of 'nervous sleep', he laid weight increasingly on the role of psychological factors in its origin. First, he came to stress the importance of sustained mental concentration rather than physiological fatigue in the induction of hypnosis, and in this connection laid great emphasis on the subject's restriction of consciousness while under hypnosis. The subject's attention is virtually absorbed by the words and actions of the hypnotist to the exclusion of all else, and this state Braid called *monoideism*. Secondly, he came to appreciate the obvious role of suggestibility in giving rise to the bizarre and on occasion dramatic phenomena that can be induced under hypnosis. In short, it is often said that Braid was the first person to appreciate that hypnotism is essentially a psychological phenomenon and cannot satisfactorily be explained wholly in terms of brain physiology.

Again like Elliotson, Braid made extensive use of hypnosis in his medical practice, and the variety of conditions he attempted to treat was indeed catholic. It was in surgery, however, that 'neurhypnology' (whether called mesmerism or hypnotism) made its most dramatic impact. As early as 1842, a Nottingham surgeon named Ward had amputated a thigh during a mesmeric trance, apparently without producing pain. Although his report gave rise to widespread incredulity and the patient was in some quarters branded as an impostor, similar cases were soon reported, some of them attested by Elliotson himself. The foremost exponent of hypnotism as a method of painless surgery was, however, the Scotsman James Esdaile (1805-59), who practised for many years in India. (See Bramwell, 1913, for an account of his work.) Esdaile reported over 300 cases in which he had performed major operations on hypnotized patients, apparently without causing pain. These included amputations of limbs and the removal of very large scrotal tumours. In spite of strong professional disapproval, his claims were endorsed by a special committee of investigation wholly composed of medical men, appointed by the deputy governor of Bengal. Indeed Esdaile continued to use hypnotism to induce analgesia until chloroform came into general use, and persisted until the end of his life in the belief that as an anaesthetic chloroform was much inferior to hypnosis. (In modern times, hypnosis has seldom, if ever, been used as an anaesthetic agent in surgery but has found some application in dentistry, particularly with children.) After Braid's death, interest in hypnosis languished for some years. This undoubtedly reflected the received view of the medical profession that it failed to meet

the criteria of 'legitimate medicine' and, in spite of the demise of animal magnetism, was still tarred with the brush of quackery. In the 1880s, however, there was a marked revival of interest in hypnosis (as hypnotism now came to be generally called), partly due to the appearance of Braid's writings in French and German translations, and partly to its endorsement by the great French neurologist J. M.*Charcot as a valuable technique in the study and treatment of*hysteria. Further, an interest developed among a number of Continental physicians, mainly French and German, in studying the phenomena of hypnosis in a relatively systematic way and without paying primary regard to its therapeutic implications. Among those who wrote widely on hypnosis at this time were Moll and Heidenhain in Germany, Forel in Switzerland (who was also an authority on the social insects), and*Binet and Féré in France. There was much discussion at this period of alleged alterations in sensory acuity and of illusions and*hallucinations, said to be evoked in highly susceptible subjects in the hypnotic state. Exceptional feats of sensory discrimination and memory were often described, although many of these claims have since proved to have been very much exaggerated. Posthypnotic suggestion, first Page 332

described by Moll and others, evoked great interest. This consists in particular actions or patterns of behaviour suggested under hypnosis but carried out by the subject some time after being awakened. It is shown by some subjects though not by all and is commonly explained or justified by the subject in terms of facile rationalization. The production of changes in nervous activities not normally under conscious control—for example, the raising of blisters in response to instruction under hypnosis—likewise attracted much interest and is still imperfectly understood. Although most of these experiments were carried out by medical men in the course of their clinical practice, it was in this period that the experimental study of hypnosis was born. Even in sceptical Britain, the results of an inquiry into the phenomena of hypnotism sponsored by the British Medical Association in 1891 left little doubt as to the genuineness of many of the phenomena hitherto described in the literature.

None the less, it was the medical applications that remained central to the study of hypnosis well into the twentieth century, and it was only then that interest largely passed from the physician to the experimental psychologist (see HYPNOSIS, EXPERIMENTAL). HERE THE LEAD WAS TAKEN BY THE FRENCH.

CHARCOT, WHO BECAME INTERESTED IN THE NATURE OF HYSTERIA LATE IN HIS CAREER, WAS MUCH STRUCK BY THE EASE WITH

WHICH MANY OF THE SIGNS AND SYMPTOMS OF THIS ILLNESS COULD BE DUPLICATED IN THE HYPNOTIC STATE. INDEED HE

QUICKLY CAME TO CONCLUDE THAT ONLY THOSE INDIVIDUALS WITH HYSTERICAL PREDISPOSITION ARE SUSCEPTIBLE TO

HYPNOSIS, WHICH IN FACT HE REGARDED AS A KIND OF 'ARTIFICIAL HYSTERIA'. HIS PUPIL, THE DISTINGUISHED MEDICAL

PSYCHOLOGIST PIERRE *Janet, argued that in both hysteria and hypnosis the patient is liable to

dissociation, i.e. the splitting of certain mental capacities, skills, or memories from the central stream of consciousness which in consequence become inaccessible though in no sense genuinely lost. For instance, the patient may lose his memory as a result of a frightening or otherwise stressful experience but it can often be restored completely by hypnotic suggestion. Janet claimed that a dissociated activity, whether produced spontaneously in hysteria or artificially in hypnosis, may continue to exercise its effects even though these are not consciously appreciated. For example, a patient suffering from hysterical blindness who genuinely claims, and believes, that he can see nothing, is seldom observed to collide with obstacles; at an automatic level, therefore, his vision continues to guide his behaviour. Following from such observations, Janet did much to arouse interest in the conception of subconscious mental activity and to introduce methods of therapy which aimed at the reintegration of the dissociated aspects of the personality.

Another pioneer in the medical applications of hypnosis was A. A. Liébault (1823-1903), of Nancy, an unpretentious provincial physician who made much use of hypnosis in his general practice (see Batmwell, 1913). Although appreciating that individuals differ markedly in their susceptibility to hypnosis, Liébault's experience convinced him that everyone in principle could be hypnotized, given a sincere wish to cooperate with the hypnotist. (Indeed he considered that the nervous and hysterical were among the most refractory of his patients.) In this connection Liébault placed great emphasis on the factor of *rapport*, i.e. sympathetic relationship between doctor and patient, in the absence of which attempts at hypnosis are seldom successful. Although *rapport* as a rule involves an element of authority, it would be wrong to suppose that hypnotism is a wholly autocratic procedure. It involves very real mutual cooperation between the hypnotist and his subject, and may indeed be viewed as in some sense a product of their relationship.

Liébault also placed a good deal of emphasis upon the factor of *suggestibility*, which even more than Braid or Charcot he regarded as a key factor in generating the effects of hypnosis. In this respect, he owed much to H. Bernheim (1837-1919), a professor of medicine at Nancy, who viewed the exaggeration of normal suggestibility as an all-embracing explanation of hypnotism. This issue of suggestibility enjoyed a considerable vogue in French psychology, being adduced not only by Charcot as a dominant characteristic of the hysterical patient, but by psychologists such as G. Le Bon in explanation of the social contagion *characteristic* of panic and mob rule. Attempts to measure suggestibility and its relationship to hypnotic susceptibility have much occupied contemporary psychologists.

As is well known, Sigmund*Freud studied with Charcot, and on his way home visited Nancy, where he met Bernheim. Although critical of his authoritarian manner, he later spoke with admiration of his 'astonishing arts'. Back in Vienna, Freud worked for some years with Josef*Breuer (1842-1925) and together they developed a method of treatment which involved the reenactment of stressful experiences under hypnosis with full and uninhibited expression of emotion. This procedure was termed* *abreaction* and is usually regarded as the precursor of the psychoanalytical method. It is still used sometimes today, especially when combined with intravenous sedation ('narcoanalysis').

Freud turned against hypnosis for several reasons, of which the chief seems to have been his distrust of all psychotherapeutic procedures based on authority rather than rational analysis. As he saw it, the

relief of neurotic symptoms by hypnosis and suggestion does nothing to help the patient to understand the nature of his symptoms or the resistances which deny him insight into their deeper significance. In short, only symptoms are relieved and the causes of neurosis are left untouched.

Although not everyone agrees that direct suggestion is never effective or that insight necessarily ensures recovery, most contemporary psychotherapists share Freud's distrust of hypnosis

Page 333

as a therapeutic tool. (For a more detailed account of Freud's views, see FREUD ON HYPNOSIS.)

HYSTERIA, long supposed disease of women, was attributed by Hippocrates to the movement of the womb (*hystera*) from its normal anatomical site into other parts of the body. The feelings of constriction in the throat, so typical of hysteria (*The Suffocation of the Mother*, by Edward Jorden, 1603), were thought to be caused by the uterus becoming lodged in that region. It followed, therefore, that men, since they do not have a womb, would not be affected by this disease, although Thomas Sydenham (1682) maintained that they were able to suffer from the symptoms experienced by the opposite sex. The belief that hysteria was a disorder confined to women had a long innings, and*Freud's report to the Vienna Medical Society in 1886 that men too could be affected by it was not well received. As an elderly surgeon remarked, 'But my dear sir, how can you talk such nonsense? Hysteria means the uterus. So how can men be hysterical?' (Stafford Clark, 1967).

Like many other words used in psychiatry, hysteria has been given many meanings. The following list shows how a disease that was once considered to be a single entity has been given different interpretations according to the nature of the symptoms and the theories proposed to explain them: (i) Hysteria as a personality disorder: for example, histrionic personality, or attentionseeking personality. (ii) Conversion hysteria, presenting a variety of neurological disturbances such as paralysis, convulsions, losses of sensation, blindness, speech abnormalities, and ataxic gait. (iii) Hysteria as a dissociation phenomenon manifested as fugues, twilight states, amnesias and multiple personality. (iv) Hysteria as a disease entity affecting women. There is also (v) hysteria as a term of abuse.

(i) Hysteria as a personality disorder. Hysterical personality is one of those misnomers that bedevils the subject, largely because it is often assumed that individuals showing the features of it are liable to develop other forms of hysteria. On the whole, the evidence does not favour this belief, and the term should be discarded in favour of one of the synonyms. The dominant characteristics are shallow, labile emotions, manipulative behaviour, a tendency to overdramatize situations, a lack of self-criticism, and a fickle flirtatiousness with little capacity for sustained sexual relationships. It has been said that these qualities add up to a caricature of femininity; and as men are rarely labelled hysterical personalities it is likely that the old association of hysteria with uterine disturbance is responsible for the transformation of hysteria as a disease into an adjectival description of a constellation of certain behavioural characteristics.

(ii) Conversion hysteria. Freud's theory of hysteria, based largely on his treatment of female patients in late nineteenth-century Vienna, proposed that repressed sexual conflicts, which, if brought to consciousness, would arouse anxiety and distress, were converted into physical symptoms that symbolized the repressed wish and permitted the anxiety to be dispelled—the so-called primary gain. As Fenichel (1955) wrote, 'In conversion, symptomatic changes of physical function occur which, unconsciously and in a distorted form, give expression to instinctual impulses that previously had been repressed.' The lack of emotional response of the patient to her symptoms, for example a paralysed limb, was referred to by Janet as 'la belle indifférence des hystériques'. In fact hysterics are by no means as free from anxiety as they might appear to be. Understandably, considering the time and place of Freud's original communications on hysteria, his emphasis on repressed sexuality in the female as a cause of neurosis aroused a good deal of hostility. But Charcot, the great neurologist in Paris, whose clinic Freud had visited, once remarked, 'Hystérie, c'est toujours la chose sexuelle'—a point reemphasized by Freud when he wrote, 'I do not think I am exaggerating when I insist that the great majority of severe neuroses in women have their origin in the marriage bed.'

As time has gone by this emphasis on repressed sexual drives as a cause of conversion hysteria has declined. Some writers have considered the roles of anxiety and depression in the genesis of hysterical symptoms, and others have stressed the importance of secondary gain, particularly when symptoms persist in compensation cases following accidental injury. The hysteric is nothing if not suggestible; and susceptibility to suggestion, especially in those of a relatively unsophisticated nature, could be an important determinant of the site and type of a conversion symptom.

(iii) Hysteria as a dissociation phenomenon. Janet considered dissociation to be an important component of some hysterical symptoms. These include fugues (wandering away from one's usual environment, with subsequent amnesia), trances, multiple personality and twilight states. The individual who enters into a fugue state is sometimes escaping from an intolerable situation or suffering from a severe depression. This wandering behaviour has been equated with an act of suicide, with the patient seeking some state of

Much attention has been given to the phenomena of multiple personality, and the famous case of Sally Beauchamp, described by Morton Prince (1854-1929), has been succeeded by other wellpublicized examples. There is reason to think that the subject's suggestibility and the amount of attention focused on the alleged change of personality to some extent perpetuate and elaborate the phenomena. Multiple personality can sometimes be of forensic interest when the defendant blames her *alter ego* for the offences of which she is accused. Obviously it is difficult to prove beyond reasonable doubt claims of this kind. In any case, multiple personality is a rare condition, and only its dramatic and bizarre nature is reason for the disproportionate interest in it. See DISSOCIATION OF THE PERSONALITY.) (iv) **Hysteria as a disease entity.** The old concept of hysteria as a disease peculiar to women was gradually abandoned in the face of evidence that a great variety of hysterical symptoms affect men as well as women. The revival of the disease entity concept by psychiatrists in St Louis, USA, under the label Briquet's syndrome—

the name derives from a French author who published a monograph on hysteria in 1859—has been criticized on the grounds that it appears to be resurrecting the ancient myth of a sexually determined illness confined to women. Indeed, many of its symptoms are functional disorders of the female reproductive system. Multiple surgery to treat such symptoms, and a variety of other abdominal complaints of a psychogenic nature, result in what is known in some hospitals as 'the thick file syndrome'. This is largely because of the sheer number of the patient's records and reports on multiple investigations that accumulate over the years. It could be argued that 'thick files' could not develop in a society which did not have welldeveloped medical and surgical technology; but all the same such patients are not the most welcome in busy outpatient departments, not only because of the time required to unravel their histories but also because of the sense of therapeutic and diagnostic hopelessness that overcomes the examining physician.

(v) **Hysteria as a term of abuse.** The layman—and sometimes the medical practitioner—faced by tiresome, noisy and overdramatic behaviour may be inclined to react with 'Pull yourself together and don't be so d—hysterical'. As the behaviour that provokes this kind of response has much in common with the chief characteristics of the hysterical personality, it is more likely to arouse antipathy when the subject is a woman. An 'attack of the vapours' is an older term used to describe such 'hysterical' behaviour by women; when the 'wandering womb' hypothesis of hysteria was discarded, it was replaced by the notion that noxious vapours could rise up from the womb to the brain and produce symptoms which today would be called conversion hysteria, especially hysterical convulsions.

Although there can be no doubt that psychological disturbances play a considerable part in the genesis of hysterical symptoms, it is important to realize that in nearly twothirds of patients presenting to hospital with such symptoms, there will be some evidence of preexisting or developing brain injury or disease (Slater, 1965;

Whitlock, 1967; Merskey and Buhrich, 1975). It has been suggested that the capacity for manifesting acute hysterical illness is something which is built into the central nervous system to protect it from overwhelming stress. If the brain is damaged or diseased, there is an increased possibility for this innate mechanism to spring into action, especially if an added psychological stress serves as a trigger. Thus hysterical symptoms may be the first indication that some hitherto unsuspected brain disease is

developing. Conversion hysteria in older patients with no previous evidence of psychiatric morbidity should alert the physician to this possibility. Indeed, given the high incidence of brain disease in patients with hysteria, it has been suggested that the time has come for the word as a noun signifying a disease entity to be relegated to psychiatric history. But this is unlikely to happen for, as Lewis (1975) has written, 'A tough old word like hysteria dies very hard. It tends to outlive its obituarists.'

I

IBN ÀRABI or IBN ALÀRABI (Sheikh AbuBakr Muhammad ibnÀli Muhyiuddin, called the Greatest Sheikh/Sheikh AlAkbar/Doctor Maximus, 11641240). He was born in Murcia, Spain, a descendant of the illustrious Arabian family of Hatim Tai, and died in Damascus. His work influenced Western thought and literature: for example, Asin Palacios and others have argued for textual copying by Dante in the *Divine Comedy*. He was a most influential*Sufi teacher who wrote, according to*Jami, over 500 works, mostly in Mecca and Damascus; in 1234 he himself reckoned them at 298 volumes. About ninety are extant, mostly in manuscript. Ibn Àrabi's *Tadbirat* (Managements) is an important manual of Sufi training. The *Fusus alHikam* (Bezels, or Phases, of Wisdom), written in 1230, is his bestknown work. Each of its twentyseven chapters is named after a prophet or teacher and deals with the Sufi principles which that teacher is said to represent.

He is associated with the doctrine of Unity of Being (*Wahdat alWujud*), which is characterized by his critics as pantheism. Although he claimed to have no master and to have been initiated into Sufism by Khidr, a spiritual being, A. E. Affifi (1939) places him firmly in the context of the Spanish Sufi thought of his time. His work constantly appeals to the Koran and traditions of Muhammad, though his interpretations are idiosyncratic. Two other major works are *The Meccan Revelations* and *The Interpreter of Desires*, both attacked by pietists as mere lovepoetry but successfully defended by the author as mystical allegories. By a curious tradition in the East, pious men sporadically assemble groups of students and charge them with the literary study of Ibn Àrabi's works. The intention is either to exhaust their capacity for research, or for them to discover the authorities who state that Ibn Àrabi's

works are not meant to be understood but to produce bafflement. This realization, according to these Sufis, drives the students to seek the current living exemplar of the teaching who alone can explain the writings.

IBN BAJJAH (AbuBakr Muhammad ibnYahya ibnalSaigh, c.110638). A major*Islamic thinker, poet and musician, scientist and mathematician, Ibn Bajjah was a forerunner of Averroës. Known to the Latin Schoolmen as Avempace, or Avenpace, he was born in Saragossa, Spain, and known in his lifetime as the prime exponent of Aristotelian thought after*Avicenna. He follows*AlFarabi and his work greatly influenced Ibn Tufail. Averroës himself states that his own ideas of mind are derived from Ibn Bajjah. His *Ilm alNafs* (Science of the Soul) is the earliest text hitherto known that gives the gist of all the three books of the *De Anima* of*Aristotle, and he is known, among other things, to Western scholars for his theory of separate substances, which they adopted from him. In his *Guide to the Solitary* he deals with the soul's return to reality by detaching itself from matter.

Leff, G. (1958). *Medieval Thought*. Harmondsworth.

IBN HAZM ('All ibnHazm, 9941064). A native of Córdoba, Spain, he was the first scholar of comparative religion, and Hitti (1951) characterizes him as anticipating theological problems only arising in Christian Europe in the sixteenth century. Guillaume (1949), in referring to this author of over 400 books, accepted in the west as the greatest scholar and the most original thinker of Spanish Islam (see ISLAMIC PHILOSOPHY), notes that he composed 'Europe's first *Religionsgeschichte* and the first systematic higher critical study of the Old and New Testaments'. This is his *AlFasl filMilal wàlAhwà wàlNihal* (the Decisive Word on Sects, Heterodoxies, and Denominations); but he also wrote lovepoems. In *The Necklace of the Dove* he extols platonic love, and his romanticism is regarded as related to the SpanishArabian influence on the formation of the troubadour mentality.

IBN KHALDUN (AbuZaid AbdalRahman ibnKhalidun, 13321406). Born in Tunis, he was one of the greatest*Islamic scholars of Moorish Spain, Arab ambassador to Pedro the Cruel, judge and professor of jurisprudence at Cairo. Author of the *Muqaddima* (Introduction), the first analysis of history by political and social pattern, Ibn Khaldun is regarded as the 'father of the science of history' and one of the founders of sociology. A*Sufi by persuasion, he is buried in the Sufi cemetery near Cairo where he died.

Ibn Khaldun was an historian, politician, sociologist, economist, a deep student of human affairs, anxious to analyse the past of mankind in order to understand its present and future ... one of the first philosophers of history, a forerunner of Machiavelli, Bodin, Vico, Comte and Cournot'—

ICONIC IMAGE. If a visual pattern is presented only very briefly (for example, by flashing a light on it in a dark chamber) an image of that pattern will persist in experience beyond its physical termination. Such an image is called an iconic image (or, alternatively, the information is said to be in a 'sensory register') and, unlike the aftereffects produced by very strong lighting, will appear very much like the pattern itself, though faded. Indeed, careful measurements have shown that observers often believe that the stimulus is still physically present when, in fact, it has been terminated a fraction of a second previously.

One implication of the latter point is that this record is remarkably complete (contains all or most of the detail of the original) especially as compared to the contents of other memory systems. George Sperling demonstrated this point directly by signalling his subjects immediately after stimulus offset to report to him the contents of one of a set of rows of letters which he had presented on a screen for 50 milliseconds. No matter which row was randomly requested, the level of accuracy was quite high.

Interestingly, however, a slight variation on this procedure drastically reduces performance. That is, if a mixture of letters and numbers is presented and the observer is requested immediately thereafter to report, for example, the letters but not the numbers, fewer successes are achieved. The implication is that although all of the items are available, they have not yet been identified, and so, in order to perform the task, the subject must identify each item whether called for or not. This is time consuming and the image disappears before the task can be completed. Thus, while iconic images may be remarkably complete, they apparently exist in a sensory, rather than properly perceptual, form.

The very 'unprocessed' nature of such records of stimulation may provide a key to their importance. It may be that such records hold information so that further, relatively time-consuming, processes such as segmentation, *figureground organization, and identification can occur. However, such a proposal must be developed cautiously. In nature the conditions under which these images have been studied are extremely rare, the rule in nature being relatively longlasting scenes which we tend to explore with our eyes by fixating upon first one place and then another. This latter point is especially

significant since it is also known that any part of an iconic image can be destroyed if new contours appear. For example, in an experiment such as Sperling's, if a particular letter on the screen is followed very quickly by another, an observer will not be able to report the former and may even indicate that it did not occur at all. The potential problem is, then, that in ordinary viewing the image produced by one fixation would be destroyed by the next, so that it would not be available for further processing. For example, what is now in the centre of the eye would destroy the image of what had been there just before the eyes moved.

Actually, the strength of this objection depends upon two assumptions: first, an assumption that the image is located in a fixed position in the retinas and, secondly, an assumption that the specific part of an image, which will be destroyed when new information arrives, will be that part which used to occupy that same place on the retina, even if the eyes have moved in the meantime.

As to the first assumption, while it is clear that some component of iconic images might be within the retinas, there is also ample evidence of a nonretinal component.

For example, if these images were retinal, then they ought to appear to move around the environment when the eyes move. On the contrary, however, Douglas Hall observed that when his subjects were requested to report a particular row of letters, they moved their eyes so as to scan the (now blank) area of the screen where those letters had been. This would hardly make sense if the image, too, had moved. Instead, those things 'seen' in the image seem to stay in their proper environmental locales. If it is further assumed that various parts of an iconic image will be destroyed only by new stimulation that occurs in the same environmental locales as those parts, then it will be appreciated that such destruction does not occur unless the scene itself changes in whole or in part. That being the case, several such images (each produced by a different fixation of the eyes) are perfectly free to coexist and may well add together in normal everyday viewing.

Whether such additivity actually occurs or not, the fact that not only do iconic images stay in place when they should, but also may appear to move when induced by moving stimulation (*anorthoscopic visual perception), suggests the involvement of some exceedingly sophisticated mechanisms.

ID. According to Freud, the unconscious reservoir of primitive instincts from which spring the forces of behaviour and the conflicts and guilts of neurosis. See FREUD

ON MENTAL STRUCTURE; FREUDIANISM: LATER DEVELOPMENTS.

IDEAL. The concept of an ideal seems to come from extrapolating from that which is seen as inadequate to some relatively perfect state. There are thus 'ideals of manhood' and general 'ideals worth striving for'. In*metaphysics, ideals can be supposed to exist, in some kind of heaven. This holds for*Plato's ideal forms of objects, including mathematical fictions such as the ideal triangle.

For Plato, mathematical and indeed all significant knowledge is of ideal unchanging forms, of which we see only transitory and imperfect replicas paraded before the senses. (See PLATONIC FORMS.) It is likely that this Platonic view has deeply affected ethics, and set up moral standards directed towards static, unchanging ideals which, in practice, cannot be realized, and, if they were, would be death.

IDEALISM. Name given to a group of philosophical doctrines which suggest that what we know as the '*external world' or the 'material universe' is in some important sense created by the mind or minddependent. (i).According to the Berkeleian version of this view, nothing exists outside the mind. To exist (*esse*) is to be perceived (*percipi*); and what we perceive can be nothing but our own ideas or sensations (see BERKELEY ON THE MIND). Subsequent 'phenomenalist' theories, which maintain that physical objects are merely 'permanent possibilities of sensation' (in J. S.*Mill's phrase), have something in common with Berkeley's view. (ii) Kantian or 'transcendental' idealism maintains that the fundamental categories in terms of which we characterize the world are not objective features of things in themselves but are structures imposed by the mind; without such organizing structures experience would not be possible (see KANT'S PHILOSOPHY OF MIND).

(iii) According to*Hegelian idealism, the whole of history consists in the progressive realization of a single 'selfpositing' mind or spirit (*Geist*).

J. C.

IDEAS might be called 'the sentences of thought'. They are expressed by language, but underlie language—for the idea comes before its expression. (Though it is sometimes said that one knows what one thinks only after one has said it!)

Philosophers have traditionally distinguished between 'simple' ideas and 'complex' ideas. Simple ideas are supposed to be directly derived from sensation. When combined, they can produce complex and abstract ideas far removed from sensory experience and expressed in shared language. Simple ideas are the 'atoms' of associationist accounts of the mind. In common speech, 'one idea leads to another': and it is this which was formalized by the eighteenth and nineteenthcentury associationists such as John*Locke, David*Hume, James*Mill, J. S.*Mill, and Alexander*Bain. But how does one have a new idea, if ideas can only follow from others, or from sensations? Is it by the*emergence—as in chemistry—of new and surprising properties of combined elements? This leads to considerations of*intelligence,*creativity, and*genius.

IDENTIFICATION PARADE. See MEMORY AND CONTEXT.

IDIOT. A person representing the lowest grade of *feeble-mindedness*. An adult idiot is technically a person having a mental age of not more than two years, or an IQ

not above 25. An *idiot savant* may have remarkable specific abilities (such as mental arithmetic), though otherwise he fits this classification. See MENTAL

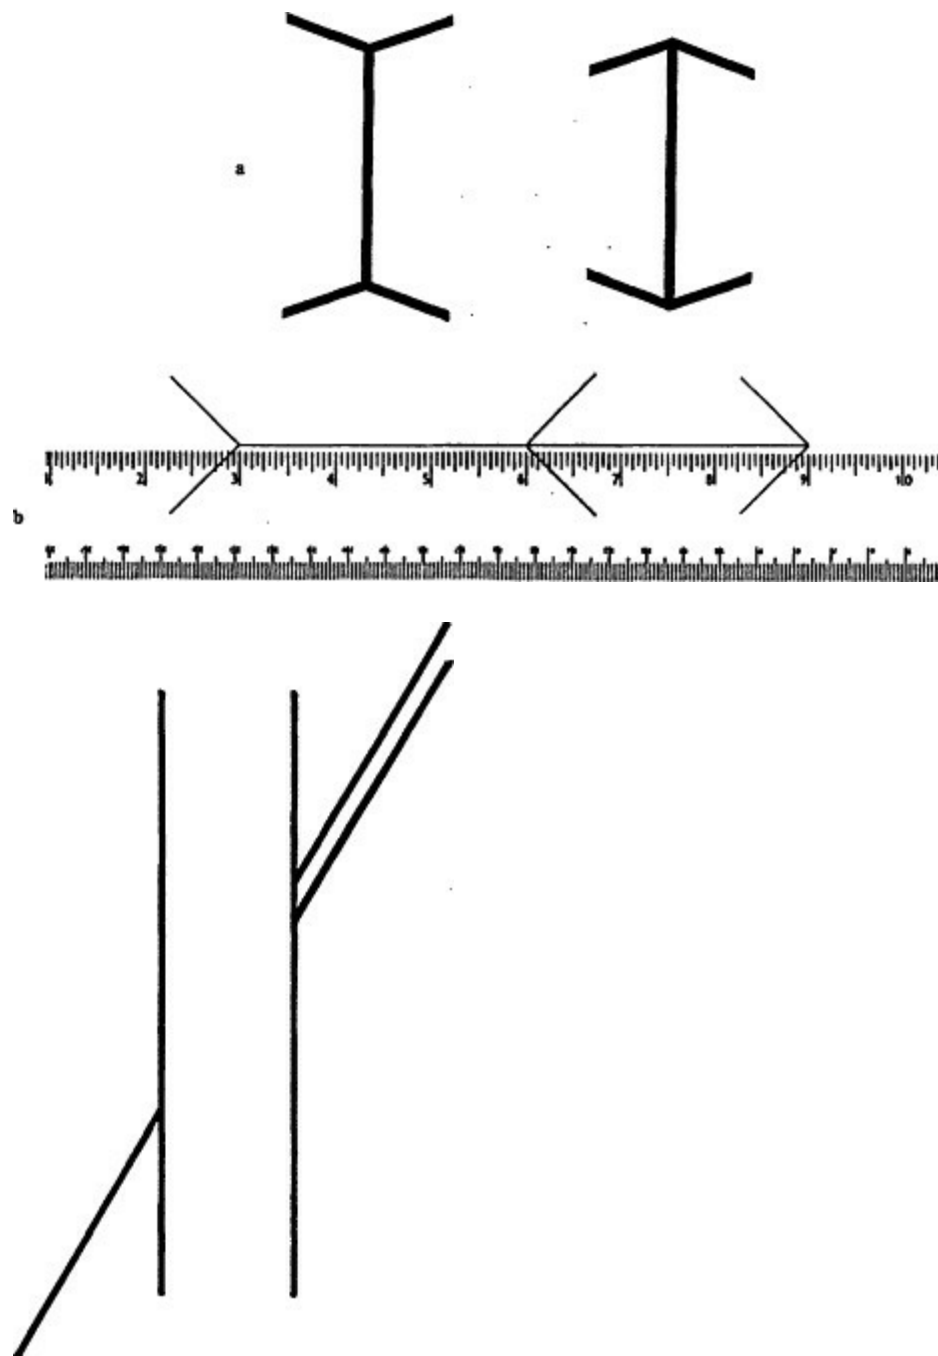

ILLNESS.

ILLUSIONS are discrepancies from truth. All the senses can suffer illusions; but because we know most about *visual**perception, visual illusions are the best known and most fully understood— though even of these many remain mysterious and controversial. All perceptions are subject to errors of many kinds; but illusions pass unnoticed except when they are strikingly inconsistent with what is accepted as true, or when there are internal inconsistencies—such as contradictory sizes or shapes, ambiguities, or paradoxes—which provide wonderful opportunities for artists, as exemplified in the ambiguous and paradoxical pictures of Maurits Escher. (See also ART AND VISUAL ABSTRACTION,)

Illusions are an embarrassment for those philosophers who would like to hold that knowledge is based securely on perception. Such a view is part of the empiricist tradition, which is the basis of science, but it is easy to show empirically that perception is not reliable; for at least in the laboratory, and the art gallery where interesting illusions abound, it is easy to fool the senses systematically so that all observers agree on what they perceive, though all are wrong. And we can all suffer misperceptions which may be disastrous in real-life situations, such as when driving a car or playing golf, or when doctors misread X-ray pictures. For everyone, the moon appears far too near, just beyond the horizon, and only about the size of an orange (smaller when high in the sky); yet we *know* it to be a quarter of a million miles distant and far larger than any earthly object.

Illusions are 'subjective' in our experience, and they affect behaviour and skill. Distortions of appearance can be measured, much as objects are measured, by comparisons with rulers or other physical references (Fig. 1). They may also be measured by *nulling*—by measuring the change in size or shape of the visually distorted object or figure necessary to compensate or 'null' the distortion, though in doing so there is a danger of changing the angles, or other parameters, responsible for the distortion (Fig. 2).

So many processes contribute to perception that it is often difficult to know which is responsible for an error, or illusion, and no doubt there are some processes going on that we know nothing about. Some illusions, such as the bright or dark*after

Page 338

Fig. 1.

a. Muller-Lyer illusion cancelled or 'nulled' by drawing the expanded (left) figure shorter than the shrunk (right) figure—no illusion is seen. b. Measuring a visual distortion by comparison with a ruler.

Fig. 2.

Measuring a visual distortion by compensating or 'nulling' it. This can be a useful method, but it has the danger that features (such as critical angles) inducing

the illusion are changed.

images that hover around after one looks at a bright light—owing to local loss of sensitivity of the retinas of the eyes following strong stimulation—are clearly due to physiological adaptation. Adaptation of physiological processes of visual systems in the brain are demonstrated by Fig. 3. Such illusions may be compared with errors made by instruments. Thus aftereffects from prolonged stimulation by curved lines are calibration errors. They are useful for the experimental investigation of the signalling and representing of brightness, curvature, tilt, colour, movement, and so on; for these and 'many other characteristics are signalled by their own neural

'channels', which may be identified as they are individually adapted and so can be isolated quite simply, to find out how they work. (See also CONTINGENT

PERCEPTUAL AFTEREFFECTS; ILLUSORY FIGURES.)

Cognitive illusions are different. Their physiological bases are more subtle and more difficult to determine. In explaining any illusion the problem is how to select and concentrate on the appropriate 'level' of perceptual processing, and how to discover the particular process in which the relevant action has gone wrong. We can then ignore all the other processes, however important they may be for perception. This is not so simple for cognitive illusions, as for them there may be nothing abnormal or wrong with the anatomy, the physiology, or any of the underlying eye or brain processes. For just as any working tool, or knowledge, may be misapplied, normally functioning processes may be misdirected to produce errors, without fault of physiological function. This may occur whenever inappropriate knowledge or assumptions are

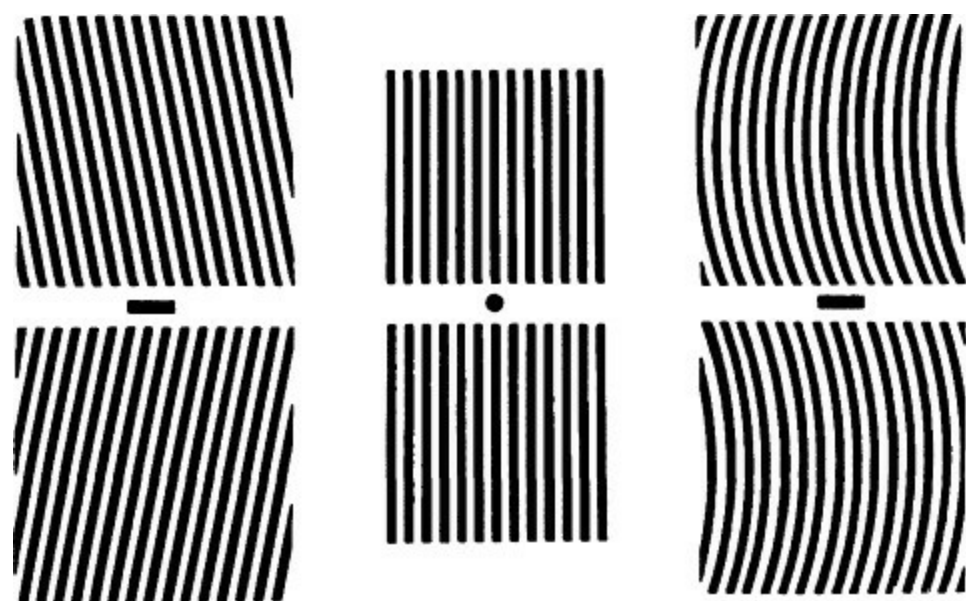

Fig. 3.

Adaptation to Curvature and tilt. Look at the short horizontal bar below the tilted lines for a few seconds, with the eyes moving left and right along it to avoid afterimages. Then look at the vertical

straight lines. Do they still look vertical? For a few seconds, they should look tilted—oppositely to the *adapting* lines. Similarly, following viewing the curved lines, the vertical lines should appear oppositely curved.

These adaptations are always opposite to the adapting stimuli—whether for shape, size, brightness, movement, or colour. It seems that specific neural channels are adapted (or fatigued), upsetting the balance of signals of position, movement, etc. The opposite colours are 'complementary' colours, such as adaptation to red producing green.

brought to bear in the 'reading' of sensory signals as evidence of an object's size, distance, colour, and so on. Thus physiologists and psychologists sometimes differ when accounting for particular illusions. Whereas, for example, the wellknown*MüllerLyer distortion illusion is generally explained by physiologists as due to some optical effect in the eye, or to disturbance of the signals from the retina by the angles of the 'arrowheads', very different explanations lie in the domain of cognitive psychology, as we shall see.

An undoubtedly cognitive effect is the*sizeweight illusion: that a small object feels heavier than a larger object (for example soup tins) of the same scale weight. One anticipates a greater weight for the larger tin, because larger objects are usually heavier than similar smaller ones, and this sets up inappropriate expectations of the musclepower required to lift them. Similarly, an empty suitcase flies up into the air (making one feel foolish!) when it is lifted, as too much force has been applied in lifting it, on the expectation that it will be heavy. This is a cognitive illusion because it is generated by an error of behaviour which is the result of a misleading assumption, or misleading knowledge.

For purposes of investigation, and discussion, cognitive illusions may be classified as *ambiguities*, *distortions*, *paradoxes*, and *fictions*.

Ambiguities. Some pictures, and sometimes ordinary objects, seem to change or turn into some other which may be quite different. Perception may switch between two or more alternatives (Fig. 4). What happens is that alternative hypotheses of what the object is (or where its parts lie in space) are entertained in turn. This occurs when the sensory data do not particularly favour just one possibility. A celebrated example of reversal in depth is the*Necker cube (Fig. 5). A threedimensional wire cube is a fascinating object: when it reverses in depth it seems to stand up on a corner, and it rotates to follow one as one moves round it. This is because the motion parallax due to the movement is 'misread', as the apparent distances of the nearer and further faces are reversed. The cube also changes in shape. Such switches in depth—or from one object to another—can occur against the evidence of other senses. Thus, holding a small wire cube in the hand while seeing it depthreversed is remarkably interesting; for when the hand is rotated the cube is seen to rotate—impossibly—against the hand's movement. The counterinformation from touch does not correct the visual depthreversals—and the wrist feels as if it is broken!

Perhaps all phenomena of ambiguity are essentially cognitive, for they depend on how sensory data are being interpreted, or 'read', in terms of

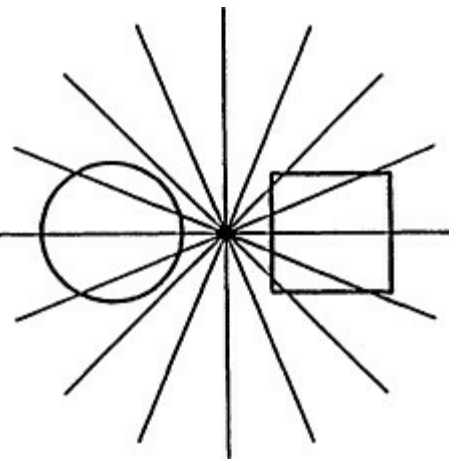

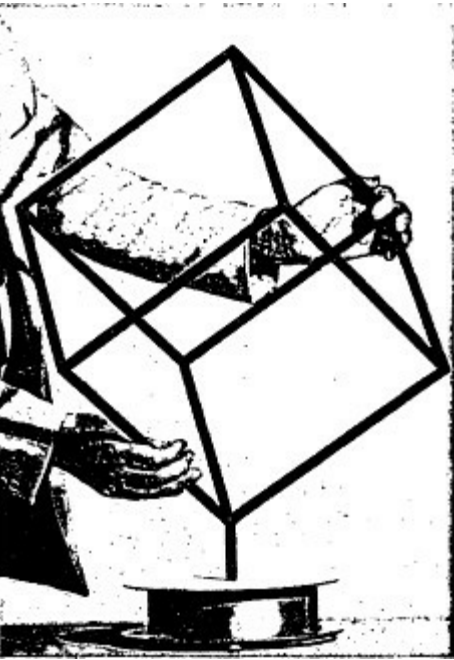

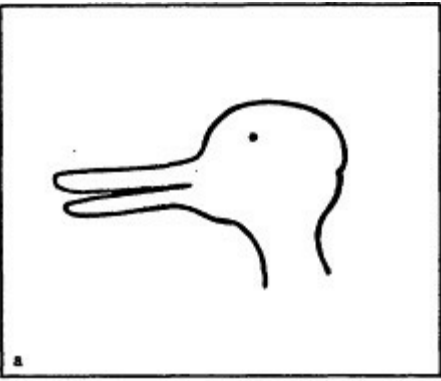

Fig. 4.

Ambiguous objects. a. Duckrabbit. b. Vasefaces.

These can appear as alternative objects, according to selected rival perceptual hypothesis.

objects. When there is one best bet, perception is stable; but when there are rival possibilities to be entertained, then perception becomes ambiguous, as each possibility is entertained in turn. Perception is intelligent, searching for solutions to the incredibly difficult problems of interpretation, that have to be solved hundreds of times every minute of the day.

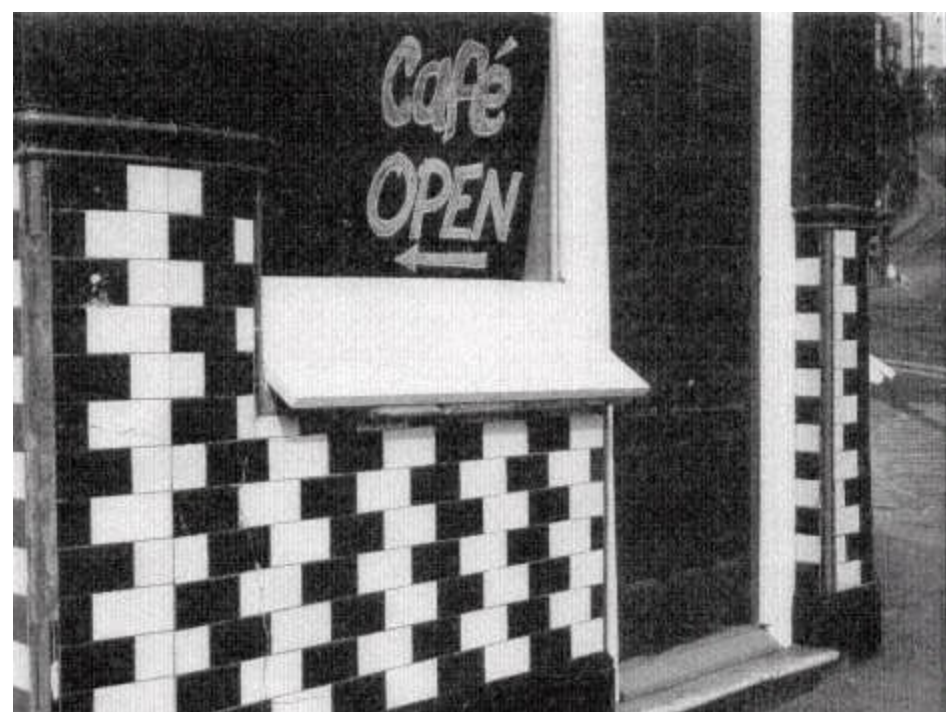

Distortions. These are the bestknown illusions: systematic distortions of size, and of length and curvature of lines or edges. Explanations remain controversial after a century of intensive investigation, by physiologists, opticians, neurologists, and psychologists—and more recently by computer programmers concerned with vision in*artificial intelligence. Many distortions were discovered by optical instrumentmakers placing wires in the eyepieces of measuring instruments; their aim was to improve visual accuracy, but many attempts produced disastrous errors. For example, it was found Fig. 5.

Necker cube. This can be seen as switching in depth, the 'front' face reversing with the 'back' face.

that converging lines produce distortions such as those of Fig. 6. These are large repeatable phenomena, which are easy to measure, and so are favourites for experiments. But what causes these distortions? There may be several causes, and there are certainly a score or so of (not all correct) theories.

Fig. 6.

Converging line distortions. One theory of why converging lines produce expansion, is that the convergence is read visually as perspective depth, or distance; this sets constancy of size for too great a distance.

Page 341

Fig. 7.

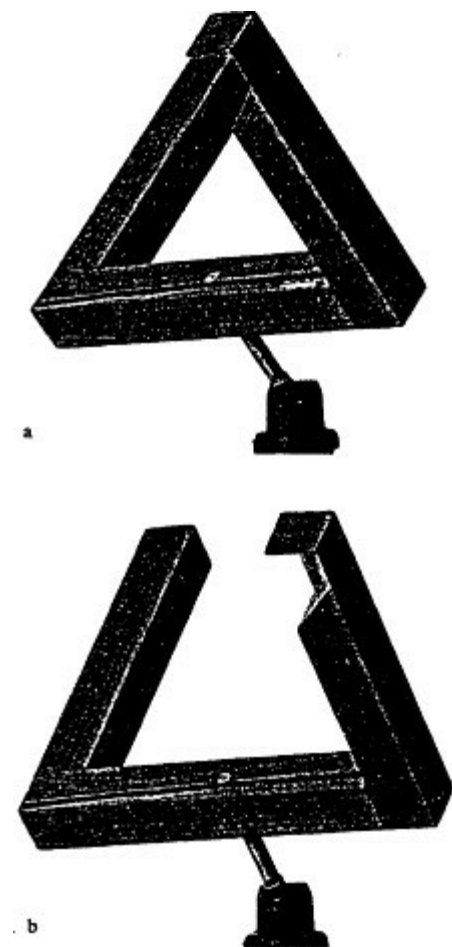

Café wall illusion. Named after a nineteenth-century café in Bristol which has this pattern of tiles. The long wedges are illusory. The distortion is unusual as it occurs in a figure (or object) having only right angles and parallel lines; it depends on the brightness-contrast of the 'tiles', and it only occurs when the brightness of the 'mortar' (which must be narrow) lies between the brightnesses of the tiles. There is no distortion with alternately different coloured tiles of the same brightness.

Many distortions—such as adaptation to the curves, or tilted lines, of Fig. 3—are straightforwardly physiological. And there may be optical distortions such as astigmatism. (See EYE DEFECTS AND THEIR CORRECTION.) A striking distortion illusion, which is almost certainly associated with physiological processes early in the visual system encoding the position of edges, is the 'café-wall illusion' (Fig. 7). A reason for believing that this effect occurs early in the visual system, prior to the cognitive processes of object recognition, is that (unlike most distortion illusions) it depends on brightness differences. When the tiles are alternately coloured, for example red and green, there is no distortion, providing the colours are set to equal brightness. Also, the distortion occurs only when the brightness of the mortar, which must be narrow, lies between the brightnesses of the dark and the light tiles. Illusions due to more 'central' cognitive processes are not likely to be affected by stimulus changes which do not alter the information provided by the picture, or object. It is often very difficult, however, to be sure whether an illusion is straightforwardly physiological, or has a cognitive cause through the brain misreading the significance of information-bearing features (Gregory and Heard, 1979).

Whether the distortions associated with (perspective) converging lines are straightforwardly physiological, or cognitive, remains controversial. The fact that they occur essentially unchanged for any brightness differences, for the colour-without-brightness contrast of isoluminance, and for any

thickness of the lines, suggests that this is a cognitive phenomenon, which depends on certain features providing information that is misinterpreted. One theory is that depthcues, such as perspectiveconvergence, set quite directly how far things appear to be, and will in some situations set distance or size incorrectly. An important depthcue is perspective. The perspective shapes of retinal images are appropriate to the distances of objects only when given by objects of normal shapes, especially having parallel edges and rightangular corners. Odd shapes may be misleading: for example, the Ames room (designed by Adelbert Ames), which is not rectangular even though it gives the same image to the eye as a rectangular room, and the rotating trapezoid window which has marked perspective (as though viewed from an extreme angle), that disconcertingly persists as the window rotates.

All pictures that offer perspective challenge the eye with problems, as they present depthcues of

Page 342

the objects they depict, in a space different from the picture plane. So it is hardly surprising if such pictures present problems that the visual system cannot solve without producing distortions. Pictures are essentially paradoxical, as they are flat while representing depth; so it is amazing that we see them as well as we do. These distortions obey certain rules. Features representing distance are perceptually expanded in compensation for the shrinking of the eye's images, for whereas actual objects normally look much the same size, whether near or fairly distant, their images shrink to half with each doubling of distance, just as for a camera. When the compensation for this optical shrinking is not set appropriately, it *must* produce such distortions (Gregory, 1963, 1968). A test is that when

depthcues are appropriate in these illusion figures, the distortions no longer occur (Gregory and Harris, 1975).

It is interesting to look at the wire cube that reverses in depth without change of the retinal image in the eye. When depthreversed, its apparently further face looks too large, so that it seems like a truncated pyramid, expanding away from the observer (Gregory, 1970). But when not reversed it looks like a true cube. Sizeconstancy follows the apparent distance of the faces of the cube, an example of Emmert's law. Visual size can be set in two ways—by perspective or other depthcues, and by apparent depth—and it can be set wrongly by either. Thus there can be distortion 'bottomup' from misleading depthcues, or 'topdown' from inappropriate assumptions of distance.

Paradoxes. It is significant that, although we tend to see what is likely, we *can see* things that are so unlikely they appear impossible—even logically paradoxical.

Striking examples are the 'impossible triangle' and 'impossible staircase' drawings of Lionel and Roger Penrose (Penrose and Penrose, 1958). But if we could see only probable objects, we would be blind to the unlikely; and this would be highly dangerous as unlikely events do sometimes occur. Indeed, if we could see only expected things there could hardly be perceptual learning. Nevertheless, it is strange that we can experience a paradox perceptually while knowing its solution conceptually, as with the 'impossible triangle' (Fig. 8). This is a simple unpainted object, made of three lengths of wood, yet from a certain point of view it looks impossible. This paradoxical perception occurs because the visual system assumes that the sides meet and touch at all three corners—though in fact at one corner they only touch *optically*, as here the sides are separated in depth. This is a cognitive effect, depending on a false assumption.

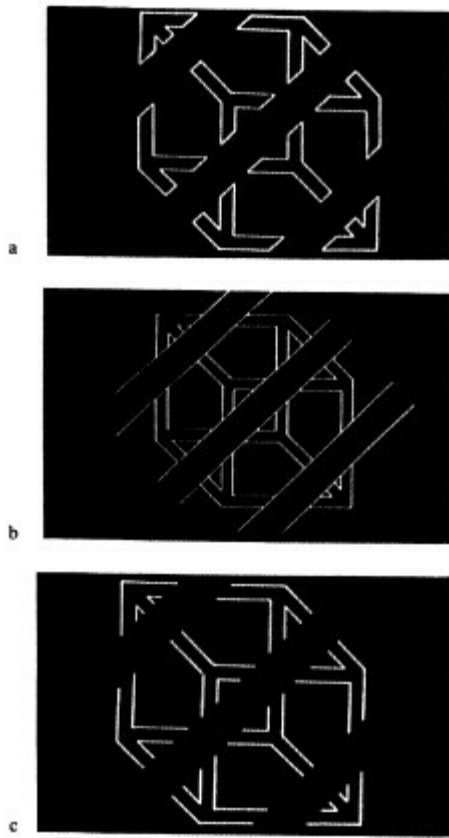

Not all perceptual paradoxes have such cognitive origins, however, for straightforward physiological errors can also produce them—as when signals arriving from one sensory channel disagree with signals from another channel, when they are differently adapted. As is well known, after one hand Fig. 3.

Impossible Triangle. a. From this viewpoint it looks paradoxical. b. When it is rotated, one sees the answer (but returning to a, it still looks impossible).

has been placed in hot water and the other in cold, tepid water will feel both hot and cold at the same time, when the differently adapted hands are placed in it.

Movement aftereffects (from a rotating spiral) are similarly paradoxical, as they can give sensations of movement though no change of position is seen. This shows that movement and position are signalled by different neural channels, which when they disagree can produce a paradox.

Fictions. On the general account of perceptions as predictive hypotheses which is assumed here (see PERCEPTION AS HYPOTHESES), it is not surprising that perceptions can be ambiguous, distorted, paradoxical, or even fictional. The hallucinations of schizophrenia and druginduced hallucinations apart, some striking examples of perceptual fictions are illusory edges and ghostly surfaces, which

occur in a wide variety of figures. The best examples are due to the Italian psychologist and artist Gaetano Kanizsa (Kanizsa, 1979).

Again there are several theories that attempt to account for these remarkable effects, and again there may be more than one cause. The ghostly surfaces occur in figures having surprising gaps. They are, probably, postulated by the visual system to account for the gaps, as due to occlusion or eclipsing by some nearer object or surface. In the normal course of events, parts of objects are very often hidden by nearer objects; yet we continue to recognize them as complete. The ability to recognize objects that are partly hidden is extremely useful; but to postulate a nearer object or surface on the evidence of gaps is bound to be hazardous, for sometimes gaps are surprising (Fig. 9). The tendency to postulate a surface that 'should' be, but is not there, makes us see 'ghosts' in figures that have unlikely gaps with the shapes of likely objects. The three drawings in Fig. 9 show something of

Fig. 9.

Three cubes. a. This cube appears as separate objects.

hidden behind bars. c. Removing the parallel

lines in b and the end blocking lines in a

produces illusory bars—with a partly hidden

cube behind them.

the subtlety of perceptual processes, and throw light on how the world is seen as divided up into objects. This is a basic perceptual problem, as very often retinal images do not have clearly defined edges for each object. The ear has the same problem in recognizing separate words in a sentence, the sounds of speech being mainly continuous. We cannot distinguish separate words in an unfamiliar language; all we hear is an almost unbroken stream of sound. So, in order to see what is an object, and what is the space between objects, or words, perceptual learning is important. (See also AUDITORY ILLUSIONS; MUSIC, PSYCHOLOGY OF.) Although one may know intellectually that one is seeing an illusion, one still *sees* the illusion. This difference between perceiving and conceiving, which applies to all robust illusions, may be because perception has to work very fast, for our survival into the next second or so. Vision, hearing, and our other senses must keep in step with external events, which are often threatening, and this requires a running prediction of what is likely to happen in the immediate future. This remarkable speed could not be achieved if perception drew upon all our knowledge. The access time would be too long. Therefore, just as the strategy of initial decisionmaking from a small data base is becoming necessary for large computer systems, so also is the intelligence of perception limited and subject to illusions, as sensory data are not raw, but cooked by assumptions that are often false. In many ways it is different from our total understanding—anathema though this split between perception and understanding is to philosophers expecting certainty from the senses as premises for our conceptual beliefs.

Page 344

ILLUSORY FIGURES. Under some conditions, human beings, even as young children, possess a startling tendency to see a complete figure when only a small portion of its outline is actually delineated for them. For example, a white triangle can be seen in the centre of the first pattern.

This phantom triangle, far from being an afterthought to more primary experience, is emphatically 'seen', often in sharp delineation, very slightly in front of the line segments, and with a compelling glow. In fact, of course, except for the points at which it is touched by the black lines, the perimeter of the triangle is unmarked by any real change in stimulation—most of the border is simply not there in any physical sense. Such phenomena, as visually amusing to laymen as they are intellectually stimulating to theorists, occur in great variety and have come to be known as 'subjective' or, alternatively, as 'illusory' figures. Although the latter term is adopted here for convenience, either label, if taken too literally, is deceptive. It is instructive to consider why this is so.

First of all, while the triangle seen here obviously must be a subjective construction along most of its border, there are good reasons for believing that the perception of virtually any object involves a good deal of creative (*ergo*, subjective) activity. Visual perception can seldom, if ever, be accurately described as only a passive intake of environmental facts. In the same vein, illusory figures are decidedly not unbridled selfcreations, but, like any percepts, are under the influence (although not the dictatorial control) of the stimuli presented. On the other hand, the phrase 'illusory figures' can also be misleading, suggesting, as it might, that the viewer is completely fooled. That is not the case—at any rate, not for long—with most observers. Even a child of 7 can assert (with wholesome candour considering the blatant contradiction involved) that the white triangle he sees is 'not *made* out of anything—it's just there'.

Rather oddly, widespread investigation of illusory figures developed only slowly. Early in the

twentieth century F. Schumann made the pioneering observation that an appearance of a complete white square can be induced by partially enclosing a square area with half circles to each side and horizontal lines top and bottom (Fig. 1a).

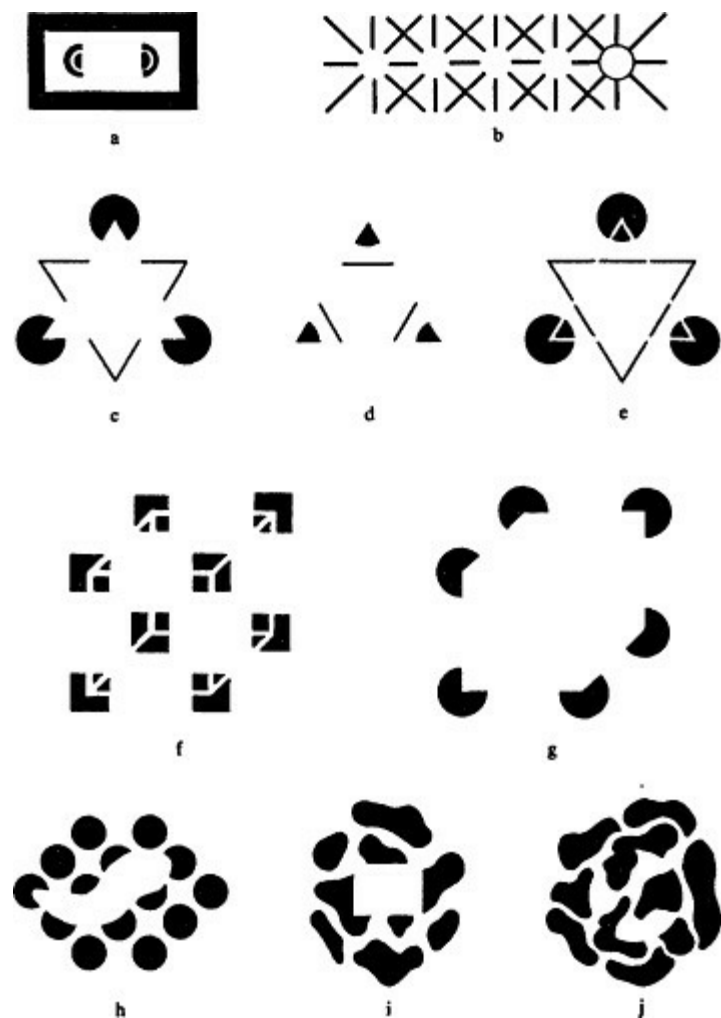

At the time, Schumann's publication was considered important enough to be made the leading article in the maiden issue of a new journal. As a goad to further studies, however, his work somehow failed to arouse much interest. Perhaps the particular example he presented was lacking in visual impact, or perhaps the uniqueness of his observation was not clear to most readers. At any rate, a few decades were to pass before another European, Walter Ehrenstein, produced illusory circles which should have been impressive enough for anyone's taste. Furthermore, he emphasized their theoretic novelty by showing that the brightness of these circles is lost when the area in question is physically outlined (Fig. 1b, far right). This latter point clearly distinguished Ehrenstein's figures from the more generally accepted notion that surrounding a white area with bits of black might tend to make that area appear whiter. If such 'simultaneous brightness contrast' were all that was involved here, then completely outlining one of the circular areas (thereby adding that much more nearby black) would have heightened the brightness rather than destroyed it. By now it should have been obvious that something new was here to be explored, but in the event interest in illusory figures did not begin to reach anything like epidemic proportions until yet another decade later when the work of Gaetano Kanizsa was published and received with enthusiasm.

Kanizsa's most famous stimulus pattern has already been shown in modified form, but can be seen in its original form in Fig. 1c. If the circle and line elements 'missing'

from Kanizsa's pattern are presented instead (Fig. 1d), then the entire surround tends to become a bright illusory surface containing a triangular 'hole' through which the black pieces are glimpsed. Alternatively, a greyish triangle is sometimes seen lying over a whiter background. It is amusing to combine the previous two situations (Fig.

1e), in which case the window of Fig. 1d can be made to pierce through the surface of the illusory triangle of Fig. 1c, producing a thin white frame superimposed over the black elements.

While such displays can, therefore, be quite elegant, even more complex effects are possible. To a patient observer Fig. 1f reveals the impression of a cube formed of thin white members whose vertices are glimpsed through square holes in a nearer illusory surface. Even more impressively, Fig. 1g may produce an illusory figure which is, itself, a suggestion of a three-dimensional cube, complete, for some observers, with 'forward' edges. Nor are illusory figures found only in response to paper-and-ink presentations. John Kennedy and his colleague Colin Ware have devised ingenious three-dimensional constructions which, if held and viewed in normal surroundings, produce clear illusory lines and surfaces embedded *within* the constructions. Finally, the importance of illusory figures to our understanding of everyday experience becomes even more apparent when we realize, as Kanizsa himself did, that more naturalistic shapes can also be produced (Fig. 1h) and that more naturalistic elements may be employed

Page 345

Fig. 1.

(Fig. 1i). Furthermore, such elements may be present within, as well as round, the area of the illusory figure (Fig. 1j).

These last examples make explicit what might only be suggested by more planegeometric cases: that the tendency to see illusory figures might be closely linked to the ability to see natural objects in a normal environment—not only in detecting 'deliberately' camouflaged animate things, but in such common acts as discerning a gnarled and heavily grained stick lying on a forest floor as thatched with dead limbs and crosshatched with shadows. By this argument, in order to understand the processes which yield illusory figures, it is first necessary to consider the enormous problems faced by the visual system when it seeks to delineate the natural visual environment into individual objects of certain shape and fixed dimensions. In other words, the suggestion is that the present laboratory stimuli are simplified examples of a general sort of challenge nature continuously presents. That challenge consists, in part, in the fact that a sharp difference in brightness or hue cannot always be taken as the extreme edge of an object of interest, since it might, instead, represent only a surface feature or an irrelevant shadow. Furthermore, those differences which do occur along an object's edge might be no more marked than differences produced by markings and shadows within the object. What then can be taken to be the extreme edge of 'an' object?

In the case of strongly three-dimensional situations, movement (of either the observer or the observed) provides useful information, as do such clues to relative depth as can be supplied by disparity, by changes in convergence and focus, or

Page 346

by systematic changes in texture. Inevitably, however, the system must make decisions and inevitably it must deal with probabilities. This, as Richard Gregory emphasizes (see ILLUSIONS), is the heart of the matter: those sharp changes in brightness or hue that *are* present and detected must form part of a pool of data upon which *hypotheses* are constructed as to the arrangement and shape of physical objects that *may* be present. Such hypotheses necessarily go beyond the given data if they are to be useful. They must, for example, accept only some observed differences as actually marking the perimeters of objects. Finally, once entertained, these hypotheses become as much the 'stuff' of visual experience as more mundane experiences of light and hue. That they are an integral part of seeing is, in fact, one of the most awesome senses in which vision is not merely photographic.

Going a step further, Irvin Rock argues that, in forming such hypotheses, a basic rule seems to be an abhorrence of excessive coincidence. Thus, while any particular part of the edge of any particular patch of dark might be 'completely ambiguous if taken alone, if too many patches terminate too abruptly and in too neat a fashion, it becomes increasingly reasonable to posit a single cause for that orderliness—which is to say, that an edge connects (and causes) that arrangement.

It will be apparent that Rock's principle is easily applied to the examples of illusory figures reviewed above, with only the added stipulation that an enclosing object contour, once hypothesized, might be expressed in experience through an alteration in brightness across the enclosed area relative to that which surrounds it. On the other hand, brightness alterations would not always be expected since not every object discerned in the natural environment seems to glow or glower, and, in fact, as Kanizsa himself discovered, neither do all illusory figures. For example, the lower righthand corner of the triangle seen in the final pattern does not seem to glow and yet, quite remarkably, seems to retain a very real presence.

Similarly, some of the random-dot stereograms devised by Bela Julesz produce a substantial perceptual surface lying in front of a background surface, from which, however, it does not seem to differ in hue or brightness. (See VISION: THE EARLY WARNING SYSTEM.) Thus, shape, rather than always being expressed in terms of contrasting brightness or hue, is sometimes experienced as a quality which may be called, for want of a better term, 'objectness'. That is to say, a given area, while being seen as the same in brightness and hue as that which lies round it, may, nevertheless, be segregated and unified by the impression that that area is all *an* object. Of course, just as the perceptual system must disregard a shadow lying across any object in detecting the outline of that

object itself, so here its proper business remains the business involved in the detection of objects rather than only patterns of light. As a result, the present phenomenon might even be called illusory

'objects'. After all, the impression induced by these demonstrations is one of a physical object (albeit a thin one) like, for example, a thin coat of white dusting powder.

On the other hand, it is equally important to recognize that any illusory figure is, in a different sense, distinctly unsubstantial. As has been said, the system seems to retain the knowledge that the hypothesis which posited the object is only tentative. Certain edges may be possible or even probable, but if not fully supported by the data at hand, further investigation (in particular the renewed search for physical brightness differences along all parts of the perimeter) eventually leads to rejection of the hypothesis. As a result, the experience of viewing illusory figures is one of their coming and going over time; depending, apparently, on which data are being weighed at the moment and, in each instance, on what the system 'makes of' (what it hypothesizes about) the data in question. If a great many irrelevant data are present—if, for example, Kanizsa's figure is surrounded by a random array of other lines and circle segments aimed this way and that—the triangular figure may emerge only gradually or never at all. On the other hand, by deliberately including conflicting (rather than merely distracting) elements, it is possible to destroy, with a longer look, the illusory figure that emerges during a shorter look.

In summary, illusory figures result from object hypotheses which are, all in all, closely analogous to scientific hypotheses formed in response to incomplete data. Not only are such hypotheses tentative and subject to rejection, and not only do they deal in probabilities in eschewing excessive coincidence, but, most importantly, they go beyond mere reiteration of the data in seeking, in effect, to explain them. Those explanations then become an integral part of concurrent visual experience so that any hypothesis which is supported by all, or almost all, of the data at hand becomes one that may be acted upon. That, of course, is what human vision is all about.

IMAGE, RETINAL. See RETINAL IMAGE.

IMAGE ROTATION. Recent experiments by Roger Shepard, at Stanford, have shown that at least most people can 'rotate' mental images of fairly simple objects, and that this rotation can take place only at a limited rate, which varies between individuals. Remarkably, there is a precise linear relationship between the angle the mental image is rotated and the time required. What is being rotated may perhaps be some kind of analogue representation, as Shepard believes, or it may be changing parameters of a digital description. This distinction between analogue and digital representations is a fundamental one, which is one reason why these experiments are so important. See also IMAGING.

IMAGES OF THE BRAIN IN ACTION. During the 1980s safe techniques for obtaining images of the living human brain have become widely available in clinical medicine. This revolution in diagnostic imaging began with the development of Xray computed tomography (CT) in the early 1970s, followed by positron emission tomography (PET) and nuclear magnetic resonance (NMR; sometimes referred to as magnetic resonance imaging, or MRI). Each has made special contributions: CT

and NMR to the production of refined, *in vivo* anatomical images, and PET to images of brain function measured in terms of local chemistry, metabolism (i.e., the use of oxygen and glucose), and bloodflow within the brain. It is the purpose of this entry to acquaint the reader with each imaging technique, but focusing primarily on PET and its potential to image the living brain in action.

Xray Computed Tomography (CT). CT images are computergenerated images of tissue density, produced by tomographically measuring the attenuation of tissue to Xrays passed through the body at many different angles. These data have been analysed by a variety of increasingly sophisticated mathematical techniques to produce high quality images of the type shown in Fig. 1. The utility of such images for the clinical practice of neurology and neurosurgery can be recognized immediately. CT scans, almost overnight, replaced the need for more dangerous, unpleasant, and difficulttointerpret diagnostic tests. The benefit to patients has been substantial through increased safety, accuracy, and promptness of diagnosis. The revolutionary nature of this type of imaging was recognized when the Nobel prize for physiology and medicine was awarded to A. M. Cormack and G. N. Hounsfield for work leading to the development of Xray CT.

The primary contribution of Xray CT to our understanding of human brain function has been to provide highly accurate antemortem data on the location of specific areas of injury affecting the human brain function. This has permitted accurate correlations to be made between the signs and symptoms of an illness and the specific brain structures involved. The literature now abounds with

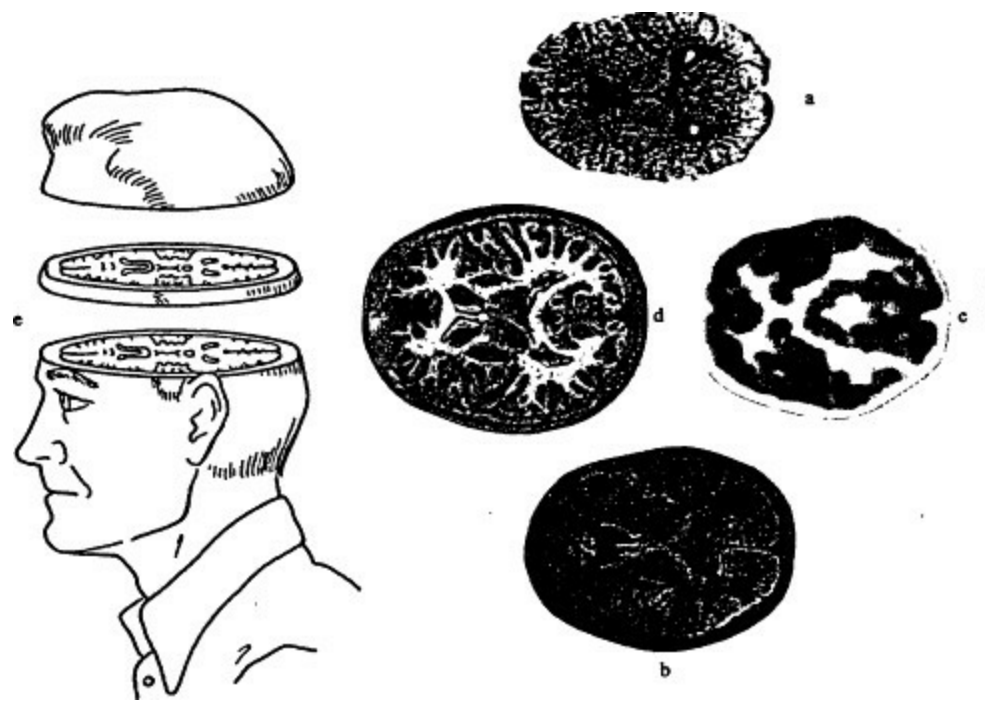

such observations. Many have provided valuable insights into the function of specific regions of the human brain.

Another important contribution of Xray CT was to immediately kindle the interest of scientists in other types of neuroimaging. For example, it was recognized that the mathematical techniques of Xray CT, used to construct an image of the density of tissue to Xrays, could also be used to construct the distribution of a radiolabelled substance within the tissue from its emitted radiation. The development of Xray CT was also a stimulus for the development of imaging techniques using the principles of NMR.

Nuclear Magnetic Resonance (NMR) is based on the fact that some atomic nuclei act like tiny bar magnets when placed in a magnetic field. When they are aligned in a magnetic field, they can be excited in controlled ways by irradiation with radio frequency energy. During recovery from such manipulations, these tiny bar magnets (or dipoles) emit radio frequency signals that contain a great deal of information about their chemical environment. Since discovery of this phenomenon by two independent investigative teams headed by Felix Block and Edward Purcell in 1946, for which they subsequently received the Nobel prize for Physics in 1952, it has been applied to the study of virtually any subjects from crystalline solids to living people.

Most NMR imaging of the brain of living human subjects makes use of the strong signal from the abundant hydrogen nuclei in tissue. These images provide exquisite anatomical detail of the human brain, varying in their appearance with the imaging strategy employed (Fig. 1). Abundant evidence now supports the use of such NMR

images in clinical medicine as an excellent way to obtain anatomical information about the human brain *in vivo*. In many respects the images are superior in their anatomical detail to those produced by Xray CT (compare images in Fig. 1). The primary contribution of proton NMR to our understanding of the human brain is similar to that of Xray CT, providing accurate information for correlations between specific areas of brain injury and the signs and symptoms of illness. Many nuclei other than hydrogen can be studied with NMR (e.g., phosphorus, sodium, and carbon), portending biochemical and metabolic studies of the human brain

Page 348

Fig. 1.

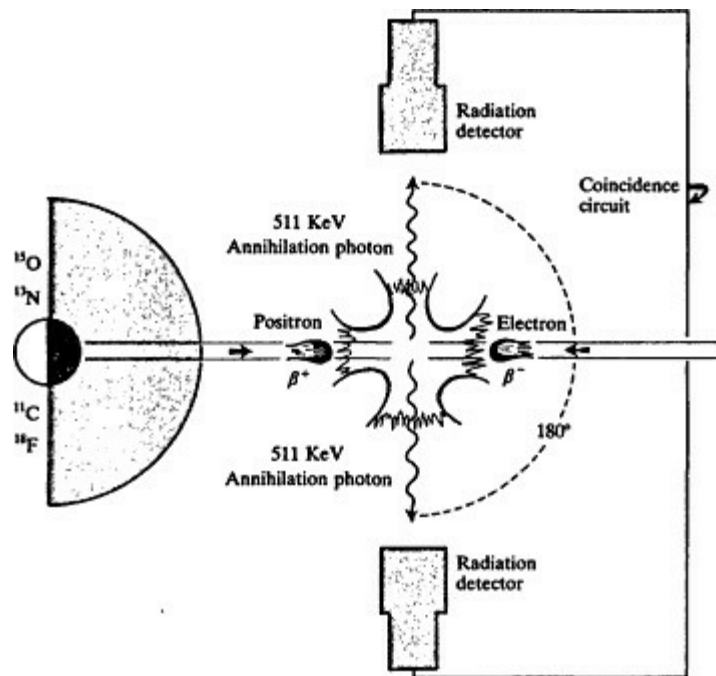

Images of the normal adult human brain obtained with a. Xray computed tomography; b. nuclear magnetic resonance (NMR); and c. position emission tomography (PET). These images, obtained in living human subjects, are to be compared with a representative anatomical section of the human brain obtained in the same horizontal plane d. The approximate orientation of these images is shown in the line drawing on the left e. The CT image reflects the density of the tissue to Xrays, thus bone and calcified tissue appear most dense (white), brain parenchyma less dense (grey), and fluid bathing the brain least dense (black). The NMR image reflects the proton density of the tissue. In contrast to the CT image, bone is not visualized. Note the striking demarcation between grey and white matter in the brain and the exquisite anatomical detail as revealed by the presence of small blood vessels (fine black lines within the brain). The PET image represents a quantitative map of local glucose utilization in the structures depicted in the other images and the anatomical section. Areas highest in glucose utilization are dark. Areas with lower glucose utilization appear lighter.

with NMR (Prichard and Shulman, 1986). However, technical difficulties have so far precluded high spatial resolution biochemical and metabolic studies of the human brain *in vivo* (Raichle, 1986).

Positron Emission Tomography (PET). Emission tomography is a nuclear medicine technique that produces an image of the distribution of radioactivity in the human body, resulting from the administration of a substance containing radioactive atoms. Positron emission tomography (PET) uses the unique properties of radioactive atoms, that decay by the release of positively charged particles called positrons, to provide an image that is a highly faithful representation of the spatial distribution of radioactivity in selected planes through the tissue. The radioactive atoms most frequently employed in PET are atoms with very short halflives that are commonly utilized in the body's physiological processes, such as oxygen¹⁵ (122 seconds), nitrogen¹³ (10 minutes), and carbon¹¹ (20 minutes). Because of the development of ingenious labelling techniques, radiochemists can incorporate these

atoms into compounds utilized normally by the body, such as glucose or oxygen, permitting *clinical* investigators to monitor safely and accurately such important physiological processes as brain metabolism and bloodflow with PET.

PET images are based on the *in vivo* detection of two highenergy, annihilation radiation photons (511 kilo electron volts) that simultaneously emerge from tissue, after the local interaction of a positron with an electron (Fig. 2). Detection of the annihilation radiation is based on the use of

Page 349

Fig. 2.

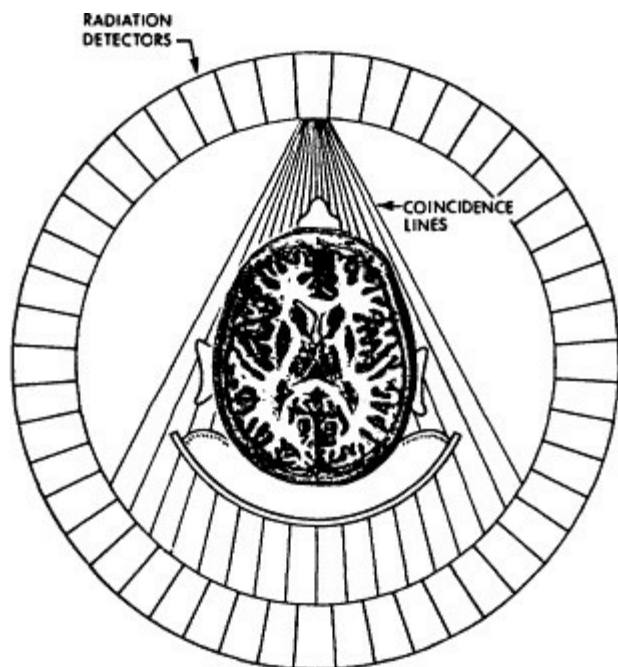

Detection scheme for positron emission tomography (PET). Radioactive atoms employed in PET decay by β^+ emission of positrons. Positrons lose their kinetic energy in matter after travelling a finite distance (~ 16 mm) and, when brought to rest, interact with electrons. The 2 particles are annihilated, and their mass is converted to 2

annihilation photons travelling in opposite directions from each other with an energy of 511 kilo electron volts. Annihilation photons are detected by imaging devices using opposing radiation detectors, connected by electronic coincidence circuits that record an event only when 2 photons arrive simultaneously. (From Raichie (1983), reproduced, with permission, from the Annual Review of Neuroscience, 1983 by Annual Review Inc.) coincidence circuits, in which two opposing radiation detectors record an event in the tissue between them only when two annihilation photons strike the detector coincidentally (Fig. 2). To optimize the efficiency of such a system, detectors are usually arrayed about the head in a circular fashion (Fig. 3). The use of several rings of detectors permits the simultaneous measurement of radioactivity in several tomographic slices of the tissue. A typical PET imaging device is shown in Fig. 4. A discussion of the process by which PET measurements of tissue radioactivity are converted into quantitative crosssectional maps of local bloodflow, metabolism (Fig. 1), or other physiological variables is beyond the scope or intent of this entry. Several general

reviews are available (Raichle, 1983; Leenders et al., 1984; Phelps and Mazziotta, 1985).

PET has demonstrated its capacity to contribute to a better understanding of normal brain function. This work, in its most sophisticated form, is based upon the relationship of local nerve cell activity to brain bloodflow. Interest in the relationship between brain bloodflow and local functional activity has spanned nearly a century. The initial interest crystallized when Roy and Sherrington (1890) published their seminal paper in which they put forth the suggestion that there exists 'an automatic mechanism by which the blood supply of any part of the cerebral tissue is varied in accordance with the activity of the chemical changes which underlie the functional action of that part. Bearing in mind that strong evidence exists of localization of function in the brain, we are of the opinion that an automatic mechanism, of the kind just referred to, is well fitted to provide for a local variation of the blood supply in accordance with local variations of the functional activity.' (See LOCALIZATION OF FUNCTION AND CORTICAL MAPS.) The hypothesis of Roy and Sherrington has compelled investigators to pursue the envisioned relationships in order to better understand the function of the brain.

Even before the development of modern radiotracer methodology in the middle of the twentieth century, and nearly 50 years before the first PET scanners, several early experiments indicated the correctness of the hypothesis of Roy and Sherrington. In 1927 S. Cobb and J. H. Talbot performed tests in rabbits in which vigorous nasal stimulation with smelling salts produced increased blood supply to that portion of the brain serving the

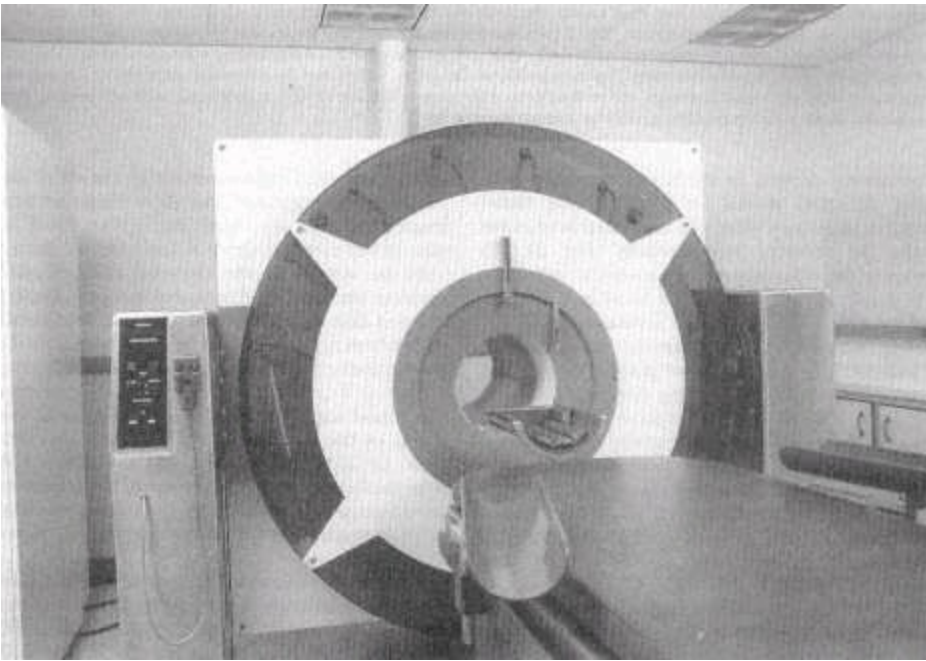

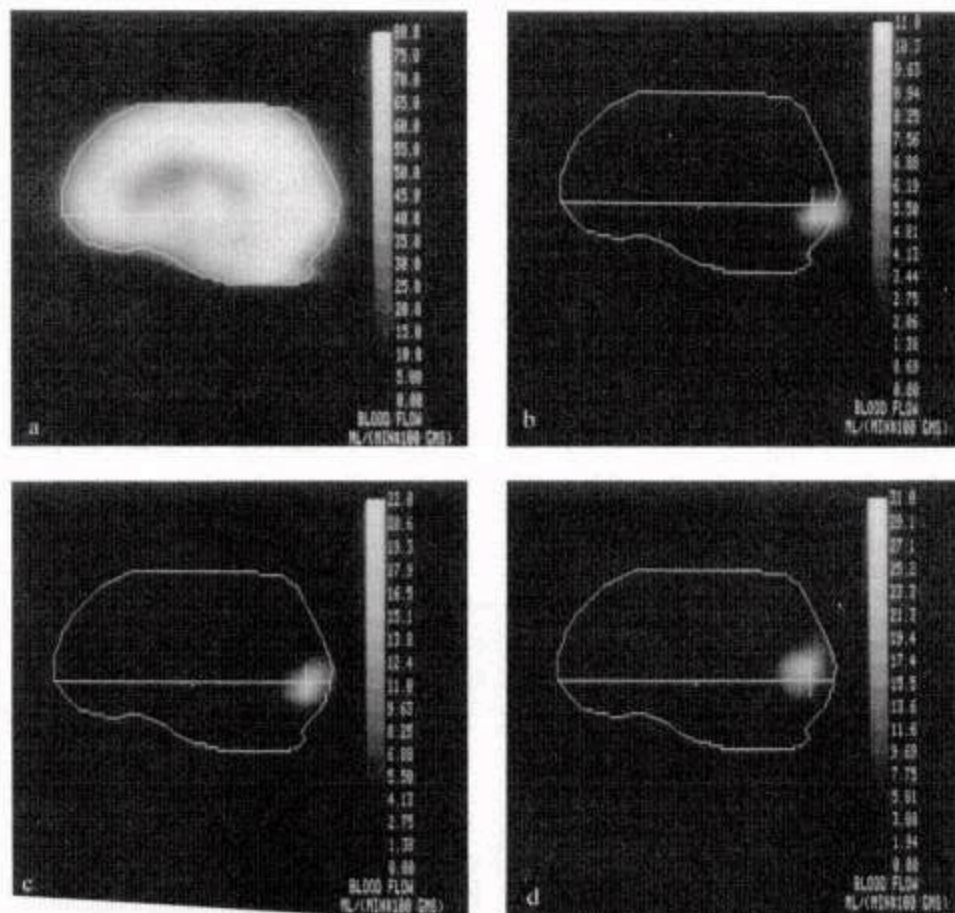

Fig. 3.

Geometry employed in positron emission tomography (PET).

Multiple radiation detectors (type depicted in Fig. 2) are arranged about the subject's head and connected by coincidence circuits. Data from coincidence lines between detectors are used to form a quantitative image of the distribution of radioactive atoms within the brain. From these images, it is possible to measure a variety of physiological processes depending upon the behaviour of the particular compound in which the radioactive atom is delivered to the subject.

Fig. 4.

A typical positron emission tomography (PET) imaging device designed specifically for the study of the human brain (Super Pett IIH; designed and built by M. M. TerPogossian and colleagues at Washington University, St Louis). The subject lies on the couch in the foreground with his head in a specially designed head holder. The subject is positioned with his head in the central aperture of the imaging device and is surrounded by the radiation detectors contained in the gantry.

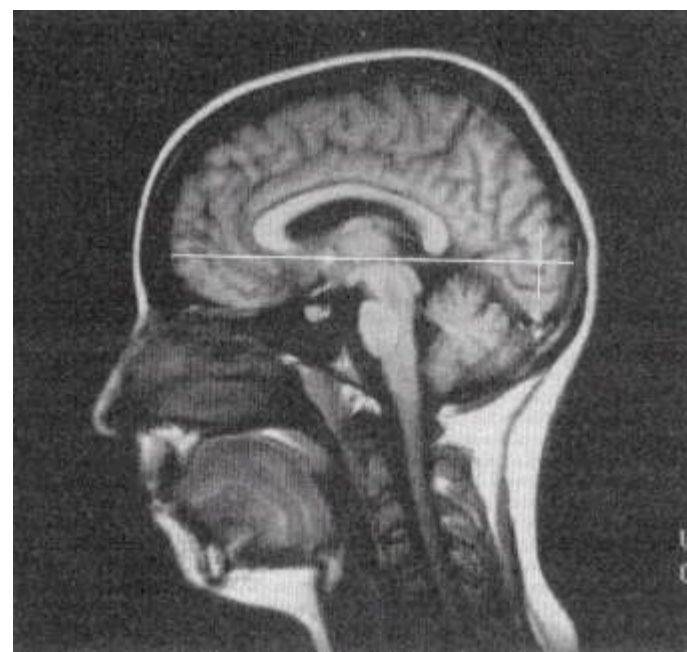

Page 351

sense of smell, whereas other areas of the brain remained unchanged. The first observations in humans were reported a year later by Fulton (1928) who studied a patient of the American neurosurgeon, Dr Harvey Cushing, at the Peter Bent Brigham Hospital in Boston. The patient was operated on for an abnormal collection of blood vessels located at the back of the brain, in the region of the cerebral cortex known to receive and process visual information. The blood vessels could not be removed and the patient was left with a small defect in the bones of the skull. By placing a stethoscope over the scalp in this area physicians could hear a pulsating noise as blood was pumped through the malformation by each heart beat. This noise was also heard by the patient who reported that the noise in the back of his head intensified whenever he used his eyes. Fulton pursued this

Fig. 5.

Positron emission tomography (PET) images of local brain bloodflow during stimulation of visual centres of the human brain. The orientation of these images is best appreciated by reference to Fig. 6, which is an NMR image reconstructed in the same anatomical plane and contains the same fiducial markers for easy reference. a. Resting image of bloodflow in the brain. The scale on the right is calibrated in the units of bloodflow, i.e. millilitres (ml) of blood per 100 grams (gins) of brain per minute (min). b. An image of the difference in bloodflow between the resting and stimulated state obtained by subtracting image a. from the image obtained during the stimulation of the very centre of the subject's visual field. The centre of the area of increased activity is located at the back of the visual cortex. c. An image of the difference in bloodflow produced by stimulating the subject's visual

field slightly away from the centre of the visual field. d. An image of the difference in bloodflow produced by stimulating the periphery of the visual field. All images were obtained in the same subject. The stimulus consisted of an annulus composed of red on black chequerboards alternating colours 10 times per second, and presented to the subject on a television monitor visible to him while lying in the PET scanner. The size of the annulus was varied to stimulate various parts of the visual field. Note that, as the stimulus moved from the centre of the visual field to the periphery, the area of activation moved systematically along the visual cortex. This corresponds to a well known map of visual space existing in this part of the brain. The centre of areas of activation such as these can be determined with an accuracy of approximately 1 mm (Fox et al., 1986).

Page 352

observation and was able to confirm that the noise over the visual cortex increased during visual stimulation (for example, reading a newspaper) but not during any other type of activity. This unique observation provided the first direct evidence in a human subject of the close link between local neuronal activity and bloodflow.

Abundant evidence now indicates that functional brain activity of all types (for example, somesthesia, hearing, movements of all types, vision, language, as well as covert cognitive activity) causes striking changes in local brain bloodflow and metabolism. Analysis of such images has progressed from simple, qualitative, uncontrolled demonstrations of anticipated changes to much more sophisticated studies using rigorously controlled experimental paradigms and precise analytical techniques (Raichle, 1987). A good example of such a study is shown in Fig. 5. By combining the physiological information from such PET images and the anatomical information from an NMR image (Fig. 6) it is now possible to visualize safely, and with considerable precision, the relationship between physiology and anatomy in the normal, living, human subject.

PET will also contribute to an understanding of brain function by providing a new understanding of the effect of localized areas of injury on the function of the brain.

For many years neurologists have studied the effects of localized disease of the brain, usually*strokes and occasionally other diseases such as*epilepsy, on the function of the human brain. It was through many years of painstaking study of such lesions, first at the autopsy table, and more recently with CT and NMR imaging, that we have obtained our current understanding of such complex human functions as language and memory. What such lesion studies reveal is the relationship between an anatomical lesion and a patient's signs and symptoms. What they fail to reveal are areas of the brain remote from the lesion where function is significantly altered due to the disruption of normal relationships between regions within the brain. Because altered neuronal function causes alterations in bloodflow and metabolism, PET is ideally suited to detect these areas of altered function remote from the actual area of brain damage (Metter et al., 1985). A typical example is shown in Fig. 7 where a small stroke deep within the cerebral hemisphere causes a large metabolic abnormality in overlying cerebral cortex, in an area with no gross pathological abnormality.

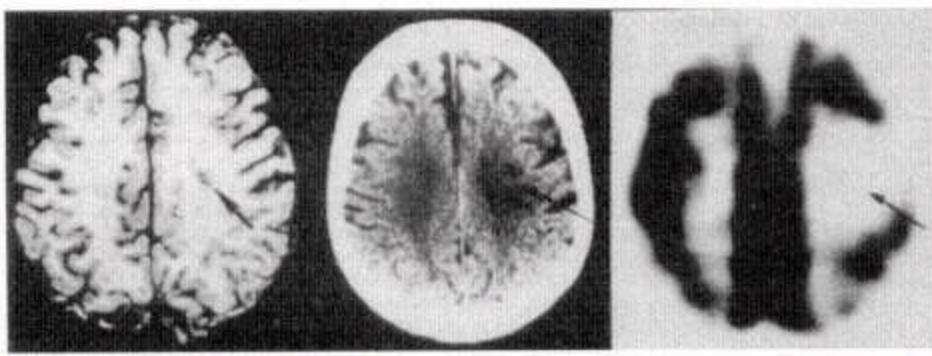

A systematic study of the clinical significance of these remote physiological effects of brain injury has yet to be conducted. It seems safe to say, however, that the availability of this new physiological information will enhance our understanding of human brain function.

Finally, some recovery of function often occurs despite irreversible injury to a particular region of the human brain (see BRAIN FUNCTION AND AWARENESS).

One hypothesis is that such recovery is due to a reorganization of the brain, such that a new region of the brain now serves that particular function. Our ability to observe the local activity of the brain during the performance of the recovered function should permit a much better understanding of this process of reorganization and ultimately

Fig. 6.

A nuclear magnetic resonance (NMR) image of a normal human subject reconstructed in the midsagittal plane. The orientation of this image corresponds to the PET images shown in Fig. 5. The fiducial markers on the image correspond to similar markers on the PET images in Fig. 5. The intersection of these two lines corresponds, approximately, to the centre of the primary visual cortex in humans.

Page 353

Fig. 7.

Gross pathological section, Xray CT scan, and corresponding PET study of glucose metabolism in a patient with a small subcortical stroke. The area of brain injury is clearly seen in the CT image and the section of brain obtained following the patient's death (arrow). This small area of brain damage resulted in a large area of functional impairment as demonstrated by the area of reduced cortical glucose metabolism remote from the stroke itself.

lead to more rational treatment of affected individuals.

It might be argued by some that, despite the developments described above in our ability to do functional mapping of the human brain, it is virtually impossible for PET

to reveal the underlying neuronal elements participating in such changes, and hence they contribute little to our understanding of how the brain works. It seems fair to assume, however, that once PET has safely identified a specific area of human brain responsible for a welldefined type function, a task it is uniquely equipped to do, other neurobiological techniques can be brought to bear on the exact nature of the process. Complementary interaction of this type will benefit both clinical investigators and brain scientists.

IMAGING. Most people can imagine the appearance of a loved person's face, of a familiar and often used room, or even, with the lights suddenly turned out, the approximate dimensions and organizations of the place they are in. Most people can report the reveries of a daydream, the somewhat hallucinated state that often precedes sleep, or the dreams of sleep itself. Barring those who are neurologically damaged, people can with their eyes closed touch a finger to their chin or throw a dart with enough force just to hit a nearby wall; can hear the voice of the writer when they read a letter from a friend, or the voice of an adviser when in a situation of conflict; or taste a remembered food, or experience the aroma of an object not present. And, indeed, most people can rise from their chairs and walk across the room with their eyes closed, navigating the intervening space safely and accurately. In all these many conditions people can be said to be imaging. The nature of the mental image, its role in mind and behaviour, and even how to account for imagery in a theoretically satisfactory way, are all puzzles of great interest to a number of philosophers and psychologists.

Often the notion of mental image is taken as a 'picture in the mind', the richly pictorial evocation of a scene not present to view, so not all of the events listed above are customarily thought of as images. All of the sense departments—vision, hearing, touch, smell, taste—can be involved in the production of imagery, however, although some sorts of image may be evoked somewhat more readily than others. People differ in their preferred

Page 354

way of encoding the world; some say they learn a subject better by reading about it, whereas others claim that a lecture is more informative. An early division of people into audiles and visiles—those preferring listening to reading, for example—broke down when it was found that these allegedly constitutional differences were often a matter of strategy, or preference, or appropriateness to the occasion.

The way the image may function in mental life, and even its nature as an object of mind, are debated issues at present. Some investigators endow mental images, especially spatial images, with the very properties they are alleged to represent in mind; others maintain that the content of mind is not a suitable descriptor and assert that all mental experience can be captured with the structured propositional representation of the logician; and yet others maintain that imagery is best thought of as a kind of private*symbol system that people use for different purposes: to orient themselves in space, aid their recall of some event, or even, as on a sort of mental scratchpad, to work out solutions to problems. Whereas the first two groups concern themselves with the question of what an image is and how best to describe it, the third group recommends studying how imaging may, among other kinds of symbolizing, function in mental life.

It is important to realize that an image of an experience is sometimes not readily distinguished from the perception of a physical encounter, a fact that has strengthened those concerned with identity of the image, although a few minor tests can quickly reveal the difference. The image is not readily manipulated (see IMAGE

ROTATION), nor does it withstand the detailed scrutiny that a physical object can. In a test made many years ago a psychologist exposed matrices of letters and digits to people recognized as ready visualizers. After the people had examined each matrix for some moments it was removed and they were asked to form a mental image of it and to name the letters or digits in a row or column. If the matrix were present to view, the letters could be named in any direction in about the same amount of time, although a favoured reading direction might give a slight advantage. In fact, people were not able to manipulate their images of the matrix so as to read off its contents in unfamiliar directions without some sort of rehearsal. Thus, its appearance may not by itself allow one to judge accurately whether an event is stimulated by some object of the environment external to the person or is constructed by the person wholly from within; however, suitable tests of manipulation, scrutiny, and evaluation resolve the puzzle. Many different sorts of events can result in similar appearances, so that appearance alone can never be used reliably as a guide to identity.

Eidetic imagery seems to challenge some of the assertions made above. Found more readily in children than among adults, the eidetic image is said to have more of a richly pictorial quality than other images have. Shown a complex drawing for a few minutes, some children can subsequently report on many of its features, even seeming to reexamine it in detail when questioned about something not yet reported. Very little more is known about this ability.

The role of imagery in mental life has puzzled and entranced philosophers and psychologists alike for many years. One reason for this, stemming from the empiricist theory of mind, has to do with the way we acquire knowledge of the external world. An early, and recently revived, theory has it that the

visual system forms brief images—'snapshots', so to speak—which the linguistic system then encodes and deposits in*memory. The image here serves as a first stage in some chain of information acquisition, a notion which is, however, questioned by many. Secondly, images are thought to sustain orientation and mobility in space. And for a third reason, the proposal has been made that the mental image serves as a personal symbol.

The lack of sure knowledge regarding the nature and function of imagery stems in part from the difficulty of saying much with certainty about the mind, and in part from the bad reputation that imagery has until recently suffered. For sculptors, painters, and other artists, the notion of a richly pictorial inner life has been assumed without saying—as much as a richly linguistic inner life must mark the essayist, judge, poet, and others concerned with the sense and sound of language, a mind full of sounds the musician, or a mind full of smells the perfumer. A vivid inner life must surely characterize anyone whose work requires invention, problemsolving, organization—

anything beyond the stereotypy of mindless activity. The bad reputation developed because imagery was wholly subjective and so not available for public scrutiny. In the earliest days of experimental psychology, a proper experiment often consisted in describing as analytically as one could the bare 'sensations' that presentation of a stimulus or memory of it evoked. The contents of consciousness were thought then to be the principal data of psychology, and accounting for them to be the task of the psychologist; much as, in direct analogy, the contents of the world were taken as the data of chemistry and accounting for them—how combinations of elements yielded compounds—was taken to be the task of the chemist. Rejection of this view constituted part of the dogma of the 'behaviourist revolution' (see BEHAVIOURISM) and the enterprise of accounting for the inner life was discredited. Recent developments in psychology, philosophy, linguistics, and computer science (see ARTIFICIAL INTELLIGENCE) have restored interest, if not in the contents of mind, at least in its operations, of which imaging is one.

IMMATERIALISM. See BERKELEY, GEORGE.

IMPLICATION is the fact of being involved or implied without being plainly expressed. Thus seeing the implications of a decision, or of a course of action, requires knowledge of its consequences, and seeing the implications of what someone has said requires a knowledge of the significance or meaning of his words, given the context in which they were uttered.

It is via the notions of consequence and meaning that implication has become a term of the logician's art and a focus of philosophical study and debate. Here it is treated as that relation between two statements or propositions A and B which obtains whenever the corresponding conditional statement 'If A then B ' is true: e.g.

' ABC is a triangle' implies 'The internal angles of ABC add to 180° ' if, and only if, 'If ABC is a triangle, then its internal angles add up to 180° ' is true. Thus A implies B

if, and only if, it is that case that if A , then B . Philosophical and logical theories of implication are thus inseparably tied to analyses of conditional statements. In the most widely used formal propositional logic (that based on truth tables), conditional statements are represented by the (truth functional) connective ' \rightarrow ' expresses the relation of *material implication*. This definition has the consequences (known as the 'paradoxes of material implication') that, for example, 'Snow is red' materially implies

'Pigs can fly', and 'Dodos ate fish' materially implies 'Snow is white', since a false proposition materially implies *any* other proposition, and a true proposition is materially implied by *any* other proposition.

These examples fly in the face of our intuitions both about implication and about the meaning of 'If ... then ...' and have thus been used to cast doubt on the legitimacy of using ' q ' is true for any p . Several other notions of implication have been introduced with a view to avoiding these paradoxes but encounter problems of their own.

Haack, S. (1978). *Philosophy of Logics*, chs. 3 and 10. Carabridge.

IMPOSSIBILITY. See POSSIBILITY.

IMPRESSION. This term reflects the ancient notion that experiences are impressed on the 'wax' of the mind by the 'seal' of experience in*memory. This implies that memory is essentially passive; but modern work, following F. C.*Bartlett (*Remembering*, 1932), strongly suggests that memories are active constructions, and are often distorted towards the familiar or the wanted. So this notion of memories as impressions like seals on wax is not an appropriate model.

IMPRINTING. When recently hatched birds such as ducklings are handreared for a few days, they strongly prefer the company of their human keeper to that of their own species. This remarkable process, which can so dramatically influence the development of social relationships, is called 'filial imprinting'. A bird's experience later in life can also strikingly influence its sexual preferences. When

exposed to another species at a certain stage in development, it may subsequently prefer to mate with that species. The process influencing mate choice is known as 'sexual imprinting'.

In many ways the term 'imprinting' is a misnomer since it implies an instantaneous stamping in to the bird's memory of information that will determine its social preferences. In fact, the process is more gradual and is better likened to the painting of a portrait in which the broad outlines are first sketched and fine details are filled in by degrees. Furthermore, despite the remarkable distortions of social preferences that can occur under artificial conditions, some stimulus objects are much more effective than others. In general, objects that are most like the animal's own species are most effective in influencing its subsequent preferences.

The procedures used for studying imprinting are not associative. The experimenter merely exposes the bird at the right age to a single conspicuous object and subsequently shows that its preferences have become restricted to that object. Even so, the underlying process might be associative. If this were the case, initially significant and attractive features of the stimulus object would be linked to initially neutral features in the course of learning. Deciding whether or not this is really what happens is not easy. Even if the imprinting process that leads to the identification of parents (or future mates) is not associative, it operates simultaneously with both classical and operant*conditioning. What is more, the objects that work best for purposes of imprinting can be used with the associative procedures as rewards. Thus, the imprinting stimulus is highly effective as a reinforcer, and a young duckling can easily be trained

to press a pedal that switches on a motor and brings an object into motion. However, enough is now known about the neural mechanisms to dissociate by lesions in the brain the operant conditioning which involves learning to press a pedal, from the imprinting which involves the narrowing of preferences to a familiar object.

As it happens, filial imprinting in domestic chicks has proved to be a useful model for studying the neural basis of*learning. Using biochemical measures of neural activity and autoradiography, a site in the intermediate part of the medial hyperstriatum ventrale (IMHV) has been found to be intimately involved in filial imprinting.

When the neurones in this area are destroyed before imprinting, a chick fails to identify the object with which it has been trained; and furthermore, when they are destroyed immediately after imprinting, a chick no longer responds preferentially to the object with which it was trained. Nevertheless, lesioned birds are just as capable as intact animals of learning discriminations in which reward is involved, and will work just as readily for an imprinting object—even though they do not learn its characteristics.

Some other discoveries of the work on the neural mechanisms involved in imprinting are also striking. Storage only remains localized in the IMHV on the left side of the brain. On the right side, information is stored initially in the IMHV but within twentyfour hours it has dispersed to other, and as yet unknown, sites in the brain. In the left IMHV, where information about the imprinting object remains stored, the dendritic synapses increase in size. It would be an exciting, as well as demanding

task, to discover whether the pattern of synaptic enlargement codes the information stored in the course of imprinting.

One of the striking features of filial imprinting is that it is easiest to get birds to learn about an object at a particular stage early in life. This stage is referred to as a

'sensitive period' in development. However, it is important not to confuse the descriptive evidence for such a period with explanations for how the evidence has been generated. The nature of the timing mechanisms has proved to be subtle, and the image of a clock, opening a window on to the external world and then shutting it again, is not good enough.

Generally, the onset of sensitivity is measured in terms of time after hatching. However, birds can differ by as much as thirty hours in the stage of development at which they hatch. In other words, when eggs have been incubated under identical conditions, the time from the beginning of incubation to hatching varies greatly. It is possible, therefore, to have birds of the same posthatch age which are at different stages of development, and birds which are at the same stage of development but of different posthatch ages. The influence on imprinting of the general stage of development can be separated from the influence of experience occurring at hatching and after it. It turns out that both the age from beginning of embryonic development and the age from hatching influence the results. In other words, it looks as though the general stage of development of the bird plays a part in the onset of sensitivity, but that the events associated with hatching, or experiences subsequent to it, also play their part. Part of the increase in sensitivity is attributable to the changes in the efficiency of the visual system. This being the case, the interaction between internal and external influences is particularly easy to understand. Visual experience with patterned light has a general facilitating effect on the development of visually guided behaviour. It also serves to strengthen connections in neural pathways. Thus, it is probable that the development of the visual pathways, on which filial imprinting must depend, can be accelerated by early hatching if this means that the bird receives more experience from patterned light than the bird which is still inside the egg.

The end of sensitivity to novel objects arises from a property of the imprinting process. When a bird has formed a preference for an object, as a consequence it ignores or even escapes from other objects. Therefore, imprinting with one object prevents further imprinting with other objects from taking place. While some objects are much more effective than others in eliciting social behaviour from naive birds, domestic chicks can form social preferences for suboptimal stimuli such as the static cages in which they were isolated, although this takes several days. It follows, that if some birds are reared with nearoptimal stimuli, such as their siblings, and some are reared in isolation, it should be possible to imprint the isolated birds with a novel object at an age when the socially reared birds escape from, or are indifferent to, new things. This is clearly the case with both domestic chicks and mallard ducklings. Investigators find it difficult to get older birds to respond socially to an object, because the birds have already developed a preference for something else.

It seems, then, that the end of sensitivity of a bird to a wide range of objects is generated by a runaway process in which the consequences of an initial change in state generate the conditions for further and more rapid changes. When the bird is poised to learn, all that is required is the presence

of a suitable external stimulus to trigger the process. As a result of learning about a particular object, the bird escapes from those it can detect as being different. This escape from strange objects intensifies the young bird's contact with a familiar object, and the range of acceptable companions rapidly contracts so that in the natural world the bird ends up with a distinct preference for its own mother. Enforced contact with something other than the preferred familiar object may wear down the behavioural constraints to the point where the bird does form a new preference. Escape from novel objects can be habituated, and domestic *chicks* that have developed a preference for object A can be induced to prefer object B to object A by

Page 357

sufficiently long exposure to the second object. It turns out that the early preference is not forgotten and may resurface after isolation from both types of object. So, it would seem, the protection of preferences from subsequent disruption is accomplished not only by behavioural means, but also by internal processes as well.

For many years it was thought that imprinting enabled an animal to learn about its species. However, it is becoming apparent that imprinting serves a more subtle but equally important purpose, enabling the young to recognize one or both of their parents as individuals. The species that are leathered and active at hatching must learn the parental characteristics quickly because, on leaving the place where it was hatched, the young bird must stay near a parent. If it approaches another adult of its own species, it may be attacked or even killed. For this reason, as soon as the young animal is able to recognize its parent (or a substitute parent in an experiment), it escapes from anything that is noticeably different. The rapid attachment to the first conspicuous objects encountered after hatching is characteristic of the precocious species. In birds like the swallow, which are hatched naked and helpless, learning occurs later in development, and the young only respond selectively to their parents when they have left the nest about two weeks after hatching. Sexual imprinting probably occurs later in development because birds need to know the characteristics of their siblings' adult appearance when they come to choose a mate. The ideal mate must be a bit different but not too different from close relatives in order to avoid the dangers of inbreeding and, at the other extreme, the dangers of mating with a genetically incompatible partner such as a member of another species. Some animals are so careful in their choice of sexual partner that, having been reared with their siblings, they then choose first cousins as mates. This has been discovered in Japanese quail and also in mice. Indeed, it is becoming apparent that processes similar to those first described in birds are equally important in mammals. The biological need to recognize close kin, both early in life and when adult, is a general one.

P.P.G.B.

INDIAN IDEAS OF MIND. A short survey cannot do justice to the enormous range of ideas of the mind produced in India. In an unbroken cultural tradition of some three thousand years, which has given birth to Hinduism (itself the name not of a single religion but of a family of religions), Buddhism, and Jainism, one of the main topics of conceptual interest has been in philosophical psychology: how the mind is to be analysed, trained, and developed, in order to explain and obtain

the religious goal of enlightenment and release from rebirth. Here it is possible only to indicate some of the main structures and attitudes of Indian thought; and certainly exceptions to everything said here have existed.

Among the many words which can be translated as 'mind' are: *manas*, from *man*, to think; *citta* or *cetas*, from *cit*, to perceive or attend to (these latter two are often better translated as 'heart', the Western term for the affective and intentional centre of personality. Indeed the word usually translated as heart, *hrdaya*, itself is often used to refer to cognitive acts); *buddhi*, from *budh*, to be awake or aware; *vijñāna*, from *jñā*, to know or be conscious; and, finally, in many philosophical contexts the term *antahkarana*, literally inner activity or inner organ, is used to refer collectively to a variety of perceptual, intentional and cognitive functions or agencies. Often some or all of these terms are to be regarded as synonymous; in particular systems they can also be taken to refer to different things. In no case can we assume anything simply comparable to Western*mindbody dualism; nor has much attention been paid to the specific mindbrain problem. In so far as mind or*consciousness has been given a physical location, or at least been associated with particular locations in the body, it has been in terms of the mystical physiology of *cakras*, circles or centres of energy, twelve of which are thought to be located in various parts of the body; different kinds of consciousness are then associated with different *cakras*.

The first and most general point to make about Indian ideas of the mind is that they have been elaborated in a conceptual context derived from, or at least constantly in interaction with, religious concerns. The basic structure of the religious worldview is given by the following three terms. (i) *Samsāra*—'the round of rebirth'—is the idea that each person (however that is conceived) lives through a series of lives, which can occur in various forms both in this world and elsewhere. (ii) *Karma*—

'action', 'moral retribution'—is the belief that it is action which causes this process of rebirth, and experience within it; the moral quality of actions performed previously usually but not necessarily in past lives—determines the happiness or suffering experienced thereafter. This gives both one type of explanation of suffering and evil, and a possible rubric for religious and moral behaviour which tries to improve one's lot in the future. One may hope for rebirth in better circumstances, or for an escape from rebirth entirely. (iii) *Mokṣa*—'release', 'liberation' (in Buddhism usually called *nirāṇa*)—refers to the escape from rebirth, to an ultimate state variously conceived, but usually involving some or all of the qualities of freedom, bliss, transcendental knowledge, and power.

This conceptual system is understood in at least two main ways. Firstly in a literal or mythological sense, it can be taken straightforwardly to refer to a sequence of births, lives, and deaths, and to escape from them. Secondly, it can be interpreted in a psychological or 'demythologized' sense—that is, as referring to different ways of perceiving and evaluating the temporal world, rather than to different lifehistories or destinies within it or beyond Page 358

it. In this sense, *samsāra* is best taken as something like 'differentiated perception', or 'unenlightened understanding'—that is, seeing the multiform and in itself unreal ordinary world as ultimately real and desirable, in contrast with *mokṣa*, which is seeing the word in its eternally true light (a true light, of

course, very differently described by different systems). Here, instead of the religious goal of enlightenment being taken in a horizontal perspective—as something awaiting the holy man at the end of his earthly life—it is taken in a vertical perspective, as a possibility of moral-mystical experience *now*. (Of course, these two perspectives are not mutually exclusive; the symbolic, psychological sense can be, and is regularly taken to be, the means of operation of the literal, religious-destiny sense.) A very fine expression of the vertical, demythologized interpretation of these concepts is given by the tenth-century theologian Abhinavagupta, for whom the ultimate subjective reality of the self and the objective reality of the experienced universe are both God, known as Siva or Bhairava. It is God's essential nature, as pure consciousness, constantly to manifest or emanate the individual selves and objects of the ordinary world (*samsara*) as both its efficient and its material cause. Thus we read that (Liberation *is* knowledge; it is not a separate phenomenon which knowledge produces), for liberation *is* the revelation of one's true identity; and the identity of the self is consciousness.... When one has established oneself in the sphere of prediscursive intuition one may become supreme Siva, through any of the levels of manifestation, from the grossest impenetrable matter to the subtlest Siva. One's awareness becomes supreme Siva by these (various inroads, by centredness) in the light which manifests itself as these ordered aspects as they shine in their primal brilliance.... One becomes Bhairava by the revelation that within one's own identity as the void of consciousness one is oneself causing the universe to appear and that as one creates it one is it. 'This entire system of the six parts of the cosmos is reflected in me alone and it is I that sustain its existence.' Thus shines forth one's identity with everything. 'This universe is dissolving into me as I roar with the fire of absolute awareness beyond time.' With this vision he comes to rest. The realization that one is Siva (is) the surging holocaust (which) burns to nothingness the dream-palace of *samsara*, with its infinite, diverse and beautiful chambers. (*Tantraloka*, I, 156; I, 21112; III, 2836, translated by Alexis Sanderson.) In this general religious context, ideas of the mind depend on different notions of the enlightening realization, and specifically on different notions of what is the soul or self which is realized and liberated. Answers to this latter question vary greatly: there is the view, as we have just seen, that the single and ultimately real self is (a personal) god; the real self can be seen as the impersonal cosmic spirit or essence, usually called *brahman* (as in the *Vedanta*); it can be a separate, eternally monadic soul or person (as in Jainism and *Samkhya*). These two systems are atheistic: elsewhere such a monadic soul is also related, devotionally, to a god); and finally, as in Buddhism, the ultimate realization is that there is no self at all.

In all these systems, what we call the human mind is *not* part of what is released; it is in itself either an obstacle to, or at most merely an instrument of release, on a par with the physical senses. One system which exemplifies this, and which was used in various developed forms by many later traditions, is the classical *Samkhya* ('Discrimination'). It is a dualism, but not at all in the Cartesian sense. On the one hand, the real self is called *purusa*, 'person'; it is eternally inactive, a mere spectator at the show of existence. On the other hand, *prakṛti*, 'matter' or 'nature', evolves from within itself the whole drama of rebirth and release. From an undifferentiated state of equilibrium, at the start of each cosmic aeon, there evolve first something called *mahat*, the great, or *buddhi*, will, or determinative awareness, then *ahamkara*, 'I-maker' or ego, and then *manas*, mind, conceived as a *sensus communis*, a cognitive organization and recognition of sensory activity and experience.

(Subsequently there evolve five senseorgans, five organs of action—these, together with *manas*, in fact evolve together and are called the eleven faculties—five subtle elements, the 'sensedata' perceived by the senses, and five gross elements, the external substances thus perceived.) The first three evolutes are together termed *antahkarana*, inner organ, or in a general sense 'mind'. This mind is constantly changing, moving and being moved in the ordinary world of action and experience. In itself it is unconscious and inanimate; it is only the presence of the static and inactive *purusa* which, as an animating catalyst, transforms mental activity into conscious experience. This conjunction of the *purusa* and the 'material' mental/sensory apparatus is likened to that of a lame man and a blind man: separately incapable of movement and sight, respectively, but together capable of progress (toward enlightenment) (*Samkhya Karika*, XXI). Another image conveys the notion of a release which comes to the 'witnessing' person, entirely without activity on its part, but rather from the material mind's own cessation of action: a dancer, whose dancingshow, beautiful but temporary, is finished, gracefully withdraws from the stage, leaving the spectator free (ibid., LXVLXVI).

Thus the religious context of Indian thought puts ideas of the mind into this sort of conceptual structure. Equally, it influences these ideas by its overriding moral and spiritual attitudes. Generally speaking, the senses and mind are regarded as appetitive, as desiring, grasping, and relishing their objects, in the very act of sensing or knowing them. In the unenlightened, this rapaciousness is wayward and uncontrolled; enlightenment requires the imposition of control on it, either to stop ordinary experience entirely, or to let it proceed seen in its true light, seen as it really is. The *Katha Upanisad* (c. sixthfifth century BC) uses an image familiar in the West, and widely used in India:

Know the self as the chariotowner (i.e. he who is carried,

Page 359

inactively, by it), the body as the chariot. Know awareness (*buddhi*) as the driver, the mind (*manas*) as the reins. The senses, they say, are the horses, senseobjects the path they range over. The self joined to mind and senses, wise men say, is the experiencer. He who is without understanding, whose mind is ever unharnessed, his senses are out of control, as bad horses are for a charioteer. (*Katha Upanisad*, I, 35.)

In the *Bhagavad Gita* (c. third century Be) India's most popular religious text, we read of the unenlightened that 'when a man's mind follows after the wandering senses, his wisdom is carried away, as the wind (carries away) a ship on water'. Contrastingly, 'when everywhere a man withdraws his senses from their objects like a tortoise (withdrawing) his limbs, then his wisdom is firmly established' (II, 67; II, 58). The Buddha taught that 'just as a monkey in a big forest seizes one branch, lets it go and seizes another, so too that which is called mind (*citta*), thought (*manas*), or consciousness (*viññana*) by night and by day at one moment arises as one thing, (the next moment) ceases as another' (*Samyutta Nikaya*, II, 945).

This last text embodies the Buddhist idea that the mind itself changes as rapidly as do its objects; and this points to a very general fact about Indian ideas of the mind.

Whereas the true self, or whatever lies behind the ordinary experienced world (in Buddhism not a self or an 'absolute' of any sort, but the fact of emptiness) is unchanging and timeless, the mind and its temporal experiences are constantly changing; but further, the mind changes *together with* its objects, because the mind and the senses conform to the nature of what they cognize or perceive. A regular idea of perception, for example, is that a ray of light goes out from the eye, makes contact with, and takes on the form of its object, and then carries vision of the object back to the eye (see, e.g., the thirdcentury BC *Nyaya Sūtras*, III, 32f.). In a medieval *Vedānta* text (cited from *Panchadasi: a treatise on advaita metaphysics*, trans. Hari Prasad Shastri, London, 1956) it is said that 'the mind, which is the illuminator of all objects, assumes the forms of the objects it perceives, just as sunlight assumes the forms of the objects which it illumines' (IV, 29).

From this notion that the mind assumes the form of its object arise various other Indian ideas. In certain devotional schools of Hinduism, since intense mental concentration of any sort on God will transform the mind into God, even intense hatred will produce Godrealization and thus liberation in the hater's mind. Similarly, in certain meditation traditions in Buddhism and Hinduism, when the mind concentrates on a certain level of the psychologicalcosmological hierarchy, it 'becomes' that level, and (particularly if the mind is in this state at death) the meditator will be reborn in the corresponding heaven. If, in contrast, an ordinary man's mind is regularly characterized by a predominant emotion, he will be reborn in an appropriate sphere—greed, for example, might produce rebirth as a dog. In the traditions of religious thought and practice known as the *tantra*, this pattern of ideas explains the attainment both of thisworldly pleasure and powers (*bhukti*) and of final release (*mukti*).

In order to achieve a particular good (or, in what we call black magic, a harm), the religious specialist will concentrate his mind on the particular deity who controls the desired object, usually in that god's *mantra* form. (A *mantra* is a hymn, sound or 'spell'. Language—that is, Sanskrit—is regularly thought to be the ground of all thought and consciousness; so particular gods, and the supreme God, have two forms of representation, one visual and iconographic, the other sonic and 'bodied forth'

in *mantras*.) In this way, the mind concentrates on and becomes the *mantra*, and thus becomes the god, and so gains control over the god's domain. When this technique is applied to lowerlevel gods, for thisworldly goods or harms, we tend to see it as magic; it becomes more recognizably religious when final release is sought, when the human microcosmic mind seeks identification with (or, as it is expressed, 'possession by') the macrocosmic supreme divinity. In both these contexts, an image regularly used is that of the god's seal, *mudra*, impressing itself on the wax of the disciple's mind.

In all contexts, magical, religious and philosophical, the simple description of the workings of the mind is embedded in their moral evaluation. This can be seen in (though not proved by) the terminology used: the standard terms for the functioning of consciousness, regardless of its ultimate subject (or lack of one) are *grahaka*, *grahya* and *grahana*, grasper, grasped and grasping, subject, object and (act of) knowing or perceiving. These three elements of consciousness may or may not be thought of as arising simultaneously or in one or other causal sequence. It is true that in most uses of these terms there is as little concentration on their etymologically literal meaning as there is in the case of their English translation; equally, the fact that Indian thought regularly uses concepts which do

not distinguish factual description from moral evaluation does not show (what would be false) that it cannot do so. Nevertheless, these terms are used in systems where the unenlightened mind's

'grasping' its objects *is* seen as intrinsically connected with, or a function of, the foolish desire mistakenly to take the ordinary world for true reality, by grabbing hold of the pleasure and illusory permanence of the experience of the ordinary world. The earliest text of the *Vedanta* school, Gaudapada's *Mandukyopanisadkarika* (c.

seventeenth century AD?), demonstrates this:

It is consciousness (*vijnana*), birthless, motionless and immaterial, (eternally) at peace and nondual, which seems to be born, move and perceive substance.... Just as the movement of a firebrand produces the appearance of straight and crooked (lines), so the vibration of consciousness produces the appearance of perception and perceiver.... This duality of subject and object is just a vibration of mind (*citta*). . . . (This) is the craving for what Page 360

is (ultimately) nonexistent, but in truth no (real) duality is found; he who realizes the absence of duality, beyond qualifications is not reborn. (IV, 45, 47, 72a, 75.) Just as description and evaluation are conflated in these accounts of the mind, so too moral and religious explanations of character and destiny derived from the idea of karma, enter into the account of other kinds of mental activity. The key concept here is that of 'traces' or 'impressions' (the term is usually, but not always, *vasana*,
