'perfuming'), and the notion is that each act, mental or physical, leaves behind it a trace which 'perfumes' or conditions the individual series of mental events which is the mind of the agent/experiencer, just as a sesame seed retains the smell of the flower after the flower has died. These traces in the mind can be representational—that is, a trace can be reactivated as a memory, a dream, or in some systems a perception—or they can be moral and psychological conditioning factors—that is, they may operate in the future as one of the various kinds of determining influence on an individual's character and behaviour in a particular lifetime. The location of these traces is differently described; it is often seen as a particular kind or level of the mind, for which the translation 'the unconscious' is tempting. The metaphor of depth, however, usual in (at least popular versions of) Western psychoanalysis, is not much stressed in India, even in the other image used to picture the mind's operation here, that of 'seeds' sown by action and experience, which ripen later into the 'fruits' of memory, characterdisposition and so on.

In the case of the traces being representational, the realist *Vaisesika* system holds that 'memory, dreams and dreamconsciousness arise from a particular contact between the self and the inner organ, along with traces' (*Vaisesika Sutras*, IX, 223). In the idealist school of Buddhism, the *Vijnavavada*, a comparable mechanism produces perception of a word mistakenly thought to be external, but in fact arising, just as do memory and dreams, from the traces kept in the 'store' or 'baseconsciousness' (*alayavijnana*) (e.g. in Vasubandhu's *Vimsatika*). When the traces act as moral and psychological conditions, the overall effect of such 'perfuming'

by previous unenlightened acts is to predispose the mind habitually to perform further desirebased

and ignorant deeds. The general predisposition is specified in various ways. When rebirth at one of the various levels in the cosmic hierarchy takes place, particular kinds of trace in the mind are activated, so as to produce the appropriate mental dispositions for that kind of being (e.g. *Yoga Sūtras*, IV, 811, and Commentaries). These dispositions in each life are both general, as species-specific characteristics and instincts, and particular, as those patterns of motivation and behaviour which give rise to individual personality. These individual characteristics are usually described as the predominance of one or more kinds of emotion and attitude; often they are expressed in terms of the 'humours' of traditional Indian ayurvedic medicine, which resemble the humours of ancient and medieval Western thought. Sometimes, individual character as a man is derived from the predominance of traces derived from species-specific characteristics in former lives; and this individual character can continue even after enlightenment (for although the enlightened man creates no new karma, he may well still have old karma to work off). Étienne Lamotte (in Cousins, *et al.* (eds.), *Buddhist Studies in Honour of I. B. Horner*, Dordrecht, 1974, p. 93) recounts the following story:

In Vaisali, a monkey met his death after having filled the Buddha's bowl with honey. He was reborn into a brahman family and as in recompense for his good deed he had as much honey as he needed, he received the name Madhuvasistha, 'Excellent Honey'. As soon as age allowed he took up the robe [became a monk] and attained holiness. Nevertheless he retained his monkey habits and was often seen perching on walls and climbing trees.

Indian ideas of the mind, then, are influenced by their cultural context, both by the kind of conceptual structure in which they are cast, and the kinds of moral and religious attitude which arise from the various ways of construing the belief system of rebirth and release. What happens to the mind when release is achieved is variously imagined. The opening lines of the *Yoga Sūtras* declare uncompromisingly that 'Yoga is the cessation of mental activity', and frequently the religious training of the mind consists in an ever-deepening meditative absorption and implosion, in what Mircea Eliade (1958) has called ecstasy. The difference between this kind of quietistic vision of the enlightened mind and more activist conceptions can be illustrated by the following two examples of ocean imagery. In the *Vijñānavāda* school of Buddhism, objects of thought and perception, as well as the illusion of a real subject, are said to arise from within the mind, from the 'store' (*ālaya*). Thus we read that 'just as on the ocean, waves stirred up by the wind dance and roll unceasingly, so the (*ālaya*) mind-sea, constantly stirred up by sense-objects, dances and rolls with its multiform consciousness-waves' (*Lankavatāra Sūtra*, 46). The attainment of enlightenment here is then conceived as a calming of the storms of ordinary consciousness; and the mind-ocean finally stops at the 'further shore' of nirvana. In nondualistic Śaivism, contrastingly, while God (Śiva) is the only reality, subjectively and objectively, he is not conceived as a quiescent and transcendent divinity, but as the radically immanent and active event of consciousness. Enlightenment consists then not in calming the mind to an absolute stillness, but in the full realization of God's nature in all its self-manifestation. Thus we read (*Tantrāloka*, I, 116; I, 56, trans. Alexis Sanderson) of Śiva, whose nature is nothing other than self-transformation through the energies of consciousness (expressed mythologically as goddesses):

The undivided lord, consciousness, has creative awareness

as his innermost nature; (thus) the totality of the waves of this consciousness is contemplated and worshipped in various specific conformations, mild or wrathful.... (His) power of freedom, the impulse to project himself as order (in space and time) and his embodiment as this order: may this triad of goddesses, the allinclusive glory of the allpervading lord, shine within me revealing my ultimate nature. May Ganesa, son of Siva's consort, the unique ego which controls the faculties of cognition and action, and whose inner nature is as the lord of the great rays which are the fullness of those three (great) goddesses—may Ganesa, offspring of absolute awareness, radiant full moon, swell the tide of the ocean of my consciousness.

INDUCTION is a term encompassing a variety of forms of inference, commonly, but not always, in contrast to*deduction. If 'proposition' is defined as a thought expressible by a grammatical sentence having either prescriptive or descriptive force, 'inference' may be defined as a transition in thought between one or more propositions (premisses) and a further proposition (conclusion), where the premisses purport to be reasons for the conclusion. The conclusions of deductive inferences cannot be rejected without contradicting the thoughts contained in the premisses, and in this sense are already contained in the premisses. Deductive inferences were consequently classified by C. S.*Peirce as 'explicative', while inferences whose conclusions were not already implicit in their premisses were called 'ampliative'.

'Induction' is sometimes used in the sense of 'ampliative inference'. Classically, however, following*Aristotle's use of ' *epagoge*' (from the Latin translation of which we have 'induction'), the term applies to a subclass of ampliative inferences, namely those in which the conclusion is more general (applies to a wider range of instances) than the premisses.

The root idea of a movement in thought from particular to general has given rise to the practice of applying the term 'induction' to two forms of inference which are in fact deductive. The first of these is complete induction (in Aristotle, 'deduction from induction, *ex epagoges sullogismos*'), where the premisses are all less general than the conclusion, but collectively exhaust the instances covered by the conclusion. If chimpanzees, gorillas, humans, etc., are found species by species to react in a certain way to a certain virus, and these species exhaust the class of Primates, one may conclude that all Primates react in this way to the given virus. The second is the large family of proof procedures used by mathematicians on a variety of order structures, the simplest example of which is numerical induction: if (1) F is a property of the number one and (2) if F is a property of the number n , then it is a property of $n + 1$, then (1) and (2) together*entail that F is a property of all (natural) numbers.

The narrower classical idea of induction as inference from particular to general excludes certain ampliative inferences involving probability, e.g. inferring that x is F from the high probability that a

member of a class, C , to which x belongs, will be F . It also excludes ampliative inference from one or more descriptions of an individual case to some further descriptions of that case. (Where the further description stands as the best explanation of why the first descriptions apply to that case, Peirce distinguished what he regarded as a scientifically vital form of inference, and which he called 'hypothesis' or 'abduction'.) It is clear from this account that ampliative inferences are by definition not deductions and hence not deductively valid. Where, in other words, an induction is not complete—that is, the cases covered in the premisses do not exhaust those referred to in the conclusion (e.g. when concluding that all chimpanzees react in a certain way to a certain virus on the basis of having examined any number, n , of chimpanzees)—the premisses may all be true and the conclusion false, and the inference may be reasonable but unfortunately misleading. This gives rise to the so-called problem of induction, but from a purely logical standpoint it can appear to be a matter of lamenting the fact that not all of the inferences which we make have the rigour and compulsion of deductions, coupled, perhaps, with the insinuation that only deductive inferences are rationally grounded. But, against the insinuation, it is far from obvious why good reasons for a conclusion must preclude its negation on pain of contradiction. It is clearly possible to distinguish good from bad reasoning which is not in this way absolutely compelling.

From the standpoint of certain epistemological presuppositions, however, the problem is acute. If we assume, as is done in traditional empiricism, that all our knowledge is founded on (sensory) observations of individual instances, inductive inference presents itself as the only, however doubtful, means at our disposal for building on this modest foundation the vast edifice of our beliefs about the natural world. Unless there are general statements whose truth can be known *a priori*, all premisses of our deductions must be reached by induction; and every attempt to infer what holds for some unobserved or unobservable case on the basis of what has been observed must explicitly or implicitly appeal to a general proposition, which can only rest on induction from observed cases.

But the most, it is held, we are able to observe in individual cases are certain similarities among them, and it seems reckless in the extreme to expect such similarities to appear elsewhere unless we can identify some *cause* or *constraint* which ensures that a pattern we have observed will occur elsewhere. However, in seeking such a causal constraint in what we observe, all we will find are further patterns of similarities in the features of what we observe which are constantly conjoined. We can find, in other words, no basis for a causal

Page 362

constraint which is not itself in need of the very justification which we are seeking to provide.

David Hume, who is the classic source for this problem (although he did not formulate it using the word 'induction') considered whether a global principle such as the uniformity of nature could underwrite our inferences from observed to unobserved cases. But such a global principle seems a nonstarter: nature is uniform only in certain respects, and in other respects is highly variable. This is reflected in our practice of making inductive inferences. In some cases it is reasonable to generalize on the basis of very few instances; in others a very large number of observed instances is no basis at all for a generalization. Traditional empiricism tends to obscure this difference because it presents all

inductive inferences as ultimately proceeding by 'simple enumerations', which have to be assessed in the absence of any background of established beliefs and experimental techniques. Popular and oversimplified views of Karl Popper's response to Hume, namely that science does not rely on induction but on finding exceptions to its generalizations, are likewise based on the notion that induction is simply a matter of projecting a similarity in our experience of part of a class of cases on to the whole of that class (e.g. of expecting what we have observed in some chimpanzees to hold of all chimpanzees which have yet to be observed). In fact we move no closer to real science by saying that the aim is rather to find exceptions to such attempts at superficial generalization.

Francis*Bacon rejected the procedure of applying a global principle as 'childish', insisting that induction must proceed 'by proper rejections and exclusions'. The underlying principle of this genuine Baconian induction (known as 'eliminative induction') is the control we exercise over the circumstances of our observations. We must, in other words, move beyond simply projecting our observations to cases not yet observed and project in the form of experimental hypotheses, which ascribe a network of links between circumstances, that can be varied, and phenomena, which we can observe. We have observed a link between heavy smoking and lung cancer, but do not yet know how the circumstances may be varied so as to interfere with the link (and therefore cannot yet explain why many heavy smokers do not get lung cancer). In this spirit Peirce defined induction as 'the operation of testing a hypothesis by experiment'.

J. S.*Mill's 'four methods of experimental inquiry' were designed to help identify the laws and causal factors governing phenomena. We need (i) to find what is common among the differences in the instances which we have observed ('method of agreement') and (ii) to compare the instances in which the phenomena occur with those in which they do not ('method of difference'). We can (iii) 'subduct' from the phenomena all portions which we can assign to known causes, and the remainder will be the effects of causes still to be determined ('method of residues'). And we can (iv) look for functional relations between variations in phenomena ('method of concomitant variations'). The application of such methods and the testing of the hypotheses which they yield evidently involve a procedure of thought which goes well beyond the projection of superficial similarities (expecting future crows to be black because all observed crows have been black); it requires an account of the causal mechanism, which we can then test by creating circumstances which would very likely not occur in nature without our intervention.

Arguably, traditional empiricism generalized inadequately on the procedures by which all humans learn about their environment. Some things are learned by simple*habituation, developing a uniform response to similar stimuli, but a great deal of human learning involves interfering with the environment.

Such a response to traditional empiricism and the problem it has with induction, however, will appear to beg the question unless at the same time one calls into question the assumptions that observation consists in the passive reception of sensory qualities and that the concepts we apply to what we observe derive wholly from this source rather than, in a large and important part, from the control we are able to exercise over what we observe. Bacon, for one, saw that induction properly conducted (i.e. as experimental inquiry) needed to be used not only 'to discover axioms but also in the

formation of notions'. If we allow that induction is a procedure through which we develop our concepts of what is or is not a (natural)*possibility, the traditional problem of induction appears in a quite different light.

INFANCY, MIND IN. Theories of mental life show their axioms in the way they describe the*intelligence of infants. Empiricists, who tend to be materialists, see*consciousness coming into existence through learning—by remembering experiences. They claim the infant to be a reflex organism, making adaptive responses to stimuli and possessing drives for survival, but inert mentally and amoral. With experience, representations of objects in the world are synthesized and new motivations are built up. A child gains thinking, perception of meanings, and values entirely through imitation and training—from parents and then from a wider society of peers and elders. Thus are collective knowledge and consciousness of meanings and purposes passed on from generation
Page 363

to generation. Individuality arises from each subject's unique voyage of experience.

Romantic nativists, however, have a quite different view. They assert that the infant is born with unspoken wisdom: a human spirit with awareness and feelings who has simply to grow in strength and skill and in knowledge of the specifics of reality while acting on inherent human impulses. All humans, they believe, have the same basic forms of consciousness and the same motives. In health human minds grow on the same overall specifications. The characters of individuals differ in their particular natural gifts, as well as in the opportunities these have had to grow.

Other ways of describing infants combine elements of the extreme philosophies. Psychoanalysis, by focusing on organizing processes of the self, created a new interest in the development of the child's separate mental identity: an individual motivation and consciousness crystallizing out from the protective motherchild relationship.

Cognitivists emphasize the novelty-seeking and problem-solving tendencies of infants, and they explain development as a construction of increasingly complex cognitive programmes focused on mastery of physical reality and its patterns of change. The Swiss educational psychologist Jean*Piaget, who made meticulous observations of infants solving problems, is this century's great rationalist among developmental psychologists. He portrays the child as an autonomous experimenter who acquires

representations of objects in the world and who gains rational awareness by recording the effects of his acts. For both Sigmund*Freud and Piaget the newborn infant has little but reflex powers of integration. Separation of 'self' from 'outside world' and from 'the other' who shares life with one is achieved by the learning of distinctions and forms of relationship that arise in interaction of subject with environment. This is called the 'object concept' and the formation of an 'object relation'.

Recent research with infants has cast new light on these questions. It has brought support for a more nativist position in opposition to a physiological empiricism that dates from Ivan*Pavlov. Beyond that, the increased detail of our knowledge makes a selfcontrolled process of differentiation in the child's mind, which tests experience, more and more obvious. The mind of the infant is neither simple nor incoherent. Children do not develop intentional integrity by the linking up of sensorymotor reflexes through conditioning, as the behaviourists said they did. They seem, rather, to be seeking to refine their reactions to particular events and formulate specialized skills within a coherent general ability to perceive and understand both physical objects and persons. They are born with several complementary forms of knowing, and they use these to develop experience of the particular world they are in, assisted by communicating. They do not, at any stage, confuse themselves with objects 'outside' nor do they fail to recognize that other persons are separate sources of motives and emotions.

Recent experimental studies give data for a rigorous presentation of this thesis. They prove that infants have organized cognitive activities that regulate uptake of experience in one mental time/space frame. Moreover, these activities are found to have remarkable foresightfulness. For example, babies no more than a few minutes old may adapt their orientations and states of alertness to fit the motion of objects that are remote from their bodies. Newborns can detect patterns in the recurrence of particular things, so it is obvious that they rapidly acquire rules for making perceptual distinctions, and they record the timing and location of recent happenings.

Babies adapt, by coordinated movements, to the time, place, and nature of events that have importance for them. Events caused by human movements hold the greatest interest for them.

Conditioning tests, in which newborn infants have to react to and anticipate repeated events, show that they may generate predictive strategies, seeking new rules for keeping track of a changing world near them. These tests depend upon accurate observation of the infant's looking and listening behaviour, of breathing, or of sucking on a pressuresensitive nipple. The latter two measures detect fluctuations in attending, since visual and auditory focusing compete with sucking and breathing.

Evidence for complex reactions to events also comes from video and film studies of the facial expressions and hand movements of infants. Expressions of concentrated puzzlement, surprise, pleasure, and displeasure are clearly delineated, and arms and hands make movements that vary systematically with the other signs of attending.

Evidently babies are ready to show a variety of feelings to others.

In the last few years there has been increasing effort to describe the first signs of mental activity in newborns and development in early months. The neonate period, from minutes after birth to about

three weeks old, is highly specialized. It is true that survival is the baby's main preoccupation then. Functions of suckling, breathing, and protective action against threatening variations of temperature or injurious contact with hard objects or dangerous animals are all adjusted quickly to an environment which has been radically transformed at birth. The quick and effective movements of newborns to gasp air, to find the nipple, and to seek comfort and protection are remarkable. They are classically described as *reflexes and assumed to be due to relatively simple neural links from special receptor zones of the brainstem and spinal cord to motor nerve centres. But a healthy baby born without complications is immediately capable of more than mere fixed responses to physical stimuli and much of the behaviour is spontaneous. Even the true reflex responses to artificial stimulation with touches, sounds, or flashing lights are powerfully modulated by central physiological

Page 364

processes (called 'state variables') that arouse the brain's activities, or quiet them down. Experiments with supposedly simple events produce highly variable and complex results, because the infant's state is changing.

Given quiet and gentle attention, a baby born without trauma or sedation is strikingly alert within minutes of birth to the new world of sights and sounds. The wideopen eyes make finely coordinated stepping movements (see SACCADDES) aimed in different directions round the body. They may stop or change direction to fixate bright places, or track stimuli in motion. They also clearly orient to the face of a person who approaches close and speaks gently in a tone of greeting. The eye movements are coupled with small pulsating rotations of the head. Films of newborns orienting to and tracking objects with their eyes reveal that a reachandgrasp movement of arm and hand is inherently coordinated within a visual spacetime field of awareness. The movements are a wellformed prototype of the movement an adult makes to take hold of an object. This automatic movement of prehension, linked to perception of the changing reality outside the body, is a necessary basis for the eventual consciousness of objects and intentional command of actions. If a higher mental command is to work, it must eventually decide about goals in a richly patterned world, and the lowerlevel problems of perceptual locating and motor patterning must be solved without reflection. Apparently some of the required solutions have been formulated in outline during rectal stages of brain growth. They are ready for adjustment to perceptions of certain goals very soon after birth.

Critical tests show that the newborn has almost no capacity to modulate the form of the basic reachandgrasp automatism, by changing its duration or size in relation to different kinds of object with different kinds of motion, but the old idea that visual field and aiming of the hand have to be linked together by experience is disproved.

Reactions to persons are the most remarkable. Tests show that newborns will turn in the direction of a voice from a loudspeaker behind a curtain, orienting not only the head and ears but the eyes as well, as if searching to see the person who calls. Simultaneously, hands and face move in ways which indicate a total involvement of a coordinated expressive system in the brain. At birth a baby prefers to hear its own mother's voice. Her particular vocal characteristics have been learned *in utero*.

In the first few days the sounds of different syllables in speech, as well as their emotional tone, are discriminated by the baby. Observations of face movements of both premature babies and fullterm neonates prove that not only the musculature but also the nerve centres exciting the muscles are organized, so that a wide repertoire of wellformed expressions is present before the baby has had an opportunity to learn from adult exemplars of these human movements. Paediatricians and mothers unconsciously observe the infant's facial expressions, hand activity, and body posturings to make sensitive appraisal of a baby's state and needs; but the movements, which may be small and fleeting, are only now being accurately charted by developmental scientists.

Much of a neonate's life is spent in sleep. Although infants are usually wide awake and active just after birth, for two or three weeks thereafter the most common state of a baby is either one of sleep with eyes closed, or a vague openeyed condition in which awareness of the outside world appears weak and fluctuating. The routine cycle of sleep and wakefulness is very weakly foreshadowed at birth. It needs shaping by the consistent behaviour of a responsive caretaker. Often a wakeful newborn is actively and effectively avoidant of experiences, and this is particularly noticeable in unfamiliar circumstances. It is important, in this connection, to note that the tissues of the brain undergo enormous developments in these few weeks (see BRAIN DEVELOPMENT). Intercellular connections are rapidly multiplying. There is evidence that nerve circuits in this condition powerfully limit their own excitation by controlling the motor functions which direct sensory pathways away from stimuli.

In spite of this avoidant state, which is comparable with the darkseeking, closedeyed condition of a nestling kitten, controlled observations show that newborns are capable, like other newly born mammals, of rapid conditioning. With the assistance of a mother's routine, a newborn's sleep cycles become adjusted to time of day and night. The opinion of many mothers that a baby learns in a couple of feeds to find the breast with more skill, and that her baby soon knows her and the father as particular individuals, different from others, is confirmed. Olfactory, gustatory, visual, auditory, and bodycontact senses have all been implicated in this recognition by familiar caregivers. The mother is known even when she takes the baby up silently in the dark. The individual appearance of her face is learned in two or three days.

Psychologists, and mothers alike, are astonished by recent demonstrations that babies less than a month of age are capable of imitating facial expressions. Indeed, with some babies, it is easy for a mother to see for herself that her newborn, just minutes old, may watch her mouth intently if she protrudes her tongue or opens her mouth wide, then move his mouth and appropriately poke out his tongue or open wide his mouth. The model is accurately copied. Expressions of happiness, sadness, or surprise are also imitated. With calling vocalizations, a similarly prompt imitation can be obtained, when the baby is a few weeks older. Imitation of movements of the hands opening or coming together has also been seen. All these movements, like the expressions of smiling, knitting of the brows, etc., and hand movements of gesture, including making a fist, extending all fingers, or pointing with the index finger, may

occur also without a model—but prompt and welldifferentiated imitation of some of them is undeniable. At the very least, this phenomenon proves that the infant has made a reasonably

well-differentiated perceptual image of the model act of the mother's face, vocal apparatus, or hands. This image must be formed in close relation to the appropriate motor command which sets off the right imitative response almost immediately after focused attending to the model the first time it is presented. Denial of this ability to imitate reflects a strange, culturally induced belief that a newborn cannot have awareness of persons as such. Luckily, both mothers and doctors may act at variance with overcautious scientific prejudices that have no obvious virtue. Mothers are certainly made happy by this simple test that shows their babies know them in a complex way. Clinically, systematic use of such relatively complex behaviours would seem to have potential value for diagnosis of sensory or motivational differences and abnormalities.

Besides imitating, neonates can smile and coo and make hand gestures when spoken to. A majority of newborns raise the right hand more than the left. These signs to persons become much more responsive in the second month, after the perceptual systems of the cerebral cortex have developed, especially for vision. Contented facial expressions of a baby may be stimulated by soft handling and gentle speech; quite different patterns are evoked by loud, impatient, or aggressive speech and abrupt movements. The split-second timing of exchanges of expression between the infant and the mother have been analysed, to prove that both of them are actively controlling the exchange. A highly significant series of experiments has begun to examine infants' responses, in the second and third month, to broken or unreal communication, or to the attentions of a distressed mother. Threatening expressions or inconsistencies in a partner's behaviour cause the baby to make expressions of sadness or fear. When being spoken to in the normal way, babies show quickly changing patterns of face movement, alternating between the appearance of puzzled attending, with knit brows and mouth depressed, and a face full of pleasure and greeting with raising of the eyebrows and a smile. The subtlety of these positive expressions, and the speed of their disappearance when a mother holds her face artificially still on a prearranged signal proves that the baby is highly perceptive that

'something has gone wrong with mother'.

This work has helped determine how the baby may enter into control of the communication of moods and levels of awareness with another human being. But we have much description to do before we can give a full account of how the baby perceives other persons. Microanalysis of ordinary face-to-face play between mothers and their two-month-old babies reveals a precise conversation-like timing in the way they address one another and reply. Babies stimulate gentle and questioning 'baby talk' which has a regular beat and characteristic expression of mood in its changing intonation, rhythm, and accompaniment of movements of head, eyebrows, eyes, and so forth. The infant watches the maternal display intently and then makes a reply, on the beat, with a smile, head and body movements, cooing, hand movements, and even lip and tongue movements which are called 'prespeech'. Photographic records suggest they are developmental precursors of actual speech. These attempts at vocal expression are synchronized with hand gestures. It is not claimed that babies have things to say, or that they can hear words as such, but they are certainly perceptive of certain identifying features in the sight and sound of human speech. They even appear to want to make rudimentary utterances themselves when persons excite them by friendly greetings. The outbursts of infant expressive movement last two or three seconds, with characteristic beginning, climax, and end. Sometimes they contain coos or calls—but often there is no vocalization at this age, merely activity of mouth and

hands. Their regularly repeated form helps the mother give the right support and encouragement in her welltimed movements and speech (Fig. 1).

The intensity of interest and the delicacy of response of young babies to persons who speak to them also helps to establish an affectionate personal relationship, which has great importance in the baby's mental development. In the 'bond' (in the sense of a compact of mutual trust) which develops between them, infant and favourite companion begin to develop a shared repertoire of expressive tricks and exchanges of feeling (see BONDING). As the babies' cognitive powers increase by selective retention of mental rules that work better and better to control objects, and after actions have become more alert and discriminating, mutual interest with the mother undergoes a subtle but pervasive change. There develops a conflict between pursuit of purpose in subjugation of objects and ways of exploring them, on the one hand (i.e. development of an 'object concept'), and the sharing of interpersonal interest, on the other. But out of this complication appears a new kind of playfulness which offers a crucial bridge for sharing motives and, eventually, knowledge.

The nature of*humour and play has long baffled philosophers and psychologists. Whatever it is for, play certainly has a key role in the taking of this major developmental step in infancy. As soon as infants gain the ability to reach and grasp objects, so they become susceptible to gentle responsive teasing about their gropings after a changing target and to the mother's emotional attunement to everything the baby does. An affectionate mother of a blind baby will tease the gropings of her infant after an object heard or felt, with much lively vocalization, and cause her baby to laugh. Frequently, a sixmonthold will try to grasp the mother's face or her hand. This leads to many games in which the mother moves the attractive

Page 366

Fig. 1.

A sixweekold girl smiles at her mother, coos and gestures, raising her right hand more than her left. Her mother is speaking gentle 'baby talk' on a steady beat and watching closely.

part of her about, tempting and dodging the infant's interest. Games of 'peekaboo', 'pop goes the weasel', and creeping of the hands up the baby's body ('round and round the garden') will easily come to mind. Such games, with their wellmarked patterns in time, all tease the infant's growing curiosity, and they give companionship.

Traditional musical formulae in nursery songs, chants, and rhymes, found in all cultures, are purposebuilt to entertain a baby at this age. They show that all babies gain a sense of fun and appreciation of musical communication long before they speak (Figs. 2 and 3).

Out of the intertwined and interacting developments of objectperceiving and communicating with persons emerge extremely powerful mental functions which pave the way for language, effective logical formulae for reasoning, and other key artefacts of human culture. Before a baby is nine months

old, he or she is clever at handling and mouthing objects, very alert to the sight and sound of happenings, including effects of their own manipulations, and clear about the distinctions between the familiar and the strange. Life with others is enlivened by humorous games and clowning, created mutually, and sometimes there are conflicts of purpose that the baby learns to adjust to with strong and unambiguous expressions of refusal or acquiescence. But there is rarely any sign of specific interest in another's wishes or intentions in regard to the shared reality before the baby is nine months old (Fig. 3). Then, within two or three weeks, this selfdirectedness (called egocentricity by some psychologists who see it as a limitation of immaturity, rather than a necessary process of development in autonomy) changes fundamentally. By one year a baby starts to both express and respond to a new kind of mental relationship, in which the purposes and experiences of another in Fig. 2.

Paul, at 36 weeks, plays happily with his mother

trying to 'catch' a ball, but he is shy then

sad with a friendly stranger.

Page 367

Fig. 3.

Emma, at 28 weeks, has learned to play a traditional hand game ('clappa, clappa hahdies') with her mother. Songs for infants have similar musical form in different cultures. Emma is a genetic lefthander; already she claps left hand over right. Esme, 40 weeks, enjoys playing with and exploring wooden dolls and a truck, but has to be physically 'persuaded' to obey the instruction 'Put the man in the truck'. She does not understand her mother's gestures and spoken instructions.

relation to the world outside both of them become of primary interest (Fig. 4).

Towards the end of the first year, the infant develops a clear awareness of the existence of objects in

their own right, and a shortterm memory that can direct a search for them when they have been hidden by someone in view of the infant. But there are other developments, too, that change the infant's communication. Before nine months, babies do not 'offer to give to' or seek 'to have help from' or 'point to direct the attention of' the person with whom they play. They gesture and babble in a highly expressive way, obviously playing with the postures and sounds, and with effects on others, but they do not make utterances about their experiences that are addressed to others as comments or enquiries that seek affirmation or complement. They do not make baby words to specify objects to others. Nor do they appear to recognize the mother's names for objects. But, by the end of the first year most babies everywhere do all of these things. They quickly learn intricate reciprocal or cooperative games where they purposefully share the effort to build something, look at a book, create an amusing effect. They become aware of and are interested in the changing directions of another person's interest. The motivation for this kind of cooperative play is strong, and people who know the baby well become aware of an intense companionship in it. It leads to a sharing of experiences, and of symbols, that is uniquely human.

Fig. 4.

Basilie, one year old, cooperates. When her mother hands her the doll, saying, 'Put the man in the truck', Basilie does so immediately, then looks at her mother and grins. She understands her mother's wishes, and can use 'protolanguage' of gesture

and vocal expression to influence others. Basilie is a

righthander.

Page 368

Through the last six months of the first year babies show strong selective affection for their principal caretakers, usually mothers, and they become highly sensitive to approaches from strangers—acting afraid or distressed (Fig. 2). This sign of trust in the familiar, with matching anxiety about the unfamiliar, seems to relate to the great increase, at 9 months, in complexity of the baby's interest in the knowledge and skills that can be shared with steady companions. The familiar playmate is an integral and necessary part of the baby's developing consciousness.

There is much attention in contemporary developmental psychology to the start of spoken language when, properly, a child ceases to be an infant (*infans*: unable to speak). (See LANGUAGE: DEVELOPMENT IN CHILDREN, and LANGUAGE: LEARNING WORD MEANINGS.) Language, and the symbolic understanding of moods, purposes, and meanings, is central in human nature. Evidence from the interpersonal skills of infants strongly supports the idea that language skills are built on a sharing of motives that begins soon after a baby is born. The speedy and rich exchange of thoughts that is made possible when insubstantial words stand for all manner of actions and physical objects and events is preceded by the infant's ability to enter into the minds of others, first by their direct expression of interest and mood in affectionate relationship, then by their playful teasing, and finally by their willingness to share significant moments in the experience of surroundings and what may be done inside this joint experience.

A oneyearold does not merely want to keep close to mother. He or she wants to take note of comments, give and take, share the looking and handling of things, and try to follow the words that seem to be given special emphasis in these interactions. The baby. will make vocalizations with gestures in order to mean something, or to give a deliberate message; a demand, a request, a refusal, etc. At two years the same baby is not only walking about, but also speaking. For speaking, objects of interest have to become significant, with conventional meaning and symbolic value. No regimen of conditioning can explain these transformations of a child's mind.

They must be motivated within the child by growth of mental processes that are ready for the instructions and examples that come from older companions.

It would appear as if we are beginning to describe the fundamental form of human motive processes in the brain by gaining detailed evidence on how cooperative understandings emerge in infancy, from the sensitivity of the neonate to human care and human emotions to the intelligent cooperativeness of a twoyearold. In the process, we seem to be learning a new philosophy of mind that does not set the empiricist against the nativist, and that does not wholly segregate the material from the mental. How else can we attempt to conceptualize an inherent set of motives to share experience with others and to learn ways of communicating?

INFERIORITY COMPLEX. His view that*Freud had put too much emphasis on sexuality in the genesis of neurosis and too little on the 'will to power' was one of the reasons why Alfred*Adler broke away from psychoanalysis in 1911 and formed the more or less independent school of 'individual psychology'. According to Adler's theory an individual adopts a style of life which tends to relieve feelings of inferiority. Thus a boy feeling himself to be inferior in sports devotes himself to his studies. Demosthenes, finding a way to overcome his stammer by speaking on the seashore with pebbles in his mouth, became the greatest orator in Greece. Or a person may hold to conceited fantasies which falsify a discouraging reality. Striving for success, selfassertion, and selfaggrandizement thus reflect both the will to power and its obverse, a sense of inferiority. This has its roots in the circumstances of childhood. A child feels inferior if he lacks affection, acceptance, and approval.

Physical or 'organ' inferiority may play an important part. Position in order of birth, in particular, as Adler pointed out, moulds a child's style in competitive situations.

Inferiority and*complex were put together to make a portmanteau phrase. This soon became popular because it offered an explanation, albeit a simplified one, of inappropriate or neurotic behaviour in terms of underlying ideas and feelings which are part of most people's experience.

INFORMATION THEORY. The idea of measuring information might at first seem as senseless as that of weighing the Theorem of Pythagoras; but it was in fact among hardheaded communication engineers that the need to do so was first recognized. A communication channel exists (and is paid for) in order to 'transmit information'. In order to compare the efficiencies of alternative methods we must be able to estimate the 'capacity' of each to do the job.

In ordinary language we say we have received information when *what we know* has changed. The bigger the change in what we know, the more information we have received. Information, then, like energy, does *work*: but whereas energy does physical work, information does logical work. There are various ways of measuring the size of the logical job done when a communication signal is received. Different measures are relevant in different contexts. The main consideration is whether the output of the communication channel has to be *constructed* by the signal, or merely *selected* (identified) by it from a range of prefabricated forms. Some examples will make this clear.

Construction. When a camera shutter is opened, we say that 'information' is transmitted from the scene to the film. By this we mean that the image on the film is constructed by the action of the light signal received. In comparing results from two cameras, two quite different criteria may be relevant. (i) We might compare the number of distinguishable pictureelements, which is called the *structural informationcontent* of each picture. A picture taken with poor optical resolution would have a low structural informationcontent. (The unit of structural informationcontent, 1 *logon*, specifies one independent element or 'degree of freedom' of a signal.) (ii) Alternatively, or additionally, we might compare the statistical weight of evidence gathered by the two films, or their *metrical informationcontent*. A picture taken with too short an exposure, for example, would be deficient in metrical informationcontent. (The unit of metrical informationcontent, 1 *metron*, represents a certain minimum weight of statistical evidence.)

Selection. Although in many telecommunication systems (such as domestic telephones, radio, and TV) the signal has to construct the output, in other cases (such as telegraphy and teleprinting), where the range of possible outputs is small, and is known in advance, a much more economical approach is possible. This is known as encoding. Instead of transmitting a complete description of the output required, a code system transmits only instructions to select (identify) that output from a range of prefabricated outputs (for example, letters of the alphabet) available at the receiving end. Thus, whereas the construction of a television picture of a page of type might require several million independent signals, the same page of type can be specified by only a few thousand selective code

signals controlling a teleprinter.

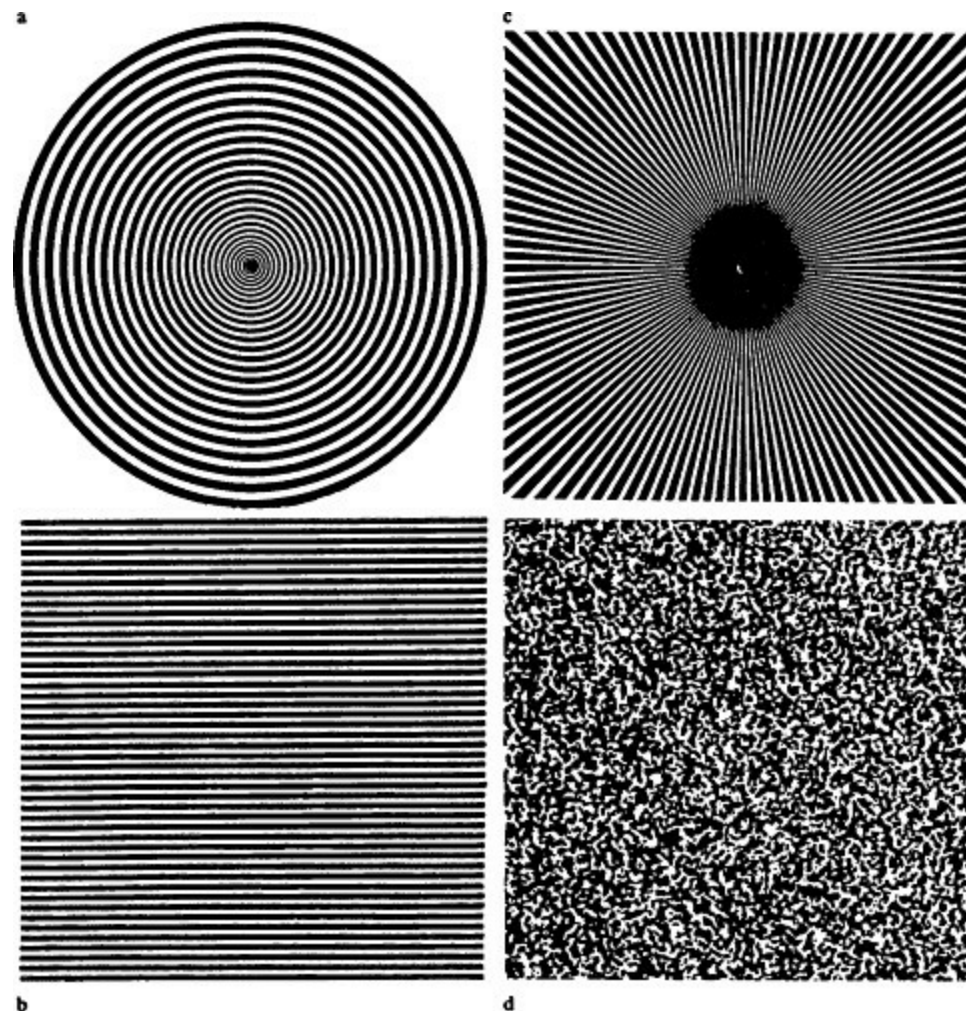

In this context, the size of the selective job done by a signal depends not on the size or complexity of the output as such, but on the number of alternative forms that it might have taken, and on the relative likelihood of each. The simplest selective operation is the identification of one out of two equally likely possibilities—as in the game of 'Twenty Questions'. This, in the jargon of communication engineers, has a *selective information content* of one 'bit' or *binary* digit. Selection of one out of four equally likely possibilities requires two bits; one out of eight requires three; and so on. In general, then, selective information content measures the statistical unexpectedness of the event in question. The precise form of the event is irrelevant, except as it may affect its prior probability. The more improbable an event, the larger its selective information content. This way of measuring information flow was developed chiefly by the American engineer C. E. Shannon (Shannon and Weaver, 1949) and the mathematician Norbert Wiener (1948). (Mathematically, the number of bits per event is $\log(1/p)$. Where events 1, 2... i have prior probabilities $p_1, p_2 \dots p_i$,

the average selective information content or 'entropy' $H = -\sum p_i \log(1/p_i)$.) The average unexpectedness or selective information content per event is greatest when all possible events are equally probable. The communication channel is then being used with full 'informational efficiency'. If some events are much more or much less probable than others, the average number of bits per event is correspondingly reduced, and the sequence is said to have 'redundancy'. (Redundancy is defined as $1 - H/H_{\max}$, where H is the value of H when all p are equal.) A redundancy of \max

i

50 per cent means that the average number of bits per event is only half what it could be if all events were equally probable.

Despite its pejorative label, redundancy has one great merit. It allows a communication system in principle to tolerate a corresponding amount of random transmission error or 'noise'. If the right kind of code is used, it is even possible to achieve almost errorfree transmission up to a certain rate, despite the presence of 'noise', by building in redundancy in such a way that errors can be identified and corrected. Although this may sound almost magical, it is similar in principle to what a human reader does when spotting and correcting printers' errors. The detection of misprints in an unfamiliar passage is possible only because the sequence of letters in typical English text is about 50 per cent redundant. With a table of random numbers, it would be impossible! Saying the same thing several times in different ways (a device familiar to teachers and public speakers) is another sensible way of building in redundancy, so as to make a message more resistant to distortion, either by noise in the communication channel or through misperception by the recipient.

By analogous reasoning, it has been proved that networks of computing elements can be constructed with redundant connections in such a way as to perform without errors, even if individual elements were to break down at random. Here again, the amount of malfunctioning that can be tolerated depends directly on the amount of redundancy built in. There is reason to believe that the amazing reliability of the human brain (despite a steady loss of nerve cells throughout life) depends on a sophisticated use of redundancy on these lines.

Since the Theory of Information embraces communication processes of all kinds, whether in human societies, in nervous systems, or in machines, it inspired at first some exaggerated expectations. Early efforts to measure the flow of information through sense organs, or through human operators controlling machines, were sometimes frustrated because the probabilities attached to events by the experimenter were not the same as those represented in the subject's nervous system. In other cases, where there was no reason to believe that the neural systems concerned worked on a selective principle, the use of Shannon's measure gave irrelevant or trivial results.

On the other hand, the development and spread of informationtheoretical ideas has made notable contributions to brain research by suggesting new ways of looking at the function of the nervous system and new kinds of experimental questions. To take one of the earliest examples, Hick (1952) found that the reaction time of human subjects to a stimulus depended in a particularly simple way on

Fig. 1.

a to c. Examples of visual stimuli incorporating a high degree of structural redundancy. d. A sample of 'visual noise' with minimal redundancy.

Page 371

its selective information content. In other words, what mattered in his experiment was not the form of the stimulus *per se*, but rather the number of alternative forms that it might have taken but did not. The idea that the range of forms *not* taken by the input might be an important part of its specification is typical of the shift in emphasis brought to psychology by information theory.

Again, both physiologists and psychologists now make extensive use of test signals originally developed by communication engineers to measure the performance of TV and radio channels. Both highly redundant signals such as regularly repetitive patterns (Fig. 1a-c), and completely nonredundant patterns of 'noise' (Fig. 1d), can induce the nervous system to reveal characteristics that might have remained unsuspected without their use.

It is now commonplace to regard the impulses that flow along nerve fibres as 'conveying information'; but just how information about the world is represented in the brain remains an unresolved question. Although nerve impulses do not function like the code signals in a digital computer, the general ideas of information engineering are proving increasingly useful in suggesting experiments to throw light on the way they do operate. One of the chief advantages of these ideas is that they belong in a sense to both the psychological and the physiological levels. They thus offer an invaluable working link or 'conceptual bridge' by which data and questions at either level can be brought to bear on hypotheses at the other.

For the application of information theory to the visual system, see VISUAL INFORMATION RATE.

INNATE IDEA. The philosophical theory of innate ideas has its roots in*Plato. In the *Meno*, Socrates manages to get a slave boy to recognize certain mathematical truths (the example concerns the properties of a square) simply by asking the right questions. The conclusion drawn is that the boy already has the knowledge within him; Socrates was merely 'drawing it out'. Innate ideas play a crucial role in the metaphysical systems of the seventeenthcentury rationalists. For*Descartes, the mind possesses innate awareness of certain fundamental concepts (God, triangle, mind, body), and as well as of certain elementary propositions of logic (such as 'it is impossible for the same thing to be and not to be'). The infant may be distracted by bodily stimuli from reflecting on these truths but 'nonetheless it has them in itself, and does not acquire them later on; if it were taken out of the prison of the body, it would find them within itself' (letter of 1641). Such theories receive short shrift from empiricist philosophers—notably John*Locke in the *Essay Concerning Human Understanding* (1690). According to Locke, talk of innate knowledge must imply conscious awareness; yet many people are obviously unaware of many of the allegedly innate principles: children, for example, 'have not the least apprehension or thought of them'. To this*Leibniz replies (in the *New Essays on Human Understanding*, written 1705, that 'we must not expect that we can read the eternal laws of reason in the soul as in an open book'. The ideas are present not in a fully developed form but as dispositions or *virtualités*.

In recent years the debate between rationalists and empiricists over innate ideas has aroused fresh interest in the context of the linguistic theories of Noam Chomsky.

According to Chomsky, the ability of children to become language users, i.e. to acquire a set of highly complex and creative skills on the basis of very meagre sensory data, suggests that the child has innate knowledge of the principles of 'universal grammar' (see LANGUAGE: CHOMSKY'S THEORY). However, while the human ability to master language does suggest the presence of innate, genetically determined structures and predispositions in our brains, it is doubtful whether such structures should be said to amount to 'knowledge' of concepts or principles in anything like the sense supposed by the traditional theory of innate ideas.

INQUISITIVENESS. Seeking knowledge without prospect of immediate gain or reward is a characteristic of higher animals, and is most marked by far in man. It implies a degree of risktaking, since the unknown is explored, and is difficult to explain in theories of behaviour based on motivation and drive reduction; but it clearly has survival value, when combined with rapid learning. One might say that man is unique as a species through his extraordinary inquisitiveness.

INSANITY: EARLY THEORIES. Although attempts to find logically satisfactory definitions of

insanity have been dogged with failure, their construction has given much scope to the imagination. Two broad and irreconcilable traditions can be discerned: the Galenic and the Aristotelian views of madness.*Aristotle is alleged to have asked, 'Why is it that all those who have become eminent in philosophy or politics or poetry or the arts are clearly of an atrabilious temperament and some of them to such an extent as to be affected by diseases caused by black bile?' Robert*Burton is firmly
Page 372

within this tradition when in *The Anatomy of Melancholy* (1621) he describes melancholy men as 'of a deep reach, excellent apprehension, judicious, wise and witty'.

On the other hand, the tradition which stems from*Galen sees madness as due to an imbalance of the four humours. According to Galen the four bodily humours were blood, phlegm, choler, and black bile, and they were endowed with the elementary qualities of heat and moisture. The preponderance of a particular humour determined a person's temperament, thus providing an early schema of psychosomatic or constitutional types. The theory was a comprehensive one in that it was able to account for health, temperament, and the type of illness to which a person was likely to succumb. In the essential characteristics of their outlook these two traditions have persisted to the present day, and can be recognized in the writings of contemporary psychiatrists.

Temperament

Humour

Blood (warm and moist)

Sanguine

Phlegm (cold and moist)

Phlegmatic

Choler (hot and dry)

Choleric

Black bile (cold and dry)

Melancholic

Although it is possible to construct elaborate and exhaustive typologies of psychiatric terminology for each particular age—and, indeed, this has been done (see, for example, Karl Menninger's appendix to *The Vital Balance*)—at any one given period one diagnosis predominates and serves to describe a variety of ills.

Alternatively, several terms are used interchangeably. For example, in sixteenth and

seventeenth century England all varieties of psychological distress were described as melancholy. Renaissance psychopathology could be dealt with under a single rubric. No wonder that melancholy had many aspects! Robert Burton wrote: 'Proteus himself is not so diverse; you may as well make the *moon* a new coat, as a true character of a melancholy man; as soon find the motion of a bird in the air as the heart of a melancholy man.'

By the eighteenth century a new term, 'the spleen', had become fashionable. The spleen referred not only to the bodily organ of that name, but also to the disease associated with it. The spleen, being the source of black bile and hence of the melancholy temperament, is clearly a development of earlier Elizabethan melancholy and also a reaffirmation of links with the Galenic pathology of the humours. During the course of the century the spleen acquired a number of additional names: the vapours, hypochondriasis, hysteria, and the English malady. William Stukeley in his book *Of the Spleen* (1723) enumerates a long list of symptoms of the spleen: When the head is attack'd, coma's, epilepsy, apoplexy, or the numbness of a part ensue, or talkativeness, tremors, spasms, headach; when the heart, palpitation, swooning, anxiety; when the breast, sighing, shortbreath, cough; when the diaphragm, laughing; when the belly (and more frequently being the seat of the morbid minera) rugitus, cardialgia, colic, iliac passions, etc.

Thus the spleen could strike the unwary in myriad unsuspected forms. According to a physician, Thomas Dover (1732), the difficulty of detecting the spleen was accentuated by the fact that it could mimic the symptoms of other illnesses. Thus the accounts of many of these early concepts somewhat resemble the*Freudian view of hysteria. In view of the diversity of its symptoms, it is not surprising that preoccupation with the spleen spread rapidly throughout England and encouraged both a growth in the number of physicians and a diversity of opinion. Both in England and abroad the spleen earned the title of the English disease.

The fashionable and wellknown physician George Cheyne (1671-1743) regarded the corrosive and viscid humour associated with splenic disorders as being caused by 'the English climate, the richness and heaviness of our food, the quality of the soil, the wealth and abundance of the inhabitants, the inactivity and sedentary occupations of the better Sort and the Humour of living in great, populous and unhealthy towns'. However, he attached prime importance to diet and in his *Essay on Health and Long Life* (1724) he advocated a milk and seed diet. Nevertheless, madness continued to be associated with inner excellence and social quality. Cheyne himself suffered from depression and claimed that 'those of the liveliest and quickest natural Parts ... whose genius is most keen and penetrating', were most prone to such disorders. Firstly, the spleen, unlike lowness of spirits, was an indicator of high social rank. Secondly, it also implied a degree of intelligence, imagination, and sensitivity in the sufferer. As a youth, David*Hume was in correspondence with Cheyne. After describing his symptoms, Hume was flattered and reassured to learn that his was no ordinary complaint, but 'a disease of the learned'. Thus, even a rankorder in illnesses was acknowledged. Eighteenth century writers on the spleen are also concerned with the relationship between imagination and the spleen and, in particular, with the possible dangers of too much imagination. The fear of imagination developed from and is related to the fear of passion. Thomas Wright was able to voice these fears most clearly and forcefully (*The Passions of the Minde in Generall*, 1620). He described the evil effects of unrestrained passions as: 'blindness of understanding, persuasion of will,

alteration of humours; and by them maladies and diseases and troublesomeness and disquietness of the soul'. The paradoxical demands of reason and imagination and the precariousness of their relationships were recognized well in advance of Freud's discussion of the dilemmas of civilized man. Foremost among the eighteenthcentury distrusters of imagination is Samuel Johnson, who waged a lifelong battle against melancholy. Idleness and solitude were both to be avoided on the grounds that they provided a fertile breeding

Page 373

ground for the imagination. Solitude 'is dangerous to reason, without being favourable to virtue.... Remember ... that the solitary mortal is certainly luxurious, probably superstitious and probably mad: the mind stagnates for want of employment, grows morbid and is extinguished like a candle in foul air.' Idleness is condemned not because of its later associations with poverty, but because it promotes inner stagnation and decay.

Early nineteenthcentury writing on insanity is dominated by the work of the moral managers. Their ideas developed from faculty psychology, according to which man possessed three souls: the rational, the sensitive, and the vegetative. The rational soul is concerned with understanding and the will; the sensitive soul is concerned with the imagination, memory, and perception; and the vegetative soul is concerned with growth, nutrition, and reproduction. Health depends upon the right relationship between the rational and the sensitive soul, namely one of dominance and control. The moral managers held that insanity was a 'lesion of understanding' and that the will could be trained to cope with the possibility of madness. John*Locke had first put forward the view that madness was a selfcontained defect of reason and thus left open the possibility that other pans of the self could be enlisted to combat this weakness. In *An Essay Concerning Human Understanding*, Locke wrote that madmen do not appear to have lost the faculty of reasoning, but having joined together some ideas very wrongly they mistake them for truths ... as though incoherent ideas have been cemented together so powerfully as to remain united. But there are degrees of madness as of folly; the disorderly jumbling ideas together in some more, in some, less. In short, herein seems to lie the difference between idiots and madmen. That madmen put wrong ideas together, and so make wrong propositions, but argue and reason right from them. But idiots make very few or no propositions, but argue and reason scarce at all.

Now that the seat of madness had been isolated, optimism and cure became possible. In fact, much of the writing on insanity in the first half of the nineteenth century was concerned with delineating the strategic role played by the will. One such book which crystallizes' the early nineteenthcentury outlook is called *Man's Power over Himself to Prevent or Control Insanity*, published anonymously in 1843. The author assigns the following role to the will: The affection of the brain which causes delusions is not madness, but the want of power or will to examine them, is. Nothing then but an extent of disease which destroys at once all possibility of reasoning, by annihilating, or entirely changing the structure of the organ, can make a man necessarily mad. in all other cases, the being sane or otherwise, notwithstanding considerable disease of brain, depends on the individual himself. He who has given a proper direction to the intellectual force and thus obtained an early command over the bodily organ by habituating it to processes of calm reasoning, remains sane amid all the vagaries

of sense.

Within asylums treatment consisted of the cultivation of character and the rediscovery and strengthening of willpower.

During this period there is one important change of emphasis in the accounts of madness. James Cowles Prichard, ethnologist and physician, first introduced the term

'moral insanity' in 1833, and defined it as follows: 'This form of mental disease ... consists of a morbid perversion of the feelings, affections, habits, without any hallucination or erroneous conviction impressed upon the understanding; it sometimes coexists with an apparently unimpaired state of the intellectual faculties.' Thus the will was no longer the impenetrable stronghold against insanity, and madness had shifted from defective reasoning to the emotions. Given that the will in man was seen to be like a pilot in a ship, this reappraisal constituted a far more serious threat to man's supremacy over madness. Incidentally, the term 'moral insanity' is often, but erroneously, claimed to be the forbear of the modern 'psychopathic personality', whose cause still remains a matter for debate.

The theme of moral decline which lunacy represented was developed in a more systematic way and on a larger scale in the last third of the nineteenth century. Henry Maudsley published *Responsibility in Mental Disease* in 1873. Misleadingly titled, it was in fact a claim for nonresponsibility in mental disease (although not in any indulgent sense) and was largely an argument against the claims of the moral managers. Maudsley was not concerned with cure so much as with identifying and segregating the morally degenerate. Man's life is governed by genetic laws, and thought and volition are determined by them as much as are all other aspects of human life. Maudsley called this genetic determinism 'the tyranny of organisation'. He writes:

Individuals are born with such a flaw or warp of nature that all the care in the world will not prevent them from being vicious or criminal, or becoming insane.... No one can escape the tyranny of his organisation; no one can elude the destiny that is innate in him, and which unconsciously and irresistibly shapes his ends, even when he thinks he is determining them with consummate foresight and skill.

Whatever the complex intellectual and social changes that contributed towards this position (see ASYLUMS: A HISTORICAL SURVEY), it is a startling reversal of earlier accounts. Maudsley brings the dialogue with the irrational to a bleak and abrupt close. His concept of the 'tyranny of organization' seems to have been taken to its logical conclusion by Johannes Lange in his book *Crime and Destiny* (1930). Later studies of twins involved in crime have given as much emphasis to environmental as to hereditary factors as causes of felony

V. S.

INSPIRATION. The use of this word both for 'breathing' and for 'a bright idea' is not accidental. It derives from the notion of the ancient Greeks that mind pervades the universe, and is a subtle

vapour—the pneuma. (Pneumatic bliss is, indeed, a state of mind!)

INSTINCT. St Thomas*Aquinas wrote that animal judgement is not free but implanted by nature. Thus, from an early time, instinctive behaviour was regarded as the counterpart to voluntary behaviour. In everyday, though not in scientific, speech the term 'instinct' is still used to imply 'without thought'. For example, if I heard a taxidriver say 'I instinctively stamped on the brakes', I would assume that he meant that his behaviour was*reflex or involuntary, and not that he was born with an innate ability to apply the brakes in motor cars.

The associationists believed that human behaviour is maintained by the knowledge of, and desire for, particular consequences of behaviour, and they looked upon notions of instinct with disfavour. However, John*Locke did concede that there was 'an uneasiness of the mind for want of some absent good.... God has put into man the uneasiness of hunger and thirst, and other natural desires ... to move and determine their wills for the preservation of themselves and the continuation of the species' (*An Essay concerning Human Understanding*, 1690). Francis Hutcheson argued that instinct produces action prior to any thought of the consequences (*An Essay on the Nature and Conduct of Passions and Affections*, 1728). Thus Hutcheson made instinct into a kind of motivational force, and this concept was taken up by the nineteenthcentury rationalists, such as William*James, who conceived of human nature as a combination of blind instinct and rational thought.

The irrational forces in man's nature were emphasized by*Freud, but the ideas of*McDougall probably had a greater influence upon the scientific development of the concept of instinct. McDougall regarded instincts as irrational and compelling motivational forces. He enumerated particular instincts, each of which was accompanied by an*emotion. Examples are: pugnacity and the emotion of anger; flight and the emotion of fear; repulsion and the emotion of disgust (*Instincts and their Vicissitudes, Collected Papers*, 1915). McDougall's views do not find favour with modern psychologists because they are derived from subjective experience and are therefore hard to verify. There is inevitable disagreement among psychologists as to the number of instincts that should be allowed.

A different line of thought was initiated by Charles*Darwin. In his *Origin of Species* (1859), Darwin treated instincts as complex reflexes that were made up of inherited units and therefore subject to natural selection. Such instincts would evolve together with other aspects of the animal's morphology and behaviour. Darwin laid the foundations of the classical ethological view propounded by Konrad Lorenz and Niko Tinbergen.

Lorenz maintained that animal behaviour included a number of fixedaction patterns that were characteristic of species and largely genetically determined. He subsequently postulated that each fixedaction pattern or instinct was motivated by actionspecific energy. The actionspecific energy was likened to liquid in a reservoir. Each instinct corresponded to a separate reservoir, and when an appropriate releasing stimulus was presented the liquid was discharged in the form of an instinctive drive which gave rise to the appropriate behaviour. Tinbergen proposed that the reservoirs, or

instinct centres, were arranged in a hierarchy so that the energy responsible for one class of activity, such as reproduction, would drive a number of subordinate activities, such as nestbuilding, courting, and parental care.

The concept of instinct that is identified with classical ethology does not find favour with the majority of presentday behavioural scientists, for two main reasons. The first reason is connected with the idea that there are instinctive forces, or drives, that determine certain aspects of behaviour. Although the notion of drive as an energizer has been very influential in psychology, it involves a misuse of the concept of energy. In the physical sciences, energy is not a causal agent but a descriptive term arising from mathematically formulated laws. Analogous laws can be formulated for animal behaviour, but they do not lead to a concept of energy that corresponds to the notions of drive popular with the early psychologists and ethologists. Although the idea of drive as an energizer of behaviour has intuitive appeal, this is not nowadays regarded as sufficient justification for a scientific concept. In addition there are empirical problems. Early psychologists sought to identify a drive for every aspect of behaviour: a hunger drive responsible for feeding, a thirst drive, a sex drive, etc. It proved impossible to classify animal behaviour in this way without resorting to a *reductio ad absurdum* involving drives for thumbsucking, nailbiting, and other minutiae of behaviour. A more modern view is that animals choose from among the set of alternative courses of action that is available at a particular time, in accordance with certain precisely formulated principles of decisionmaking. This approach obviates the view that animals are driven by instinctive forces to perform particular behaviour patterns.

The second reason for abandoning the classical concepts of instinct is an objection to the implication that certain aspects of behaviour are innate in the sense that they develop independently of environmental influences. Most scientists now recognize that all behaviour is influenced both by the animal's genetic makeup and by the environmental conditions that exist during development. The extent to which the influences of nature and nurture determine behaviour varies greatly from activity to activity and from species to species. For example, the vocalizations of pigeons and doves are relatively stereotyped and characteristic of each species, and are not influenced by auditory experience after hatching. The vocalizations of

Page 375

other birds, however, may depend heavily upon such experience, as in the strongly imitative birds, or they may be partly influenced by experience. For example, chaffinches will learn the song they hear during a particular sensitive period of early life, provided it is similar to the normal song.

While the influence of particular genes may be necessary for the development of a behaviour pattern, it is never a sufficient condition. All types of behaviour require a suitable embryonic environment for the correct nervous connections, etc., to develop. Normally, the physiological medium provided by the parent is designed to ensure that normal embryonic development occurs. Just as the parent provides an environment suitable for the development of the embryo, so it may provide an environment suitable for the development of a juvenile. Thus a chaffinch is normally reared in an environment in which it inevitably hears the song of other chaffinches, and so it develops the song that

is characteristic of its own species.

Even apparently stereotyped activities may, upon closer examination, be shown to be influenced by the environment. For example, the newly hatched chicks of herring gulls peck at the tip of the parent's bill, which bears a characteristic red spot on a yellow background. The chick's behaviour induces the parent to regurgitate food.

The behaviour is typical of all newly hatched chicks, is performed in an apparently stereotyped manner, and would appear to be a classic example of instinctive behaviour. Upon closer examination, however, it can be seen that the initial behaviour of individual chicks varies considerably in force and rapidity of pecking, angle of approach, and accuracy. As the chicks gain experience their pecking accuracy improves, and the pecking movements become more stereotyped. Some of these changes are due to maturation. The chicks become more stable on their feet as their muscles develop, and their pecking coordination improves. Some of the changes are due to learning. Initially the *chicks* peck at any elongated object of a suitable size. Although the red spot on the parent's bill is attractive to them, it is not their only target. Once the chicks begin to receive food they learn to exercise greater discrimination. It is not surprising that the behaviour of different chicks develops along similar lines, because in the natural environment they are all confronted with a similar situation. Practice and experience in similar situations lead to similar results, and the behaviour of the older chick consequently becomes more and more like that of its peers.

The concept of instinct has undergone many changes over the years. Whereas, at one time, instinctive behaviour was seen as inborn, stereotyped, and driven from within, the modern approach is to treat the innate, the reflex, and the motivational aspects as separate issues. While much animal and human behaviour is innate in the sense that it inevitably appears as part of the repertoire under natural conditions, this does not mean that genetic factors are solely responsible. Maturational factors and modes of learning that are characteristic of the species may be just as important. Much of the naturenurture controversy, particularly that associated with sexual and racial differences among humans, results from a failure to recognize the vast complexity of developmental processes.

INSTRUMENTAL CONDITIONING. See

CONDITIONING.

INTELLECT. Mental abilities, usually distinguished from feelings,*emotions, and also*perception—though perception, we now generally believe (following Hermann von*Helmholtz), in fact depends upon unconscious inferences. The word is seldom applied to animals; and an 'intellectual' person means someone concerned with problems requiring high*intelligence and much learning. The intellect is associated with cortical brain function.

INTELLIGENCE. Innumerable tests are available for measuring intelligence (see INTELLIGENCE: ITS ASSESSMENT), yet no one is quite certain of what intelligence is, or even of just what it is that

the available tests are measuring. There have been any number of attempts to resolve these uncertainties, attempts that have differed in their approach to the problem, and in the outcome of applying each given approach.

One timehonoured approach to discovering the meaning of a construct is to seek expert opinion regarding its definition. This is exactly what the editors of a major psychological journal did in 1921, when they sought the opinions of experts in the field of intelligence regarding what they 'conceive "intelligence" to be, and by what means it can best be measured by group tests' ('Intelligence and its Measurement', 1921, p. 123). Fourteen experts replied, with definitions of intelligence such as the following: (i) the power of good responses from the point of view of truth or fact (E. L.*Thorndike); (ii) the ability to carry on abstract thinking (L. M.*Terman); (iii) having learned or ability to learn to adjust oneself to the environment (S. S. Colvin); (iv) the ability to adapt oneself adequately to relatively new situations in life (R.

Pintner); (v) the capacity for knowledge, and knowledge possessed (V. A. C. Henmon); (vi) a biological mechanism by which the effects of a complexity of stimuli are brought together and given a somewhat unified effect in behaviour (J. Peterson); (vii) the capacity to inhibit an instinctive adjustment, the capacity to redefine the inhibited instinctive adjustment in the light of imaginably experienced trial and error, and the volitional capacity to realize the modified instinctive adjustment into overt behaviour to the advantage of the individual as a social animal (L. L.*Thurstone); (viii) the capacity to acquire capacity (H. Woodrow); (ix) the capacity to learn or to profit by

Page 376

experience (W. F. Dearborn). The other experts did not answer the question directly.

Viewed narrowly, there seem to be almost as many definitions of intelligence as there were experts asked to define it. Viewed broadly, however, two themes seem to run through at least several of these definitions: the capacity to learn from experience, and adaptation to one's environment. Indeed, an earlier definition often cited by these experts viewed intelligence as general adaptability to new problems and conditions of life. (For an update of the 1921 symposium, see Sternberg and Detterman, 1986.)

If one is dissatisfied with the heterogeneity in these definitions, one can attempt to answer the question of what intelligence is by begging the question. Edwin*Boring (1923) did just that when he defined intelligence as whatever it is that the tests measure. This definition tells us no more than we knew when we started, and it may tell us less: no two tests measure exactly the same thing, so that one is left with as many definitions of intelligence as there are tests (which is certainly a number greater even than that of experts in the field!).

A more recent and sophisticated version of the definitional approach to discovering what intelligence is has been suggested by Ulric Neisser (1979). According to Neisser, the concept of intelligence is organized around a 'prototype', or ideal case. One is intelligent to the extent that one resembles this ideal case: There are no definitive criteria of intelligence, just as there are none for chairness; it is a

fuzzyedged concept to which many features are relevant. Two people may both be quite intelligent and yet have very few traits in common—they resemble the prototype along different dimensions.... [Intelligence] is a resemblance between two individuals, one real and the other prototypical (p. 185).

If there is a single prototype, or ideal case, Neisser's notion will give us a concept of intelligence validated by consensus, if not a concrete definition. There are at least two problems with Neisser's approach, however. First, there exist multiple prototypes, or ideal cases, not just a single one (Sternberg *et al.*, 1981). Different groups of people have somewhat different prototypes. Which one do we use? If we use all of them, including those of various groups of experts and laymen, we end up with as many ideal concepts of intelligence as there are different prototypes, and we are no better off than we were when appealing to experts' definitions. Secondly, the

'ideal case' approach seems to be an excellent way of discovering what people mean by 'intelligence', but not of discovering what 'intelligence' means. Neisser would argue that the two are indistinguishable, but I suspect they are not. Suppose, for example, that people in some culture view their ideal case as able to harmonize with Kron, the god of nature. This description tells us what these people think intelligence is, but it doesn't tell us much about the nature of intelligence: we still have to find out what it means to harmonize with Kron. In our culture, an analogous notion might be the ability to adapt to natural events. Again, we still need to find out what kinds of mental events and physical behaviours result in the ability to adapt. What is it that people who are able to adapt well do that people who are not able to adapt well do not do?

Questions such as this one have led some theorists of intelligence to seek the nature of intelligence by the analysis of individual differences. The question asked here, as above, is what aspects of mental functioning distinguish more intelligent people from less intelligent ones. The nub of this individual differences approach is to have people perform a large number of tasks that seem to predict intelligent performance (in school, on the job, or wherever), and to analyse patterns of individual differences in task performance. These patterns of individual differences have usually been analysed through the use of a method of statistical analysis called 'factor analysis'. The idea is to identify the 'factors' of human intellect.

The earliest factorial theory of the nature of intelligence was formulated by the inventor of factor analysis, Charles* Spearman. Spearman's (1927) analysis of relations among the kinds of mental tests he and other psychologists had been administering led him to propose a 'twofactor' theory of intelligence. According to this theory, intelligence comprises two kinds of factors—a general factor and specific factors. General ability, or *g* as measured by the general factor, is required for performance of mental tests of all kinds. Each specific ability, as measured by each specific factor, is required for performance of just one kind of mental test. Thus, there are as many specific factors as there are tests, but only a single general factor. Spearman suggested that the ability underlying the general factor could best be understood as a kind of 'mental energy'.

Godfrey Thomson's (1939) reassessment of Spearman's individual differences data led him to accept Spearman's hypothesis of a general factor running through the range of mental ability tests; however, it led him to reject Spearman's interpretation of this factor. Thomson disputed Spearman's claim that the

general factor represented a single underlying source of individual differences. Instead, he proposed that the appearance of a general factor was due to the workings of a multitude of mental 'bonds', including reflexes, learned associations between stimuli, and the like. Performance of any particular task activates large numbers of these bonds. Some bonds will be required for the performance of virtually any task requiring mental effort, and these bonds will in combination give rise to the appearance of a general factor.

L. L. Thurstone (1938), like Thomson, accepted Spearman's hypothesis of a general factor. But he disputed the importance of this factor. He argued that it is a

'secondorder' factor or phenomenon, one which arises only because the primary or 'firstorder' factors are related to each other. What are Page 377

these primary factors, or, as Thurstone called them, 'primary mental abilities'? Thurstone suggested that they include verbal comprehension (measured by tests such as knowledge of vocabulary), word fluency (measured by tests requiring rapid word production—for example, a listing of as many words as a person can think of that have c as their third letter), number (measured by tests of arithmetical reasoning and computation), spatial visualization (measured by tests requiring mental manipulation of geometric forms), perceptual speed (measured by tests requiring rapid visual scanning, for example, proofreading),*memory (measured by tests of recall and recognition of previously presented information), and reasoning (measured by tests such as number series, which require people to say which of several numbers should come next in a given series).

J. P. Guilford (1967) parted company from the majority of factorial theorists by refusing to acknowledge the existence of any general factor at all in human intelligence.

Instead, he proposed that intelligence comprises 120 elementary abilities, each of which involves the action of some operation upon some content to produce some product. An example of an ability in Guilford's system is 'cognition of verbal relations'. This ability involves recognition of a conceptual connection between two words: for example, recognition that a *caboose* is often the last car in a *train*.

Probably the most widely accepted factorial description of intelligence is a hierarchical one. A good example of this class of descriptions was proposed by P. E.

Vernon (1971). He proposed that intelligence can be described as comprising abilities at varying levels of generality: at the highest level of generality (the top of the hierarchy) is general ability as identified by Spearman; at the next level are 'major group' factors, such as verbaleducational ability (the kind of ability needed for successful performance in courses such as English, history, and social studies) and practicalmechanical ability (the kind of ability needed for successful performance in courses such as draughtsmanship and car mechanics); at the next level are 'minor group' factors, which can be obtained by subdividing the major group factors; and at the lowest level (the bottom of the hierarchy) are specific factors; again of the kind identified by Spearman. This description of intelligence may be viewed as filling in the gaps between the two extreme kinds of factors proposed

by Spearman: in between the general and specific factors are group factors of intermediate levels of generality.

The factorial views of intelligence are unlike the definitional ones in that they are based on the analysis of intelligent functioning (on ability tests), rather than merely on the speculations of one or more psychologists or laymen. The factorial views are like the definitional ones, however, in their potential number and diversity. Is it the case that one of the factorial descriptions is right and the others wrong, or is it possible that a single entity or complex of entities, intelligence, can conform to all of these different descriptions? In other words, is there some level, or common denominator, at which these various descriptions all reduce to the same thing? It is here suggested that such a level of description exists, and that it can be found by analysing the ways in which people process information when solving problems of the kind found both on intelligence tests and in everyday life.

Informationprocessing psychologists have sought to understand general intelligence in terms of elementary components (or processes) used in the solution of various kinds of problems (Carroll, 1976; Hunt et al., 1973; Newell and Simon, 1972; Sternberg, 1979 and 1979). Let us distinguish five kinds of components that people use in the processing of information. *Metacomponents* are higherorder control processes that are used for planning how a problem should be solved, for making decisions regarding alternative courses of action during*problemsolving, and for monitoring one's progress during the course of problem solution. *Performance components* are processes that are used in the actual execution of a problemsolving strategy. *Acquisition components* are processes used in learning, that is, in the acquisition of knowledge. *Retention components* are processes used in*remembering—that is, in the retrieval of previously acquired information. *Transfer components* are used in generalization—that is, in the transfer of knowledge from one task or task context to another.

Consider, for example, how each of these five kinds of components might be applied in the solution of an arithmetical problem.

Mrs Smith derided to impress Mrs Jones. She went to a costume jewellery shop and bought three imitation diamonds of equal value. She received £4 in change from the tenpound note she gave the assistant. (But as Mrs Smith was receiving her change, Mrs Jones walked into the shop!) How much did each imitation diamond cost?

Metacomponents would be used in setting up the equations for solving the problem, for example, in deriding that the problem can be solved by subtracting £4 from

£10 and dividing the difference by three; the metacomponents must also decide what information is relevant to the problem at hand, and what information is irrelevant.

Performance components would be used in the actual solution of these equations to obtain, first, £6 as the price of the three imitation diamonds and, then, £2 as the price of each item. Acquisition components were used in the problemsolver's past to learn how to set up the equations, how to subtract, how to divide, and so on.

Retention components are used to retrieve this information from memory at the time that it is needed. Transfer components are used to draw an analogy between this problem and previous ones: the problemsolver has never learned how to solve this particular problem, and must generalize his or her learning from similar problems previously encountered to the problem presently being encountered.

Page 378

How can this scheme account for the various factorial views of intelligence described earlier? According to this view, the general factor that appears in various theories of intelligence results from the operations of components that are general across the range of tasks represented on intelligence tests. For the most part, these are metacomponents—mental activities such as deciding upon the particular components to be used in the solution of problems, deciding upon a strategy for problem solution, monitoring whether the strategy that has been chosen is leading to a solution, deciding upon how quickly the strategy can be executed and still lead to a satisfactory result, and so on. Major group factors of the kind found in Vernon's theory, and primary factors of the kind found in Thurstone's theory, are obtained in factor analyses primarily as a result of the operations of performance, acquisition, retention, and transfer components. For example, verbal comprehension, as tested by vocabulary, is the product of past executions of acquisition components to learn new words, and of present executions of retention components to retrieve the meanings of these words. If vocabulary is tested by presenting the words in unfamiliar contexts, transfer components may also be involved in applying previously acquired information to the new contexts that are presented. Reasoning, as tested by problems such as numerical series completions (say, 3, 7, 12, 18, 25, ...), requires the execution of various performance components, such as encoding the terms of the problem, inferring the relations between the given pairs of numbers, applying these relations to the last given number to obtain the next number, and the production of a response.

This informationprocessing view of intelligence seems to unify what were formerly a number of disparate views regarding the nature of intelligence. A number of important questions still need to be answered, however, and it is possible to consider only a small number of them here.

First, is the meaning of intelligence the same across different societal and cultural groups? On the view proposed, the answer is both yes and no. On the one hand, the components that would be applied to the solution of a given problem in one culture or society probably overlap to a large degree, although perhaps not completely, those that would be applied to the solution of the same problem in a different culture or society. On the other hand, the kinds of problems that need to be solved may differ widely from one culture or society to another. The mental (and physical) processes needed to corner game in a hunt are very different from those needed to balance accounts. Hence, the kinds of persons who are considered intelligent may vary widely from one culture to another, as a function of the components that are important for adaptation to the requirements of living in the various cultures.

Secondly, if intelligence tests measure, in greater or lesser degree, the components of informationprocessing, why are they so imperfectly predictive of realworld performance? One reason is that they are fallible as measuring instruments: they measure only imperfectly what they are

supposed to measure. Another reason is that they do not necessarily weigh most heavily those aspects of intellectual functioning that are most important for intelligent functioning in a given environment.

Metacomponential functioning is probably underemphasized, for example, in the measurements made by most of these tests. Yet another reason, and probably the most important one, is that there is a great deal more to everyday living than what the intelligence tests measure, or even than what can reasonably be called intelligence. The tests fail to take into account such important aspects of functioning as motivation, social skills, persistence in the face of adversity, and ability to set and achieve reasonable goals. The tests provide reasonably good measures of limited aspects of functioning for most people. But even here a qualification is necessary, since there are some people whose anxieties, or inability to take tests, render their test scores meaningless or even deceptive.

Finally, is intelligence largely inherited, as has been claimed by some (for example, Jensen, 1969), or is it largely or exclusively determined by environment, as has been claimed by others (for example, Kamin, 1974)? Few bodies of evidence are more confused and confusing than that dealing with the heritability of intelligence. The probability is that heredity, environment, and the interaction between heredity and environment all play some role in intelligence as it has traditionally been measured, but it is not at all clear what the relative extents of these roles are. Nor is it clear what it means, in practical terms, to assign proportional values to the influence of each.

No matter what the proportions are, there is good evidence that at least some aspects of intelligence are trainable (see, for example, Feuerstein, 1979; Sternberg, 1981 *a*), and theoretical interest in the heritability of intelligence should not divert attention from questions about how intelligence can be modified in individuals of all levels of measured intelligence.

INTELLIGENCE, INVERTEBRATE. See INVERTEBRATE LEARNING AND INTELLIGENCE.

INTELLIGENCE: ITS ASSESSMENT. Definitions of 'intelligence' vary with the theoretical position (and also the political persuasion) of the definer. The biologist tends to stress concepts such as healthy adaptation, capacity for adjustment to the environment, and learning to learn. The more philosophically minded intellectual is liable to emphasize the element of abstraction: indeed, 'the capacity for abstract thought' was the definition offered by Lewis*Terman. But many would reject the implicit valuejudgement that abstract thinking is in some way superior to—or, in any case, more intelligent than—concrete or practical thinking. (See INTELLIGENCE for a fuller discussion.)

'Intelligence' has sometimes been contrasted with*'instinct', the latter posited as being a feature of the lower animals, common to all members of a species and relatively immutable because unlearned, i.e.

performed almost perfectly at its first manifestation. Intelligence, on the other hand, was assumed to be an attribute unique to mankind and evincing wide individual differences. Of recent years, however, such distinctions between man and beast have become blurred (as, in certain quarters, have those between man and machine). The concept of instinct has both increased in flexibility and diminished in scientific respectability, since it is held to encourage mere naming and to lack explanatory or predictive power.

The stature of 'intelligence' has, for several reasons, also declined recently. First, the assertions made by certain psychometrists as to its degree of innateness (cf.

Cyril*Burt's 'innate, general, cognitive ability') and the alleged constancy of its nature/nurture ratio (cf. Hans Eysenck's '4 : 1') are now largely discredited, as are claims for the existence of 'culturefair' intelligence tests. Secondly, the identification of tested intelligence with everyday intelligence is questionable, especially in view of the many so-called intelligence tests which lack cogency. Thirdly, the whole climate of opinion during the 1960s and early 1970s among 'progressives' was antiassessment; and while this attitude persisted, intelligence testing was bound, rightly or wrongly, to be a target for attack.

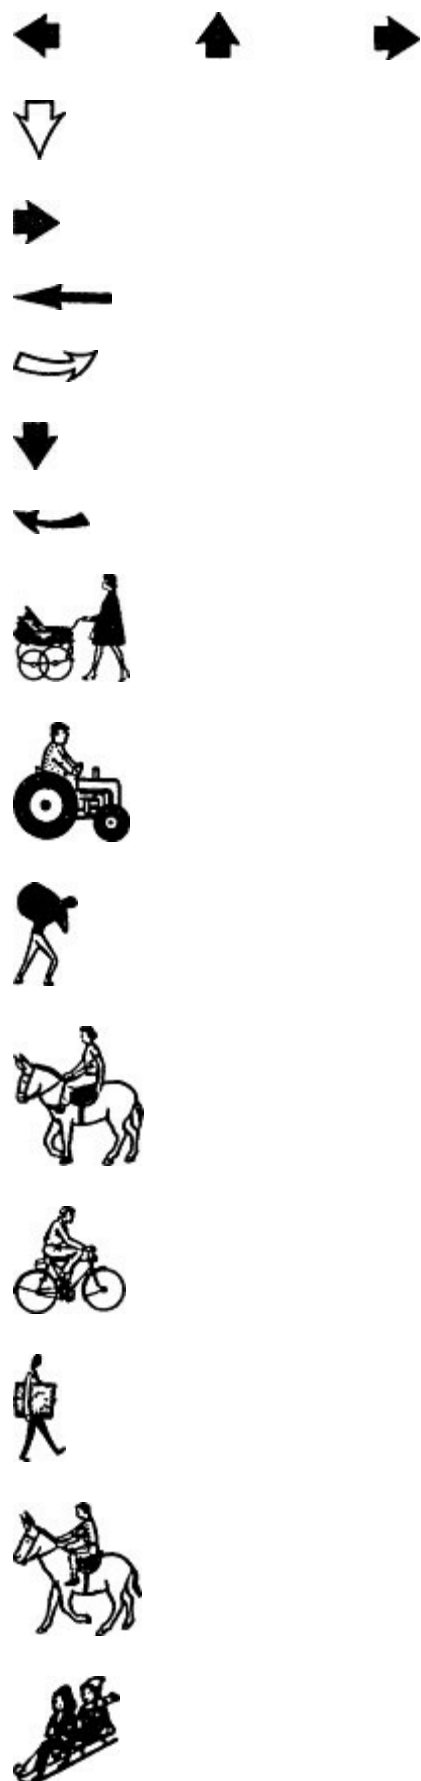

The word 'intelligence' is indeed likely to give rise to misconceptions, partly owing to the above overtones and partly to the suggestion implicit in an abstract noun that the word refers to 'something'—perhaps to something which one either possesses or lacks. This is, of course, a gross oversimplification of the issue. To avoid perpetuating such reification of intelligence (or any other factor) let us consider a *description of intelligent activity* rather than a definition of intelligence: that intelligent activity consists of grasping the essentials in a given situation and responding appropriately to them. This purposely leaves open such questions as speedversusaccuracy or abstractversuspractical; as to whether the most intelligent is he who can solve the most diverse problems or he who can answer the 64,000

dollar question; as to the existence of people who grasp the essentials but fail to react, and of others who respond appropriately but cannot explain their action. This openendedness is deliberate in order to stress the flexibility of the term 'intelligent activity' and to cover intelligence both as tested and as manifested in everyday life.

How then is this elusive quality appraised? And what are the purposes of such appraisal? The agreement on what an intelligence test actually assesses is far greater than that found among the definitions and the theories in this realm. An intelligence test is essentially a test of deductive reasoning. In fact, since 'intelligence' has become a dirty word, many psychologists prefer to talk of 'tests of reasoning'. More specifically, the phrases 'verbal reasoning' or 'numerical reasoning' or 'perceptual reasoning' may be used. Two examples of each of these are given in Fig. 1.

It may be seen from these examples that some element of acquired knowledge is assumed—i.e. the understanding of everyday words and of simple arithmetical concepts, the capacity to recognize certain features of formal shapes and to interpret representational pictures. A test which makes no such assumptions would be both impracticable and valueless. But, in so far as is possible, all the

information required to solve each problem is contained within it, and the items are unambiguous in the sense that only one of the proffered responses is defensible.

Page 381

Such problems can be devised that are appropriate for people of almost every level of ability: for the sevenyearold (e.g. no. 5), for the young adolescent (e.g. no. 1), or for the sixthformer or older (e.g. no. 3). These tests are often good predictors of academic or vocational success but they differ from examinations in that they are less dependent on memory, diligence, and congenial teaching, as they are not primarily concerned with assimilated knowledge; and they are clearly more objective than*interviews or other methods involving direct personal judgement.

The purposes of assessing intelligence are manifold. Let us consider four of the uses to which such tests are put: selection, vocational guidance, clinical work, and research. First, selection: whenever the number of applicants exceeds the number of places—whether in education, or industry, or the Civil Service—some form of assessment is necessary, in order to determine which candidates to accept. Intelligence is only one of the factors to consider, but it is nearly always relevant and it is easier to assess than such traits as conscientiousness, sense of responsibility, and the ability to get on with people. The test scores, unlike interviews, are not liable to be influenced by such factors as the applicant's clothing or accent, or his · willingness to appreciate his interviewer's sense of humour (though the *ability* to do this may well be related to intelligence!)

So much for selection. Vocational guidance is the other face of the same coin: here the psychologist advises the individual as to what kind of job is likely to give him most satisfaction and to make the best use of his talents. Advice is especially helpful in those cases where people have no idea what work would suit them or where, for one reason or another, they are in a state of conflict on the matter.

Tests of aptitudes and of interests may also be helpful in vocational guidance.

Tests are used in clinical situations as an aid, sometimes to diagnosis and sometimes to assess the progress of a patient. They can help in determining whether braindamage has occurred, and also in deciding whether one particular course of treatment is more appropriate than another.

In research, the intelligence test may be a valuable instrument either in its own right—in a study of 'slow developers', for example, or of the effects of environmental change, or of male/female intellectual differences (if such study is still within the law!)—or as a means to an end. Since it is rarely the case in human psychology that

'other things are equal', techniques such as matching members of pairs on intelligence test performance may be usefully employed in the investigation of other psychological or social variables.

Equality of opportunity is as important as ever it was, and it is gradually becoming more of a reality—partly owing to the use of intelligence tests, since they often facilitate the recognition of an able child from an underprivileged background. But to insist, as some educationists do nowadays, that equality *of ability* is the rule—

and to decry assessment of any kind, since if some are designated as brighter it follows that some must be designated as duller—is unhelpful to the individuals concerned as well as to their subsequent employers or instructors.

The intelligence test can yield valuable data, provided that it is devised with critical care, interpreted with understanding, and used always in conjunction with other procedures. Indeed, intelligence testing is most informative in those somewhat rare cases when its results are at variance with other relevant criteria.

INTELLIGENCE: THE ART OF GOOD GUESSWORK. We think that intelligence is a quality easily recognizable in other people's talk, deeds, or writings, yet the current trend among

psychologists is to deny that it can be succinctly defined or described. This avoidance of the most interesting of all general questions about intelligence results partly from intellectual revulsion against the psychometricians' simplistic arrogance in promoting the IQ as an adequate measure of an individual's mind, and partly from moral revulsion at the degradation and insult to whole racial groups that has resulted from this approach. It is also partly a historical relic, for the early discussions of the topic were singularly inconclusive and unproductive (Thorndike *et al.*, 1921). However, intelligence is something to do with the way the mind processes information and handles data, and there have been great advances in information science since the early days of intelligence tests; for this reason one's intuition that intelligence is not only recognizable, but also definable, should now be given more theoretical attention. Heat, like intelligence, shows itself in many different ways: it gives the feeling of warmth, it melts solids and vaporizes liquids, it accelerates chemical reactions, it comes from the sun or the fireplace, and so on.

Where would thermodynamics be if everyone had accepted the pervasive but pleomorphic manifestations of heat as proof that the theoretical problem of its nature was insoluble?

The notion that the biological role of intelligence is to produce good guesswork comes from a suggestion that it is the capacity to detect new, nonchance, associations (see Fatmi and Young, 1970; Barlow, 1970). Further consideration suggests that the most important use of newly detected associations is to improve the quality of the decisions that are made, and it is easy to see that anything that

Page 382

does this will be highly prized and sought after. It is reasonable to define intelligence in terms of the main benefits it confers, but the basic capacity is that of detecting new associations whose importance has long been recognized; here are some illustrations.

Consider the hungry (and intelligent) dog that leaps from its comfortable rug in front of the fire when it hears the sound of the refrigerator door being opened. That sound is associated with the availability of food, and the recognition of such associations has obvious value. But in pointing to this particular association of sensory stimuli with reward we have only skimmed the surface, for there is no unique component to the sound of the refrigerator door; what is unique is the collection of sounds made by the door, and to determine what makes up this collection is itself an associative task. Since we are primarily concerned with human intelligence we must also point to uniquely human aspects of the structure of associations: we have spoken language with words representing associations of sensory stimuli, written language compiling those associations into sentences, and books, libraries, and whole academies whose purpose is to explore and elaborate associations among mere words.

Two more points about spotting associations need emphasis. First, the *newness* of the associations that are detected is important, for we do not really grant that someone is intelligent because he is full of knowledge of past discoveries and as a result can point to associative structures that would otherwise have been missed. We feel intuitively that a bright mind discovers associations anew from direct experience, rather than relying on memory, hearsay, or the knowledge contained in books.

'New' in the definition must therefore be taken to mean new for the mind in question, not new in the sense of 'never previously detected'.

The second point is that the associations discovered must be genuine ones and not due to chance. The mind that seizes on any random coincidence and sees it as a sign of an important permanent association will not guess right and is not conceded to be intelligent, though it may at times be entertaining.

Linking intelligence to guesswork captures the commonsense view of intelligence rather than the psychometrician's, but it is worth pointing out that some of the questions in tests, empirically developed as they have been to probe the capacity of the mind thought to correspond with intelligence, do indeed probe the capacity to detect new associations and relationships. This is the case for questions that require the completion of sequences or recognition of analogies. Many other questions merely probe something more appropriately termed 'general knowledge'; however, these too would be justifiable in terms of the definition to the extent that general knowledge represents the result of past applications of the capacity to detect associations.

If guessing right depends on spotting new associations, and if this is central to intelligence, what do we learn about its measurement? In order to guess right there are three conceptually distinct tasks, namely formulating possible guesses (i.e. hypotheses about new associations), testing them to find the right ones, and working out the implications of those that escape disproof. Of these three, it is easiest to imagine an objective measure of the testing process, because the theory and practice of statistical tests for associations are well developed, and this makes it possible to compare the performance of an individual at an associative task with that of an 'ideal statistician'. The ideal will make the best possible use of the evidence, and a measure of 'associative efficiency' is obtainable from the ratio of the amounts of evidence required by the ideal and the individual being tested, when each performs at the same level of reliability; this is an absolute measure of how well the subject utilizes the information available—how well he guesses in fact. The concept of statistical efficiency (Fisher, 1929) has been used to measure human perceptual tasks (Rose, 1942;

Tanner and Birdsall, 1958; Barlow and Reeves, 1979), but has not yet been applied to the associative tasks that underlie intelligence (nor to learning for that matter).

It is satisfying that the definition allows one to point to one aspect of intelligence that could in principle be measured objectively and in absolute terms, knowing precisely what one was measuring.

The next question is 'How does the possibility of a particular association enter someone's mind?' One naturally attributes intelligence to a mind that generates its own array of plausible possibilities, and stupidity to a mind that produces inappropriate ones or has to be fed with suggestions in every new circumstance. Seeing possible solutions is an essential part of good guesswork, and the nature of this imaginative ability is a more difficult and interesting question than that of assessing statistically whether a given association is present or not. The main difficulty here is the astronomical number of possible associations: it is certainly *not* intelligent to point to any or all of them for testing, whereas it would, for instance, show a glimmer of intelligence to start looking for associations between those

events which occur with approximately the same overall frequency. It would be a formidable task to specify a catalogue of good tactics for imaginative guesswork in order to measure how well an individual was able to devise them, and a single numeric measure of imaginative inventiveness is most unlikely to emerge from such an effort. One must also pay attention to the third distinct part of intelligence.

It is not intelligent to claim as a new association something that can readily be deduced from associations that are already known. Every moment we see sights and hear sounds that can be predicted from associations already established by our own minds, or implanted in them by others. To distinguish what is new, knowledge of these pre

Page 383

existing associations must be organized so that they are taken into account. Thus the deductive reasoning required to use a background of general knowledge is a necessary part of intelligence on the current definition.

It will surprise no one that intelligence appears to be complex and requires imagination, judgement and reasoning. But this discussion has led to two novel conclusions: first, the part concerned with statistical judgement can in principle be measured on an absolute scale, using theoretical limits as a reference rather than population norms or anything like that; and second, the nature of intelligence is rather satisfactorily defined simply by stating its goal, namely guessing right. One must respect past psychometricians for their empirical development of practical tests of mental ability, but one should now hope that the theoretical basis will be strengthened and particularized (see Barlow, 1983; Sternberg, 1985). The diversity of minds and their aptitudes should not conceal the fact that there is a recognizable unity behind all the manifestations of intelligence.

INTENTION. This is one of the most difficult concepts to understand or discuss in academic psychology, although most 'commonsense' psychological explanations are in terms of intentions. Behaviour is commonly explained by intentions (such as: 'Why did the chicken cross the road . . .?'), but just what an intention is, in terms of brain processes or anything else, is exceedingly hard to say.

Intention seems to characterize mind; for we can hardly say that natural objects (atoms, molecules, tables and chairs, or planets or stars) have intentions. They are controlled, rather, according to natural laws. The forming of an intention seems to imply free will and the ability to choose. Whether such an ability is compatible with the operation of strictly causal laws at the physical level is a matter of philosophical debate.

Can a machine show intention? It has been argued for example by the philosopher Margaret Boden (1972) that artificial intelligence machines can exhibit purpose and intention.

Boden, M. (1972). *Purposive Explanation in Psychology*. Cambridge, Massachusetts.

INTENTIONALITY. Intentionality is *aboutness*. Some things are about other things: a belief can be about icebergs, but an iceberg is not about anything; an idea can be about the number 7, but the number 7 is not about anything; a book or a film can be about Paris, but Paris is not about anything. Philosophers have long been concerned with the analysis of the phenomenon of intentionality, which has seemed to many to be a fundamental feature of mental states and events. It should be clear that this use of 'intentionality' and 'intentional' is a technical use, and should not be confused with the more familiar sense (discussed in the entry, INTENTION) of doing something deliberately or on purpose. Hopes and fears, for instance, are not things we *do*, not intentional *acts* in the latter, familiar sense, but they are intentional phenomena in the technical sense, for they are *about* or *of* something.

The term was coined by the Scholastics in the Middle Ages (see, for example, AQUINAS), and derives from the Latin verb *intendo*, meaning to point (at) or aim (at) or extend (toward). Phenomena with intentionality point outside themselves, in effect to something else: whatever they are *of* or *about*. The term was revived in the nineteenth century by the philosopher and psychologist Franz Brentano, one of the most important predecessors of the school of phenomenology. Brentano claimed that intentionality is the defining distinction between the mental and the physical; all and only mental phenomena exhibit intentionality. Since intentionality is, he claimed, an irreducible feature of mental phenomena, and since no physical phenomena could exhibit it, mental phenomena could not be a species of physical phenomena. This claim, often called the Brentano thesis, or Brentano's irreducibility thesis, has often been cited to support the view that the mind cannot be the brain, but this is by no means generally accepted today.

There was a second revival of the term in the 1960s and 1970s by English and American philosophers in the analytic tradition. In response to seminal work by R.

Chisholm and W. V. Quine, a vigorous attempt was made to develop an account of intentionality in harmony with the canons of modern logic and semantics. Since the phenomenological tradition, mainly on the Continent, has continued to exploit the concept of intentionality along rather different lines, the problem of intentionality is one of the best points of convergent concern in these two largely separate—and often antagonistic—research traditions.

In spite of the attention currently devoted to the concept, there is a striking lack of received wisdom about the proper analysis of intentionality. What Page 384

agreement there is concerns the nature of the problems raised, and while some of the proposed solutions are forbiddingly technical, the problems themselves readily emerge on a little reflection.

If we make an initial rough catalogue of the things that can be about things, it will include a great variety of *mental* states and events (ideas, beliefs, desires, thoughts, hopes, *fears, *perceptions, *dreams, *hallucinations . . .), also various *linguistic* items (sentences, questions, poems, headlines, instructions . . .), and perhaps other sorts of *representations* as well (pictures, charts, films, symphonic tone poems, computer programs . . .). Many have thought that these linguistic and nonlinguistic representations are only derivatively about anything. They depend for their intentionality on their being the creations and tools of creatures with minds, and particular representations derive their specific aboutness from the specific aboutness of the ideas, beliefs, and intentions of their creators. What makes the particular sequence of ink marks on the next line:

Napoleon was exiled to Elba

about Napoleon is its role as a sentence in a language used by people who know about Napoleon, or at least have beliefs about Napoleon, and wish to communicate about Napoleon. What *representations* mean depends on what *people* mean by using them. This suggests that the primary or underived intentionality of mental states and events is a very special feature indeed—the source of all meaning in the world. On this view, sentences, pictures, diagrams, and the like are in effect prosthetic extensions of the minds of those who use them, having no intrinsic meaning but only the meaning they derive from their utilization.

With regard to conventional representational artefacts, this is surely a plausible view; but it is not so plausible to claim that *all* intentionality is either the underived intentionality of (purely) mental phenomena or the derived intentionality of such artefacts. An exposed cliff face might be said by a geologist to store information *about* the Triassic period; impulse trains in nerve bundles might be said by a neuroscientist to carry information *about* state changes in the inner ear. How is this sort of aboutness related to the aboutness discussed by philosophers under the rubric of intentionality? It is tempting to suppose that some concept of *information* underlies all these phenomena, and could serve eventually to unify mind, matter, and meaning in a single theory.

Identifying intentionality with aboutness nicely locates the concept, but hardly clarifies it, for the ordinary word 'about' is perplexing on its own. A belief can be about Paris, but a belief can also apparently be about phlogiston—and there is no phlogiston for it to be about. This curious fact, the possible nonexistence of the *object* of an intentional item, may seem to be an idle puzzle, but in fact it has proved extraordinarily resistant to either solution or dismissal. Brentano called this the *intentional inexistence* of the intentional objects of mental states and events, and it has many manifestations. I cannot want without wanting something, but what I want need not exist for me to want it. It can be true that I now want a twoton diamond even if there is not now and never has been or will be such a thing. People have believed in Poseidon, and children often believe in Santa Claus, and while in one sense we can say these believers all believe in nothing, their beliefs are quite different states of mind—they have different *objects*—and both are to be distinguished from the state of mind of the sceptic or agnostic who can be said in quite a different sense to believe in nothing.

It might seem that there is a simple and straightforward solution to these problems: although Poseidon does not exist, an idea of Poseidon surely exists in each of the believers' minds, and this idea is the object of their belief. This will not do, however, for it is one thing to believe in the existence of the *idea* of Poseidon—we can all believe in the existence of that mental item—and quite another to believe in Poseidon. Similarly, what I might want could hardly be the idea in my mind of a twoton diamond, for that is something I already have. Moreover, when, as normally happens, the object of an intentional state does exist—for example, when I believe that London is crowded—that very object, London, the city itself and not my idea of it in my mind, is what my belief is about.

The relation, then, between a state of mind—or for that matter a sentence or picture—and its intentional object or objects is a very peculiar relation in three ways.

First, for ordinary relations, like *x is sitting on y* or *x is employed by y*, *x* and *y* are identifiable entities quite apart from whether they happen to be thus related to each other. The thing which is *x* would be the same *x* whether or not it were sitting on *y* or employed by *y*. But the same is not true of intentional 'relations'. One and the same belief cannot at one moment be about a frog (that it is green, say) and at another moment be about a house (that *it* is green). The latter is a *different* belief.

What a belief is supposed to be about is crucial to which belief it is.

Second, for ordinary relations, each of the things related must exist (or have existed); but, as we have seen, intentional 'relations' can be to nonexistents.

Third, ordinary relations obtain between things regardless of how they might be specified. If I am sitting next to Jones and Jones is the Mad Strangler, then it follows that I am sitting next to the Mad Strangler, whatever anybody may think. But if I believe that Jones is harmless, or hope that he will marry my sister, it does not at all follow that I believe that the Mad Strangler is harmless or hope that the Mad Strangler will marry my sister. Even if one is tempted to object that in this case *in one sense* I do hope the Mad Strangler will marry her, there is clearly another sense in which I *might* hope this and *don't*.

For these reasons the normal logic of relations cannot accommodate the presumed relation between an intentional state and its intentional object or objects, but it has also not proved comfortable for theorists to deny on these grounds that there are such things as intentional relations—to hold that mental states, for instance, are only *apparently* relational. This, then, is the unsolved problem of intentionality.

Faced with this problem, the AngloAmerican tradition, characteristically, has tended to favour a tactical retreat, to a logical analysis of the language we use to talk about intentional states, events, and other items. This move, from the direct analysis of the phenomena to the analysis of our ways of talking about the phenomena, has been aptly called 'semantic ascent' by Quine, and its immediate advantages are twofold. First, we set aside epistemological and metaphysical distractions such as:

'How can we ever know another person's mental state anyway?' and 'Are mental states a variety of *physical* state, or are they somehow *immaterial* or *spiritual*? '.

The *things people say* about mental states are in any event out in the public world where we can get at them and study them directly. Second, switching to language puts at our disposal a number of sophisticated techniques and theories developed by philosophers, logicians, and linguists. Semantic ascent is not guaranteed to solve any problems, of course, but it may permit them to be reformulated in ways more accessible to ultimate solution.

In its new guise, the problem of intentionality concerns the semantics of the so-called *intentional idioms*—'*...believes that p*', '*... desires that q*', '*... dreams that r*', etc. (where *p*, *q*, and *r* are replaced by clauses, such as 'frogs are green' or 'Labour is returned to power'. Linguistically and logically, intentional idioms are a subset of those that Quine calls 'referentially opaque'. What this means is that many normally valid logical moves are not valid for the clauses 'within the scope' of intentional idioms. For instance, normally, if two words happen to be words for the same thing, then one can freely substitute one for the other without affecting the *truth* of the whole sentence (although one may change its meaning, or effectiveness, or style). Thus, since 'Cicero' and 'Tully' are names for the same man, from the truth of 'Cicero was an orator' we can infer the truth of 'Tully was an orator'. By contrast, however, the same substitution is not always allowable in 'Tom believes that Cicero denounced Catiline', for Tom may believe that Cicero denounced Catiline but not believe that Tully did. So '*... believes that p*' is an opaque idiom.

Clearly this is just another (and more precise) way of putting the point made earlier, that intentional relations depend on how their objects are specified. The other points have analogues too. Thus, normally, a relational statement is false if one of the alleged *relata* doesn't exist; not so within the scope of opaque idioms. And, of course, the fact that the identity of a particular belief depends on the object or objects it is supposed to be about, emerges on this treatment as the fact that the ascription of a particular belief depends crucially on the words used in the clause expressing it. We can see now that this condition is essentially the same as the first, and that the second condition (possible nonexistence of the object) is also just a special case of opacity: believing that Santa Claus is

generous and believing that Poseidon is generous are different beliefs, in spite of the fact that 'Santa Claus' and 'Poseidon' refer to 'the same thing', i.e. to nothing.

Seeing this unity in the various conditions of intentionality is one of the benefits of semantic ascent. Another is that it thus provides us with a relatively formal and uncontroversial test for the intentionality of idioms, and hence a test for appeals to intentionality in a theory. This is an interesting test, for theories relying on intentional idioms—such as classical 'rational agent' economics and cognitive psychology—cannot be formulated in any noncontroversial way within standard logic, while it seems that other theories, preeminently in the physical sciences, can be so formulated. The logical oddity of intentional idioms, and their resistance to regimentation, led Quine and several other theorists to declare the bankruptcy of all intentional theories, on grounds of logical incoherence. The only sound alternatives within the social sciences, then, would have to be theories making no appeal to meaning or intentionality at all: purely*behaviouristic or purely physiological theories. This claim strikes a familiar note: many psychologists and brain scientists have expressed great scepticism about the utility or permissibility of 'mentalistic' formulations in their fields—while others of course have held them to be indispensable. The philosophical analysis of intentionality yields a clear logical characterization of this fundamental theoretical division in the social sciences and biology: 'mentalistic' theories are all and only those making ineliminable use of intentional idioms, and hence inheriting the *logical* problems of construing those idioms coherently.

Dispensing with intentional theories is not an attractive option, however, for the abstemious behaviourisms and physiological theories so far proposed have signally failed to exhibit the predictive and explanatory power needed to account for the intelligent activities of human beings and other animals. A close examination of the most powerful of these theories reveals intentional idioms inexorably creeping in—for instance in the definition of the stimulus as the 'perceived' stimulus and the response as the 'intended' effect, or in the reliance on the imputation of 'informationbearing' properties to physiological constructs. Moreover, the apparent soundness of informationprocessing theories, and their utility in practice, has strengthened the conviction that somehow we *must* be able to make sense of the ineliminable intentional

Page 386

formulations they contain without compromising thoroughgoing materialism.

One avenue currently being explored apparently challenges the thesis that the intentionality of linguistic entities is derivative, and, turning that idea on its head, attempts to explain the intentionality of minds by analysing minds as systems of 'mental representations'; our thoughts and beliefs exhibit intentionality *because* they are couched somehow in a 'language of thought' physically embodied in our brains. The intentionality of 'expressions' in the language of thought is held to be primary—the intentionality of expressions in natural language, for instance, is supposed to be derived from it—but the hope of this research strategy is that the impressive resources of formal theories of semantics in logic, computation theory, and linguistics can render the puzzles about aboutness more tractable, and lead to their eventual solution in cognitivistic or informationtheoretic theories of the mind. If, for instance, the *theory of reference* for expressions in *public* (natural or formal) languages can be

exploited to produce a theory of reference for expressions in the language of thought, the problem of what mental states are about might be solved.

It is far from clear, however, that this is not a fundamental error, leading, for instance, to a vicious regress of languages and languageusers within the mind or brain, in spite of the beguiling constructions already devised and to some degree tested by the enthusiasts of this persuasion. It is too early to say, then, whether the semantic ascent of the analytic tradition in philosophy, and its ideological cousin, cognitive or computational psychology, will provide more durable solutions to the problems of intentionality than the more frankly metaphysical investigations of the phenomenologists.

INTENTION TREMOR. A neurological term meaning an increase in tremor, especially of the arms and hands, when close to picking up or manipulating objects. It is associated with various neurological disturbances, and is probably due (in engineering terms) to increasing the gain of the servocontrol systems of the limbs, mediated by the gammaefferent system: a small error in position (for example, when picking something up with the hand) produces an overcorrection so that the hand overshoots; this is overcorrected in its turn to produce an oscillation, or tremor. It is common, though not inevitable, in*Parkinson's disease.

INTERACTIONAL APPROACH. Experiments in psychological laboratories tend to study correlations between stimulus variables and response variables.

Responses are regarded as reactions to, and dependent upon, stimuli, which are independent, whether they are manipulated by the experimenter or not. This model proved too simple when, during the Second World War, psychologists took up the study of performance on skilled tasks. In such tasks, stimuli are not independent of responses. What the operator does, decides in part what happens next, and what stimuli then impinge on him. Outside the laboratory, stimuli often depend on what responses have been made. For instance, a person who reacts to a fall in room temperature by turning on a heater, changes the stimulus situation.

One of the first to point out that in skilled tasks human operator and machine form an interacting 'control system' was Kenneth* Craik, one of the most brilliant of F.

C.*Bartlett's pupils. In papers written in 1945, Craik described the operator as behaving as an 'intermittent correction servomechanism'. Deviation in the display of the machine evokes corrective responses, and hence a change in display and further responses. The general effect of a sequence of responses is to regulate and to restore or maintain a steady state or*homeostasis, just as a person's intermittent responses to changes in room temperature tend to be thermostatic.

Craik's work anticipated the development of a new branch of science, to which Norbert*Wiener in 1947 gave the name*cybernetics, the Greek root of which means to steer or govern. Cybernetics, now defined as the science of control and communication in animals and machines, is concerned with*feedback processes. A response—the motor output—produces feedback of two kinds: internal, due to kinaesthetic and other stimuli from the operator himself, and external, from the changes produced in the machine.

Concepts derived from cybernetics, and the related and more comprehensive general system theory, have pervaded the study of social behaviour, which is made up of the responses of individuals to one another. The responses of one provide the external feedback of the other—that is, the behaviour of one controls, and is controlled by, the behaviour of the other. When this is so, the two form a 'system', by which is meant an organization of two or more units, i.e. persons, who interact with one another in a more or less consistent way. A system is typically open, i.e. it forms part of one or more larger systems. A couple such as a husband

and wife belong usually to the larger systems of a family and of a community.

Interaction between one person and another is made up of responses which are 'messages', i.e. items of communication. Messages, which may be verbal or nonverbal, convey information and feelings more or less openly. At one extreme are the peculiar, idiosyncratic messages which represent the symptoms of mental illness, and which convey information and feelings in paradoxical, disguised, or metaphorical terms. Messages provide feedback, which is *negative* when they preserve the relationship between two people. If the feedback is *positive*, a vicious circle is initiated, action and reaction then intensifying one another; this is usually referred to as

'escalation'. An angry reaction to anger—positive feedback—leads to escalation. Breakdown in the relationship is then averted if other regulatory mechanisms are brought into operation. A conciliatory

reaction, on the other hand—negative feedback—restores the relationship.

The relationship between two people, which is based on the assumptions they make about each other, and hence their expectations of each other, tends to be stable, despite changing circumstances, because of the homeostatic tendencies shown by systems. Homeostasis may fail, and the system break down, when an event occurs of special significance or force. There is then a crisis, or turningpoint. The relationship between a husband and wife may come to a crisis when the moving away or death of the wife's mother brings a structural change in the system, or when the discovery of the infidelity of one makes it necessary for each to revise assumptions about, and expectations of, the other.

The interactional approach supposes that mental illness arises out of a crisis in a significant relationship. The symptoms of the illness—the messages sent from one to the other—reflect either the instability before the relationship is restored, i.e. the system is reorganized, or the impasse when the relationship has become stabilized on terms which involve the disabling of one or both. The psychotherapist, who serves as a third party, mediates in order to bring about a reorganization of the system and the restoration of the relationship on terms more satisfactory than before. A crucial point in the interactional approach is the recognition that the behaviour of one person cannot be modified without concomitant changes in the behaviour of the other or others related to him.

INTERNAL MODELS. This term was coined by the Cambridge psychologist Kenneth* Craik, in his important book *The Nature of Explanation* (1943). Internal models are the supposed brain representations of reality (or imagination) as accepted for perception and for setting behaviour appropriate to the world. Craik thought of internal models as analogue representations—similar to F. C.*Bartlett's 'schemas', and Donald Hebb's 'phase sequences'. His notion was an important break from the prevailing emphasis on stimulusresponse mechanisms of behaviour: it was a step towards psychological accounts based on the importance of stored knowledge;

and it drew attention to the importance of control engineering, and later, computers, for understanding brain function. Craik wrote when analogue computers were in vogue, and just before the impact of*digital computing. His internal models are analogues rather than digital programs and so are rather inflexible and not explicitly formulated.

INTERSENSORY COORDINATION. See SPATIAL COORDINATION OF THE SENSES.

INTERVIEWS. People seek interviews with their bank manager or their doctor, they are interviewed for a job or for promotion, and at work they may have an annual 'appraisal interview'. Some are interviewed as they apply for social security or other benefits, and others may be interviewed by a journalist or a market researcher.

These different encounters all have as defining characteristics a certain formality and an asymmetry. Participants' roles are specified, in that one person is the interviewer and the other is the interviewee (although in practice more than two people may be involved) and each has a fairly clear idea of the type of behaviour which is expected. The objective is for the interviewer to obtain and interpret information from the interviewee in order to make a decision or take some action.

Let us look particularly at interviews in personnel selection, where an official of an organization has to decide which candidate to select for a job from among a number of applicants. Such interviews are often criticized on the grounds that different interviewers can reach different conclusions about the same candidate, and a number of experiments have examined the ways in which interviewers can be 'calibrated' so that they reliably form similar impressions. One approach has varied the degree of structure imposed upon the interview, in terms of the requirement to obtain certain kinds of information and to draw inferences only about prespecified attributes or likely behaviours. Results indicate that increased structure yields

Page 388

significantly greater uniformity between interviewers. Similar outcomes can be achieved through training schemes which aim to make interviewers aware of possible biases and which stress the need to identify goals and important issues in advance. For example, the 'sevenpoint plan' encourages interviewers to define job requirements carefully and to obtain information about candidates in terms of physique, intelligence, aptitude, attainments, interests, disposition, and circumstances.

Although reliability can be enhanced in these ways, there remains the question whether interviewers can validly predict subsequent work behaviour. A major research problem is the difficulty of establishing acceptable measures of 'good' or 'bad' behaviour in an occupational role. Limited measures of skilled performance or of output levels may be available for some manual jobs, but professional and managerial work is much less open to quantification; and it is in those areas that interviews are particularly widespread. This problem, of adequately measuring the behaviour we

wish to predict, is endemic in all areas of personnel selection, and is often referred to as 'the criterion problem'.

However, despite the commonly expressed doubts, selection interviews are here to stay, if for no other reason than that they provide an opportunity for the candidate to ask his own questions and to reach his own conclusions about a potential employer. The interpersonal processes at work during an interview are subtle, complex, and fascinating. Consider the ways in which an interviewer will search for and integrate information about the applicant. Research has established clearly that people form impressions of each other through the application of previously established expectancies or 'inference rules'. Evidence that a person has a certain characteristic (anxiousness in the interview situation, for example) sets up a network of inferences about other characteristics. These networks are sometimes referred to as 'implicit theories of personality', and perceivers apply their own implicit theories to even the most limited pieces of evidence. Indeed, some people take pride in 'summing him up as soon as he comes through the door', whereas others may devote their energies to fighting a similar form of stereotyped perception, where extensive inferences are drawn from single cues such as 'black', 'female', or 'handicapped'. In general terms, manifested features have been found to make their greatest impact during short encounters, when other evidence is meagre. Thus many perceivers initially take the wearing of spectacles to imply intelligence and thoughtfulness (cf. HALO

EFFECT). Conventional wisdom has it that 'first impressions count', and research has looked in detail at this question. It seems that the initial impression is tested through subsequent investigation. However, there is often a predisposition in an interviewer to obtain *negative* information, material which suggests that the candidate should not be selected. This is understandable in the light of the interviewer's regular need to reject most of the applicants, but it is important for the 'first impressions count' thesis. This needs to be refined to suggest that an early negative impression is readily reached and is difficult to change, whereas an early positive impression is less easily made and is liable to be overridden if negative evidence becomes available subsequently.

One interesting research finding bears upon this issue. There is typically a significant positive correlation between the proportion of time during which the *interviewer* talks and the probability that a candidate will be offered the job. This may be interpreted in terms of an early implicit decision by an interviewer which tends to make later questioning redundant and perhaps suggests that the desirable candidate should be encouraged through conversation to maintain his interest in the vacancy.

The skills of interviewing extend to coordinating the interaction through verbal and nonverbal cues at the same time as gaining and integrating a variety of items of information. Recent research has placed emphasis on the nonverbal cues which contribute to impression formation and management: they may be relatively unchanging—as with general appearance, clothes,*facial expression, and so on—or they may be dynamic—as in*eye contact, bodily movements, or loudness of speech.

How can people learn to be good interviewers? We all have relevant experience, talking with and acquiring information from others, and there is a tendency to feel that we are quite competent. But experience without detailed feedback is often of limited value: we need to learn with some precision

about the effects of our actions and impressions so that we can improve upon them. This requirement has been the basis of recent experiments in interviewer training, and powerful procedures are now available. These have as their core the use of feedback about performance, often through the replay of videotaped practice sessions. In this way, trainees are able to chart and improve their performance over a series of practice interviews, assisted both by their tutors and their fellow trainees. Behaviour category systems are often applied to generate profiles of an interviewer's style in a way which points up strong and weak points, providing in a striking manner the feedback which is necessary for learning.

INTROSPECTION. Looking into one's own mind. Used as a psychological technique it has great dangers of misinterpretation, even though introspections may seem to provide the most direct

Page 389

knowledge of ourselves that we have. It has, however, become clear that very little that goes on in the brain associated with the mind is accessible to conscious introspection, and we regard the mind as a much broader concept than awareness, consciousness, or what is known by introspection.

INTROVERSION. See EXTRAVERSION—INTRO

VERSION.

INTUITION. This is, essentially, arriving at decisions or conclusions without explicit or conscious processes of reasoned thinking. It is sometimes thought that intuitions are reliable; and indeed we do act most of the time without knowing why or what our reasons may be. It is certainly rare to set out an argument in formal terms, and go through the steps as prescribed by logicians. In this sense, almost all judgements and behaviour are 'intuitive'.

The term is used in philosophy to denote the alleged power of the mind to perceive or 'see' certain self-evident truths (Latin *intueor*, to see). The status of intuition has, however, declined over the last century, perhaps with the increasing emphasis on formal logic and explicit data and assumptions of science.

'Woman's intuition' is, perhaps, largely the subtle use of almost subliminal cues in social situations from gestures, casual remarks, and knowledge of behaviour patterns and motives. Psychologists find

these important matters for living almost impossible to formulate.

INVENTION. Inventions may be old ideas or techniques applied in new ways: they are very often combinations of old, and even highly familiar, ideas. To some degree almost all human behaviour is inventive, for it is seldom strictly repetitive and is aimed at contingencies which, though small and trivial, nevertheless require invention even if of a humble kind. The outstanding inventions, such as the phonograph of Thomas Alva Edison, represent the extension of abilities to some degree possessed by us all. Edison had remarkable perseverance towards imaginative goals; indeed he described invention as '99 per cent perspiration and 1 per cent inspiration'. The motivations, methods, and travails of inventors are described with case histories in *The Sources of Invention*, by J. Jewkes, David Sawers, and R.

Stillerman (1958).

INVERTEBRATE LEARNING AND INTELLIGENCE. There are some signals to which an animal must respond, if it is to remain alive. It must pull back if it is hurt, and it must respond to extremes of hunger or thirst, heat or cold. One might add that it must, sooner or later, respond to the opposite sex and reproduce if the species is to survive.

Response to all other signals is optional. The fact that animals respond to a much wider range of events than those that immediately affect their physical wellbeing is a reflection of the nonrandom nature of the natural world. Stimuli of whatever sort may have predictive value, and a creature that responds appropriately can often avoid future unpleasantness and ensure the regular enjoyment of the better things in life, to the immediate benefit of itself and the ultimate survival of its species.

Learning is largely concerned with establishing the predictive value of stimuli that do not of themselves demand responses. We recognize other animals as intelligent when they predict effectively from these stimuli, and as highly intelligent when they begin to predict by analogy, generalizing to the point where they can take appropriate preemptive action without prior experience of the particular sequence of events to which they are reacting.

All invertebrate animals learn, many show glimmerings of intelligence, and some would qualify as highly intelligent by the definitions employed above. A major problem, as we shall see below, is that we are often ourselves insufficiently intelligent to devise situations that will fairly test their performance. This problem becomes particularly acute when an invertebrate is making an elaborate response in an apparently complex situation, so it is perhaps most appropriate to begin by considering 'simple' forms of learning in which it does seem to be possible (i) to define the stimuli to which the animals are responding and (ii) to recognize the likely advantage of the behaviour in question.

One such category is *habituation*. Animals, in general, soon cease to respond to stimuli that prove to have no predictive value. A shadow passes. It could signal the approach of a wouldbe predator. In the past, individuals that played safe and ducked, or froze, lived to breed. Their offspring are liable to do the same; caution is genetically determined, natural selection having eliminated the unwary over countless generations in the past history of the species. But a shadow is not invariably dangerous. It

may signal no more than a passing cloud, or the waving of a frond of seaweed. An animal that reacts to every moving shadow is doomed to a restless and economically hopeless existence, and cannot effectively compete with its less wary neighbours; in the long run the overcautious are eliminated as surely as the foolhardy. Animals must habituate if they are to remain in business, and the best assumption with which genetics can equip them is that the immediate future is likely to resemble the immediate past. If a stimulus recurs regularly, unaccompanied by consequences of importance to the animal, it is well to ignore it. Rates of habituation vary, as we might expect, because the degree of builtin caution will vary from one sort of stimulus to the next; but caution is always present.

In an opposite direction, we find that nearly all animals will *sensitize*, becoming more rather than less responsive in circumstances where anything

Page 390

that happens *is* likely to have predictive value. If recent experience has revealed that something of importance is going on, it is well for the animal to remain more than usually alert, so that it responds to stimuli that it might otherwise have ignored. An animal that has just been hurt will flinch at stimuli that have nothing to do with the damage, and an animal that has just engulfed a tasty mouthful is more than usually attentive; any event could be a signal that more of the same is in the offing. It should be noticed that such effects can be quite unspecific: if things are going badly for the animal it will sensitize in the direction of caution, and take no chances over stimuli that would normally evoke a positive reaction; and if events are proving favourable, it becomes particularly responsive to stimuli that may indicate desirable objectives, like food, or sex. The animal, in either case, is responding to the sum of events (good and bad) in its recent past, and adjusting its response levels accordingly.

Taken together, habituation and sensitization will ensure that an animal behaves economically and opportunistically, cashing in when the going is good and lying low when conditions are unfavourable. The two interact: *dishabituation*, where a sudden change in circumstances reestablishes responses to a repeated stimulus that the animal has come to ignore, is a special case of sensitization. Between them the twin processes of habituation and sensitization will ensure betterthaneven odds on an animal's responding appropriately, even under conditions where the creature is quite incapable of determining the precise nature of the stimulus to which it is responding. The system works, provided only that events occur in a nonrandom sequence—provided, in short, that the future is likely to resemble the recent past.

Inside the laboratory it may, for various reasons, be desirable to randomize trial sequences so that an animal cannot predict what is going to happen without precise identification of the stimuli offered to it, but in the wild the animal is never likely to encounter a random sequence of events. Predators hang about, or go away; food comes in patches, scattered in time and space but never quite at random.

It is relevant to an understanding of invertebrate learning and behaviour to realize that coldblooded animals in general can afford to be opportunists to an extent unthinkable in a homoiotherm. We poor warmblooded creatures consume fuel so fast that we tend to discuss motivation in terms of imperatives: hunger must be satisfied or we die. We get thirsty because we live above the temperature of our surroundings and evaporate our body water; the need to replenish the water becomes an imperative because we overheat and die if we fail to do so. This personal experience distorts our

thinking about invertebrates; we tend to assume that a starved snail or a thirsty cockroach will take risks to satisfy its needs as we would, becoming increasingly desperate as time passes. There is no evidence for this, at least on the sort of timescales that one would expect from an experience of rats and people. A fed octopus is more, rather than less, liable to attack a strange but potentially edible object lowered into its tank; it cashes in while the going is good, and can starve for weeks if conditions suggest that it is unprofitable or even dangerous to respond to the unfamiliar. Sensitization is relatively unimportant in ourselves, because we can rarely afford to accept its dictates for very long; invertebrates can lie low for months, then stuff themselves, mate, and multiply when conditions improve.

One consequence of this is that it may be difficult to investigate invertebrate learning by conventional methods, forcing the animal to become active and solve problems because it is hungry or thirsty.

A further difficulty that confronts any biologist rash enough to examine learning in the lower animals is that most of them depend predominantly upon chemical stimuli, which we find awkward to classify and almost impossible to measure in the laboratory, let alone in the wild. Experimenters tend, in consequence, to set problems based on visual and spatial cues, so that their unfortunate subjects are more often than not tested with learning problems based on our sensory capabilities rather than theirs, a situation that can only lead to persistent underestimation of their learning abilities.

At a somewhat more subtle level, it is easy to forget that the bodily construction of animals may itself preclude certain forms of learning. Many of the things that we do, and believe simple, are based on an awareness of bodily position that is probably lacking in most invertebrates. When we move, we know how the position of our limbs is changing. If I pick up and examine an object, I am continually moving my fingers; each time I change my grip I know about the new positions adopted and, putting this information together with the feel of the contacts made, I can build up a mental picture of the shape of the thing I am holding. An octopus, for example, apparently cannot. It is quite as capable as I am of feeling over an object that it touches, and there is no doubt whatever that the animal can learn by touch, since it can be taught by simple reward and punishment techniques to distinguish between a wide variety of different textures and tastes (chemoreception again!), learning to perform such discriminations with great accuracy after a dozen or so trials. But it cannot manage shapes. A cube and a sphere are alike to it, apparently because the animal has no means of assessing the relative positions of its equivalent of our fingers, the many suckers arrayed along its flexible arms.

On reflection this is perhaps not very surprising. It is the animal's very flexibility that defeats it. We can compute the precise position of our hands because the human body only bends in a few places and is even there restricted to movement in a few directions. Sense organs in and around our joints can tell us about the angle adopted at each. No such

easy computation is possible in a softbodied animal, where the position of each part depends upon the degree of contraction or relaxation of muscles all over the rest of the body. Muscle stretch receptors, which all have, are useless in this respect since they can only signal tension in the muscle concerned,

not the position achieved as a result. The jointless animal perforce lacks any equivalent of our proprioceptive sense of position.

This divides the animal kingdom rather abruptly into two groups. On the one hand there are the jointed animals, the vertebrates and the arthropods, which seem to have a double (muscle and joint) set of proprioceptors. These creatures are potentially able to learn to manipulate; they can discover by trial and error precisely which movements it pays to repeat; they can monitor the number of steps they have taken and the angle of any turns that they have made. On the other hand there is the world of the softbodied, forever debarred from learning to make skilled movements, and faced with learning to find their way about entirely from exteroceptive cues.

Arthropods, like vertebrates, can readily learn to run mazes, while many of the other things that they do or make (such as honeycombs and spiders' webs) necessitate accurate measurement of lengths and angles. A hermit crab, investigating the inside of an empty shell with its claw, plainly learns about the size and the shape of the hole he is examining before risking exposure of his soft abdomen as he quits his old home in favour of the new. In marked contrast to all this, the softbodied snails and worms (and octopuses) rarely succeed in mastering any maze more complex than a T or Y, they never seem to create patterned structures, and they never, so far as we can assess the matter, learn to carry out a skilled movement. As a result we tend to assess their learning capabilities and their intelligence generally as exceedingly limited compared with arthropods and our fellow vertebrates, which find easy the same sorts of tasks as we do ourselves. It may well be, indeed it seems very likely, that the individual adaptive capacity of worms and snails *is* very limited; but it is well to remember that most of our present evidence comes from tests appropriate to ourselves rather than the creatures we have studied.

Granted, then, that we are almost certainly underestimating the capacities of most invertebrate animals, what generalities can be made in comparing higher forms of learning in vertebrates and invertebrates? Can we, for example, detect signs of *latent learning* ('the association of indifferent stimuli in situations without patent reward') or *insight learning* ('the production of a new adaptive response as a result of the apprehension of relations') among invertebrates, as we can among the higher vertebrates?

The answer appears to be 'yes', if one searches. Many invertebrates, inevitably, show little sign of these more complex forms of learning. Any animal that lives a highly specialized existence (an aphid on a rosebush or a lugworm in the mud of a saltmarsh) is unlikely to show conspicuous signs of intelligence. It does not need to: the same very limited range of problems have cropped up generation after generation for so long that almost the totality of its behaviour has come to be programmed genetically. Wherever this is possible, because the future has always rather precisely resembled the past, learning, with its inherent capacity for errors that could be dangerous or even fatal, is plainly a luxury that will be eliminated in the course of natural selection.

To discover what invertebrates can really do, one is obliged to examine cases where the animals live in complex environments. In general, also, it is necessary to look at predators, because predators must always be a little brighter than the prey they feed upon. Two such animals will be considered below,

one softbodied (a cephalopod, of course), the other a jointed animal, an insect.

The octopus can be taught to make a wide variety of visual and tactile discriminations in the laboratory and it learns rapidly in these trial-and-error situations. It is also plain, from its lifestyle in the sea (where it returns to a home in the rocks after foraging expeditions that may carry it quite far afield) that it is capable of learning its way about a complex landscape, despite the restrictions already considered in relation to the consequences of flexibility. Observations of octopuses in the sea suggest that they can return home from any point in their range without retracing their outgoing steps, and this suggests a capacity for latent learning. In the laboratory octopuses will readily make detours to get at prey that they cannot approach directly; in a typical apparatus the animal was obliged to run out of sight of a crab, down an opaque corridor, and turn appropriately to reach its food. Even untrained octopuses manage this quite readily and will reach their goal with considerable reliability even if delayed for a minute or more by shutting them into the corridor. Plainly the animals are in some manner aware of the spatial relations of the crab and the various baffles that prevent them from reaching it—they show *insight*. (It is surprising how few vertebrates will detour successfully in similar circumstances.) Performances that are in some ways even more impressive are shown by some of the hunting wasps. *Ammophila*, for example, hunts, paralyses, and stores caterpillars. Each mated female operates alone. She digs a hole in sand, covers it over, and after a brief orientation flight in the vicinity of the nest, departs to search for caterpillars. A caterpillar is paralysed by a sting in the central nervous system and is thus preserved as a living food supply for the egg, which is subsequently deposited with it in the hole that the wasp has dug. The wasp's first problem, however, is to get the caterpillar home. Often the prey is too heavy to fly with, and the wasp sets off to drag it, often for many tens of metres, across the ground and round obstacles to the nest site. This performance is in Page 392

itself remarkable because it implies a considerable knowledge of the geography of the district round the nest, apparently derived from the brief orientation flight carded out before setting out to hunt down a caterpillar—another nice example of latent learning. Extensive tests show that the cues used are entirely visual and more often than not precisely the sort of landmarks, skyline patterns and the like, that we would choose in the same circumstances.

More impressive still, however, is the discovery that *Ammophila* will run as many as three nests, in different stages of construction, at one and the same time. After the first egg and caterpillar have been deposited, she begins and provisions a new nest. A day or two later she returns to the first nest, checks whether the egg has hatched, and if it has, begins to stuff further caterpillars down the hole to feed her grub. Any spare time is spent digging out nest three, with a visit to nest two after a couple of days to see whether that egg has now begun to develop. Quite clearly the wasp not only remembers the precise position of each separate hole, but also recalls the state of play at each site, often delaying the response that she makes as a result of an inspection visit for two or three days on end.

Performances like those of *Ammophila* and the octopus leave no reason to doubt that learning by invertebrate animals can be every bit as complex as that found in vertebrates, which have been far more extensively studied. Whether one regards such creatures as 'intelligent' is largely a matter of taste, that is to say the precise definition of that somewhat elusive property one chooses to employ.

We have come a long way from the proposition that the lower forms of life are automata, bereft of the ability to adapt and determine their individual destinies.

INVOLUNTARY NERVOUS SYSTEM. See NERVOUS. SYSTEM.

IRIS. The coloured (usually blue or brown in man) ring round the pupil of the eye. It closes in bright light, and opens in dim light as a result of the action of light on the retina—including a reflex from one eye to the other. The small pupil in bright light reduces the optical aberrations of the eye, and gives maximal depth of field (focus over a wide range of distances). These qualities are sacrificed in dim light to give greater lightgathering power. Albinos, who lack pigment in their irises, have severe visual problems.

In mammals, the pupil is controlled involuntarily, with 'smooth' muscles, by the autonomic nervous system. In birds this is quite different: the pupils of their eyes are controlled by striate muscle and at least in some parrots the pupils respond to their level of arousal. Remarkably, the pupils of talking parrots open and close in apparent relation to their attention when producing, or listening to, sounds meaningful for them. The human pupil is affected, though far less markedly than the parrot's, by emotional changes, increasing in size with autonomic emotional arousal.

IRRADIATION. In vision, the apparently greater size of a white area than a corresponding darker area. Described in detail by*Helmholtz, it is still not fully understood.

IRRITABILITY. As a technical term in biology, the triggering of responses from small stimuli, such as gentle*touch. It is a defining property of living organisms—as through their 'irritability' they do not obey Newtonian mechanics—for they are active and wholly or partly autonomous, in a way that nonliving objects (apart perhaps from some machines) are not.

ISLAMIC PHILOSOPHY. A traditional occidental theme is that the thinkers of Islam were mere synthesizers of Greek and other traditions (such as those Of India and Persia) and made no original contribution to human thought. This simplistic view originates with the assumption that such work as that of*Avicenna was the totality of Islam's philosophy: which in turn is understandable when it is realized what a profound effect Avicenna had upon the Schoolmen.

The importance of Avicenna's thought for the West cannot be overestimated. Both in its negative

aspect, such as the necessity of everything, and its more sympathetic notions, it offered a stimulus to the West. It was par *excellence* a combination of Neoplatonism and Aristotle, transforming the One into a first mover from whom all existence ultimately sprang. For Christian thinkers it offered especial attraction in distinguishing God from His creatures in terms of being; in holding essence to be the foundation of all existence; in making the effect dependent for both its being and its movement on what was prior to it; and in regarding all knowledge as the result of illumination (Gordon Left, 1958; pp. 154 f.)

Characteristically, T. P. Hughes's massive *Diction. ary of Islam* of 1885 (1964 edn., p. 452) baldly repeats: 'The whole philosophy of the Arabians was only a form of Aristotelianism tempered more or less with NeoPlatonic conceptions.'

More recently this generalization has been challenged with great vigour by both Muslim and Western scholars.

The Arab conquest and occupation of eastern and western lands from the early eighth century produced intense intellectual activity in centres of learning as widely dispersed as Baghdad and Spain, Bukhara and Egypt. The study and exercise of traditional knowledge were directly linked to the Prophet's dictum, accepted with the force of law:

Page 393

'Seek knowledge even unto China.' During much of the thousand years of the period known as the Dark Ages in Europe, the Islamic centres of learning were major agents for the preservation and transmission of accumulated knowledge; those of Spain especially being a magnet for Christian scholars. 'The Christian West became acquainted with Aristotle by way of Avicenna,*AlFarabi, and Algazel (*AlGhazzali). Gundisalvus' own encyclopaedia of knowledge relies in the main on the information he had drawn from Arabian sources' (Guillaume, 1949; s.v. 'Philosophy and Theology', p. 246).

Many Islamic theorists, including AlGhazzali, were even believed by European scholars of the time to be Christian divines. The widespread belief that the Arabian schools were the great source of wisdom, which arose at this time, was later replaced, particularly in Victorian thought, .by the thesis that they were merely run by copyists of the Greeks. More comprehensive study from a wider perspective has indicated that original contributions began to appear as the period of translation of classics and the absorption of ancient teaching advanced, after the eighth century. Work published during the twentieth century has increasingly asserted unexpected anticipations of relatively modern Western thought by the major Islamic philosophers, especially from the ninth to the fifteenth centuries.

Typically, M. S. Sheikh (1982; x and *passim*) has propounded themes in the systems of AlFarabi, Avicenna, AlGhazzali, Ibn Khaldun, and others as prefigurings of the ideas of*Descartes (methodological doubt and *cogito, ergo sum*) and*Spinoza (*idealism), of Cartesian occasionalism, of*Leibnizian preestablished harmony, of*Kant (antinomies of pure reason and metaphysical agnosticism),*Hegel (panlogism and the notion of the absolute),*Hume (denial of causality),

of Bergson's creative evolutionism, and even of logicism and positivism. The Indian Muslim poet and thinker Sir Muhammad Iqbal (1876-1938) is the best-known Islamic philosopher of modern times.

In the Islamic world, in addition to the many customary preoccupations of philosophy as expressed in logic, ethics, method, knowledge, and political thought, there were also a vast number of exponents and schools of religious philosophy and metaphysics (seen as mysticism). Among the most important were the Islamic theologians and the Sufis. The works of the latter are today increasingly studied by both East and West in newer disciplines such as psychology and sociology.

From the comparative point of view, the picture of the Islamic contribution which emerges indicates the relative freedom of speculation within the culture, as contrasted with the somewhat more restricted categories of the West in the same epoch. This may be because Islam has never had a central ideological disciplinary institution which could succeed in imposing dogmatic authority over large populations for long periods of time, and because the door of reinterpretation of the limits of philosophical speculation has remained open, being the responsibility of the courts, in the absence of a priesthood.

ISOLATION EXPERIMENTS. When people are cut off from communication with other people, or, in even more extreme cases, from almost all sensory stimulation, there is a strong tendency to develop hallucinations and hallucinogenic druglike experiences not altogether dissimilar from those of schizophrenia. There are many accounts of delusions and loss of reality and personal identity in, for example, singlehanded voyages, and many experiments have been conducted in isolation chambers in which subjects have only diffused lighting and a minimum of auditory or tactile stimulation. Many

of these experiments have been carried out on students, of an agegroup which is perhaps less stable than later adult life, and the effects may be less for older people; but nevertheless there is good evidence that loss of sensory inputs seems to free the active mind to generate fantasies which may be overwhelming. Also, upon reentering the normal world there may be dramatic visual and other*illusions (which makes these experiments dangerous unless carefully controlled), suggesting that fairly continuous inputs are required to maintain the sensory system in calibration. The results strongly suggest that, for example, space flights should be made by several crew members and not individually, and that there may be isolation problems for divers and others working and living alone (see DIVER PERFORMANCE).

Similar 'principles may apply to all levels of neural activity—hence the beneficial stimulation of companionship and competition in sport and academic activities. There seem to be important implications for education, and generally for a satisfying and productive way of life (the rich introspections of mystics and monks may be due to being cut off from stimulation they see as irrelevant and trivial).

The first experimental studies were by W. H. Bexton, W. Heron, and T. H. Scott in 1954, in Donald Hebb's laboratory at McGill. J. C. Lilly in Page 394

1956 increased the sensory isolation of his subjects by immersing them in a tank of water maintained at body temperature. Apart from a mask which covered the head, they were naked and so deprived of the sensations produced by pressure from clothing. After variable periods of time, thinking became less directed, and was eventually replaced by highly personal fantasies and hallucinations which were usually visual. Subjects were unable to distinguish between sleeping and waking—a finding of some importance as, regardless of the psychological explanations, there is evidence that episodes of microsleep occurred in which there was an early onset of *REM* dreaming sleep*. None the less, hallucinations of a similar kind may be experienced by other persons deprived of sensory stimulation, examples being prisoners in solitary confinement. Although *sensory* isolation may not be a prominent feature, being cut off from normal human intercourse when coupled with a fair measure of intense anxiety seems to produce both real*hallucinations and*pseudohallucinations.

O. L. Z.

ISOMORPHISM. Literally 'equal form'. Used by the Gestalt writers to refer to s??posed electrical brain states, or 'fields', of the ' same shape as perceived objects.

This notion has now been abandoned. See GESTALT THEORY.

ITERATIVE PROCEDURES. A computing term meaning successive approximations to a good, or the best, solution.

Page 395

J

JACKSON, JOHN HUGHLINGS (1835-1911). Widely known as the 'father' of British neurology, he was born in Yorkshire and spent the greatest part of his life in London, where he was for many years consultant physician to the then newly founded National Hospital for Nervous Diseases, Queen Square. His conception of nervous and mental disease, which owed much to the writings of Herbert*Spencer, was formulated in terms of the evolution and dissolution of the nervous system and is perhaps the most thoroughgoing attempt to explain the breakdown of neurological functions along evolutionary lines.

Jackson's most important contributions were to the study of*epilepsy and*aphasia. As regards the former, he was the first to appreciate that the sequence of involuntary movements which characterizes focal epilepsy indicates the spatial layout of excitable loci in the motor cortex. This brilliant inference was confirmed soon after by the experiments of David Ferrier and others, who demonstrated in animals that electrical stimulation of individual cortical loci elicit discrete bodily movements.

Jackson was also the first to describe perceptual illusions and other dreamlike states of consciousness evoked by focal epileptic discharges in the temporal lobes.

These have since been fully studied by Wilder*Penfield.

In his work on aphasia, Jackson laid great stress on the fact that the disorder is an affection of language rather than merely one of speech. In his view, aphasia is essentially an intellectual deficit marked by inability to formulate propositions, rather than by failure to recall individual words. He further pointed out that words or phrases may on occasion be uttered under stress of emotion when they cannot be spoken voluntarily. (See also LINGUISTICS: NEUROPSYCHOLOGY.) Although in agreement with Paul*Broca that aphasia almost invariably results from damage to the left cerebral hemisphere, Jackson suggested that visual and spatial disabilities might bear a comparable relation to the right cerebral hemisphere. Though long ignored, this idea of cerebral asymmetry of function has been widely accepted in contemporary neuropsychology.

Jackson's *Selected Papers* (2 vols, ed. James Taylor, 1931) is an indispensable source of his writings. His papers on aphasia were republished by Sir Henry Head in *Brain* (1915) 38.

O.L.Z.

JAMES, WILLIAM (1842-1910). A towering scholar, talented communicator, individualist, celebrity in his day, and a warmly empathic man who inspired genuine affection and respect. His personal charm shows through his writings, most of which follow closely the spoken lectures he gave to students and intelligent nonspecialists. His greatest work, the two-volume *Principles of Psychology* (1890), is still fresh and informative. Probably the best-known book in all psychology, it is a treasurehouse of ideas and finely turned phrases which psychologists continue to plunder with profit.

James was an American who, for most of his adult life, was associated with Harvard, where he graduated in medicine and taught successively physiology, psychology, and philosophy. He was also

very much a European. He first visited Europe before his second birthday, and almost every year of his life spent some time there, occasionally staying for a year or two at a stretch. He was fluent in German and French, competent in Italian, and personally acquainted with most of the leading intellectuals of his time, ranging from Ralph Waldo Emerson to Sigmund*Freud and Bertrand*Russell. His brother, the novelist Henry James (1843-1916), settled in England, where he, the novelist who wrote like a psychologist, often received William, the psychologist who wrote like a novelist. Both brothers were fascinated by the problem of expressing in words the phenomena of individual consciousness. Henry approached the problem through novels which exhibited the subtle uniqueness and partiality of individual people's perspectives. William approached the problem through psychology.

William was born in New York, the eldest of five children whose education was unconventional. His father, a brilliant conversationalist and writer on theology, enjoyed a large inherited fortune which enabled him to devote his time to travelling, meeting interesting people, and educating his children. Wherever father went, his wife and children went also, accompanied by a variable entourage of relatives, friends, and servants. The children were actively encouraged to absorb their surroundings, talk about their experiences, read, write, and paint. This lively nomadic troupe lodged in hotels and rented houses on both sides of the Atlantic. They everlastingly engaged in wideranging, self-analytic discussions which, often shared by visiting celebrities, dominated Jamesian life and education.

William was educated by shortstay tutors and brief attendances at private schools, but mainly by his father and family. The upshot was that he developed a formidably heterogeneous repertoire

Page 396

of academic, social, linguistic, and artistic talents. Between the ages of 18 and 30 he continued further studies and intensive programmes of private reading. He also became increasingly perturbed about what to do with his life. He was torn among so many possibilities. He suffered bouts of depression and neurotic malady, and family letters spoke of his 'ill health', 'the choice of a profession', and 'the awful responsibility of such a choice'.

At 18 he started training as a painter. He later switched to the study of science, then to medicine. Even after deciding on medicine he had doubts, and interrupted his studies to go on a geological expedition to Brazil and, again, to spend a year in Germany. He travelled in Europe in 1867-8, graduated MD from Harvard in 1869, and thereafter entered a period of black despair and took a decisive step toward resolving his existential crisis. This step averted suicide and began to heal what he later called his 'sick soul'; it also contained themes which he explored for the rest of his life and which dominated his mature work. On 30 April 1870, he wrote as follows in his private diary.

Yesterday was a crisis in my life. I finished the first part of Renouvier's 2nd Essay and saw no reason why his definition of free will—'the sustaining of a thought *because I choose to* when I might have other thoughts—need be the definition of an illusion. My first act of free will shall be to believe in free will. For the remainder of the year, I will abstain from mere speculation and contemplative *Grubelei* [musing] in which my nature takes most delight, and voluntarily cultivate the feeling of

moral freedom. . . . Today has furnished the exceptionally passionate initiative which Bain posits as needful for the acquisition of habits. . . . Now, I will go a step further with my will, not only act with it, but believe as well;

believe in my individual reality and creative power. My belief to be sure can't be optimistic—but I will posit life, (the real, the good) in the selfgoverning resistance of the ego to the world.

Once his selfadministered, existentialist cure began to work, he returned to Harvard, where he was offered a post as a teacher of physiology. He accepted and, at the age of 30, began his career as a university teacher. In 1878 he married, happily, and subsequently children were born in whom he and his wife took delight. Also in 1878, he contracted to write a book based on the lectures he was giving on psychology. The book took twelve years to write but, when *Principles of Psychology* appeared, it established James as the foremost psychologist of the day. The opening pages plunged into the recurrent Jamesian themes of individuality, *choice, and *purpose. Each of us is, within the limits of our biological potential and environmental circumstances, forever pursuing purposes, longterm and shortterm, by making choices, great and small, which cumulatively shape every aspect of our individual being. As James said elsewhere, 'Sow an action, and you reap a habit; sow a habit, and you reap a character; sow a character, and you reap a destiny.'

These themes ran through all James's work. In *The Varieties of Religious Experience* (1902), he examined the biographies of people who reported a belief 'that there is an unseen order, and that our supreme good lies in harmoniously adjusting ourselves thereto'. Such beliefs were subjective, but none the less real to the experiencer, and they had manifest effects on the individual's conduct. When such effects were 'good', he argued, the individual was fight to exercise the 'will to believe', although not to insist that others share the same belief. James's contributions to the philosophy of pragmatism were in the same vein. In brief, any hypothesis was true if the consequences of holding it were satisfactory to the individual concerned. The truth of which he spoke was not absolute but relative to each individual.

The 'pluralistic and unfinished universe' had undiscovered potentialities which different individuals might make actual through the hypotheses they held, the choices they made, and the purposes they pursued.

Between 1878 and 1899, James vigorously enjoyed work, family life, and social life. He travelled, attended conferences, lectured, kept up a massive correspondence, and took unassuming pleasure in his growing international fame. In 1899 he suffered the first of many attacks of angina, which progressively impeded his vigour even though he still continued a formidable round of activities. On 11 August 1910, he and his wife left Henry James's home at Rye in England and made what William knew to be his last Atlantic crossing. He died in America fifteen days later.

During his life, James fostered much psychological discussion and enquiry; but he was precluded, by his artistic sensitivity to the manysidedness of the human condition, from adopting any one view as final. His popular lectures inspired many people with a new sense of human worth and dignity; but he himself was never entirely free from bouts of depression. In 1875 he established at Harvard a

laboratory for psychological experiment (see LABORATORIES OF PSYCHOLOGY);

but he himself had insufficient patience to conduct experiments, make measurements, or use statistics. He was consistently protean.

His pluralistic vision is evident in the brilliant perceptiveness, intuitiveness, and inconsistency of the *Principles*. The book presents, in mastery language, a wealth of naturalistic observation about human behaviour and conscious experience, culled partly at first hand and partly from wide reading. It contains sharp intellectual analyses in which issues are turned over critically and openmindedly. It makes clear that psychology concerns, and is of concern to, the lives of individual people. It is exploratory, not consistently scientific in spirit, and arrives at no coherent theory of psychology. However, it widens horizons and raises issues that have, in the twentieth century, been approached scientifically. It raises many issues that still challenge scientific enquiry.

JAMI (Mulla Nuruddin 'Abdurrahman ibn Ahmad, 1414/92). Jami, who was born in Jam, Khurasan, and died in Herat, modern Afghanistan, is often called the last great classical poet of the Persian language. He was a most prolific writer and a great scholar, as well as being a mystic of the Naqshbandiyya ('Designers') School of Sufis. For him, God alone is absolute truth, and human duty is to reach this truth through love. In his *Lawa'ih* (Flashes) are the short utterances which encapsulate his teaching, while *Nahfat alUns* (Fragrances of Companionship) is a considerable work treating of the lives of 611 male and female Sufi sages. His *Silsilat al*

Dhahab (Chain of Gold) resembles Sanai's *Walled Garden*, and his *Baharistan* (Land of Spring) may have been suggested by Saadi's *Rose Garden*. In personality he was remarkably straightforward and free from cant, and he expected this behaviour in others: the traditional Naqshbandi attitude. His sense of humour was remarkable. When he was on his deathbed and Koranreaders had been brought in, he exclaimed: 'What is all this commotion—can't you see that I am dying?'

JANET, PIERRE (1859-1947). Pierre Janet must rank with the handful of thinkers, including William*James and Wilhelm*Wundt, who established psychology as a discipline. Yet nowadays in Britain and America he is acknowledged merely as a contributor to early psychiatric studies of*hysteria. Remarkably little is known of his ideas, although many of them have passed into common usage. His systematic theorizing is ignored, and none of the current standard English-language textbooks in experimental, clinical, cognitive, or personality psychology makes more than a passing reference to his work. Even histories of psychology and medicine refer to him only as a 'pupil' of J. M.*Charcot who studied hypnotism in relation to hysterical phenomena (see HYPNOTISM, HISTORY OF). Such accounts fail to recognize Janet's work in many other fields, his encyclopaedic scholarship, his meticulous and subtle clinical observations, his intellectual stature, and the originality of his theorizing.

What went wrong? How is it that a great psychologist, who received international acclaim in his lifetime, should now be virtually ignored by English-speaking psychologists and psychiatrists? There are a number of plausible reasons: his most interesting works have never been translated into English, and several of his major propositions have been misunderstood. It is also generally recognized that his work was overshadowed by the more dramatic and controversial propositions of his contemporary, Sigmund*Freud.

Probably a more important reason is that Janet failed to establish a school of followers who might have propagated and developed his approach. To understand why this was so involves some examination of his career. In one sense, this is a story of sparkling and untrammelled success. But closer consideration suggests that it may be viewed as an interesting case-study in the subtleties of academic and professional power politics. It is also replete with sad ironies. Janet was the product of the reigning intellectual establishment of his youth. But later he was to be the victim of departmental intrigue, as a new establishment took over. Similarly, his early research won him immediate recognition because of its contribution to an area which was preoccupying the thinkers of the time. His later studies far transcended this, but when intellectual fashions changed he was stigmatized as a promulgator of outmoded thought. Lastly, he attained one of the most coveted academic positions in France. But this was destined to cut him off from any academic 'groundroots' constituency.

Pierre Janet was born in Paris, where he was to remain for almost all of his long and active life. He came of an established, upper-middle-class family, his relatives being intellectuals and professional people. Throughout his career he was to maintain close contact with many of the leading intellectuals of metropolitan France. His immediate family was close and affectionate. He married Margaret Duchesne in 1894; they had three children, and remained happily married until Margaret's death in 1944. As a person, Janet was dignified and rather reserved but the possessor of a warm heart and dry wit.

Janet was educated at one of the oldest and most famous *lycées* in France, the Collège Sainte-Barbe. Despite a short depressive breakdown at the age of 15, he was successful in the intensely competitive admission examination for the École Normale Supérieure, which he entered in 1879.

'Normalians' were exempt from military service but were expected to teach for ten years. Thus, after graduating with distinction in 1882, Janet was posted to Châteauroux, but transferred after a few months to the more prestigious *lycée* of Le Havre, where he taught for the next six and a half years.

The person who exerted the most profound influence upon Janet's intellectual development was his uncle, Paul Janet the philosopher, who urged him to combine his study of philosophy with that of science and medicine. Thus Pierre Janet initially considered writing his doctoral thesis on the subject of hallucinations and perceptual mechanisms, and approached Dr Gibert, a local physician and psychiatrist, who was interested in 'animal magnetism' (see MESMERISM) and urged Janet to investigate hypnotic phenomena. He

Page 398

arranged for the young philosophy teacher to study a patient named Léonie, who had been a hypnotic subject in her youth (see also DLSOCIATION OF THE PERSONALITY).

The results of Janet's first series of experiments with Léonie were reported in a paper presented to the new Société de Psychologie Physiologique in Paris in November 1885. The paper was read by Paul Janet, and the meeting chaired by the Society's cofounder, the great Charcot. The findings were reported with admirable scientific caution. But they *could* be taken as evidence for hypnotism from a distance, which Janet deplored. Even so, the paper made a perfect match with the intellectual climate of the time and caused something of a sensation.

For the remainder of his period at Le Havre, Janet continued to study hysterical patients, being given facilities at the city hospital. His investigations were reported in a series of papers which formed the basis of his main doctoral thesis, *L'Automatisme psychologique*. This he successfully defended at the Sorbonne in 1889, and was appointed to a teaching position in Paris. At the same time he enrolled as a medical student, his studies being concurrent with his *lycée* teaching duties and the continuation of his research, much of which was carried out under Charcot's aegis. He graduated with distinction in 1893, and was promptly appointed by Charcot to direct a new experimental psychology laboratory at La Salpêtrière. Unfortunately, Charcot died only a few weeks later, to be succeeded by Fulgine Raymond, a neurologist not personally interested in neuroses, but who nevertheless continued to maintain the psychological laboratory and support Janet's researches. Janet also continued to teach philosophy until 1898, when he was appointed director of studies in experimental psychology at the Sorbonne.

In 1894 Janet published his textbook on philosophy. By the turn of the century he had published papers on a variety of psychological topics, and had established his reputation as a clinical teacher and outstanding expert on the neuroses. By then his interest had shifted from hysterical states to psychasthenia, a term he coined to cover what we would now call*anxiety states,*phobias, and*obsessional disorders. In 1898 he published *Névroses et idées fixes*, to be followed by *Les Obsessions et la psychasthénie* in 1903. Each of these was a massive work in which he developed a

classification of the neuroses, together with an integrative theory which encompassed both hysteria and psychasthenia. These two books introduced, for the first time, terms and concepts such as 'dissociation', and 'narrowing of the field of consciousness', which are now in general use. Janet's distinction between hysteria and psychasthenia was directly responsible for the concepts of extraversion and introversion introduced by C. J.*Jung (who attended Janet's lectures in 19023 and made many references to him). Similarly, Alfred*Adler's emphasis on inferiority feelings was directly derived from Janet's *Sentiment d'incomplétude*.

During this same period, Janet and his young colleague, Georges Dumas, were active in the establishment of a new international psychological society, and in 1904 the two men cofounded the *Journal de psychologie normal et pathologique*. In 1902, on the retirement of Theodule*Ribot, Janet was appointed professor of experimental and comparative psychology at the Collège de France, which he held until his own retirement in 1935. But despite the prestige of this appointment and the popularity of Janet's lectures, this post undoubtedly imposed constraints on his work and influence: Janet had no regular undergraduate or graduate students or research assistants. Furthermore, the Collège had no laboratories or clinics, and he was perforce obliged to rely for his case material on La Salpêtrière. Even this source disappeared when, after Raymond's death in 1910, internal political manoeuvres led to the closure of the psychological laboratory, and with it the termination of Janet's hospital appointment and clinical teaching.

Janet's intellectual activity, however, continued unabated. He now devoted himself to developing a comprehensive psychological system taking account of normal, no less than abnormal, behaviour from childhood to old age. The general idea was that psychological function is hierarchically organized, with neurosis representing a reduction of integration. It was further postulated that optimal functioning requires an appropriate deployment of psychic energy: asthenia is to be regarded as an insufficiency of available 'psychological force', manifested in lassitude and feelings of inadequacy.

Janet then went on to define and analyse a more elaborate developmental hierarchy of increasingly complex levels of organization. At the most primitive level are the

'reflexive tendencies', which are unregulated and stimulusbound. These are followed by 'tendencies' which reflect adaptation of an elementary kind, and these in turn by interactional social adaptations. The 'elementary intellectual tendencies' are at the level where actions develop into thinking: language, symbolic thought, and memory are beginning to develop. The next two levels involve the development of language, attitudes, and beliefs at the prelogical stage. The final three 'tendencies' start with the growth of voluntary control, perseverance, and the function of work. These are followed by the development of value systems, the capacity for logical thought, and the achievement of selfidentity, coupled with a responsive awareness of the needs of others. Abnormal behaviour and neurotic states are seen as failures to integrate

'tendencies' at an appropriate level; the individual may regress to, or be fixated at, an earlier stage.

In his old age, Janet continued to be active and, after the completion of his vast reconceptualiza

tion, he applied himself to the study of belief and the development of a theory of conduct. He devoted much time to the revision and preparation for publication of his lectures at the Collège de France. The lectures appeared in the form of six major books between 1928 and 1937; none of them, unfortunately, was translated into English.

Unless the English student can read French with ease, it is very difficult for him to familiarize himself with Janet's thought or even capture the flavour of his writing. The small number of Janet's works which have been translated into English are not at all representative, and in any case they, like all his books, have long been out of print.

His bestknown books are *L'Automatisme psychologique* (1892), *Les Névroses* (1905), *The Major Symptoms of Hysteria* (15 lectures delivered at the Harvard Medical School, 1907), *Psychological Healing* (translated by Eden and Cedar Paul, 2 vols. 1925), and *L'Évolution de la mémoire et de la notion du temps* (1929).

JAPANESE CONCEPT OF MIND: TRADITIONAL VIEWS. The idea, associated with Lucien LéviBruhl and E. B. Tylor, that primitive humanity passed through a prelogical phase is no longer generally accepted. 'We now know that this is not how the most primitive of men behave; they have minds and reasons of their own' (G. S. Kirk, *The Nature of Greek Myths*, 1974, p. 74). Like the *Logos* of Heraclitus, reason is common to all mankind. There are no human communities which repudiate logical inference as the basis of their thinking, though the stages of the syllogism may be differently set out, as in the Nyaya doctrine (*darshana*) of Vedanta, and even though the exposition of a doctrine or myth may appear incoherent. But differences of mentality clearly exist. In order to understand the Japanese character and outlook, it is important to grasp certain tendencies for which Western psychology offers no parallels. One is summed up in the word *amae*, or

'dependency wish', i.e. the need felt by the average Japanese for psychological support not merely in childhood but at the adult stage, differentiating him in this respect from the Westerner, who strives for ever greater independence or individuality. (See Doi Takeo, *The Anatomy of Dependence*, a translation of his *Amae no kozo*.) Secondly, there is the fundamental distinction in Japanese psychology between *omote* and *ura* (literally 'front' and 'rear'), namely 'outward thoughts' and 'innermost thoughts': what is said in public and what is thought in private. (See Doi Takeo, ' *Omote* and *Ura*: concepts derived from the Japanese twofold structure of consciousness'— *Journal of*

Nervous and Mental Disease, 157 (1973), 4, 25861.) Such behavioural characteristics must entail in the end a different outlook on the world, a particular *Weltanschauung*. Again, if you believe that everything in nature possesses its own special divinity, your pantheon will tend to be overcrowded.

Thus the ancestral religion of the Japanese, Shinto ('the way of the Gods') moulded their character, conditioned their everyday behaviour, and laid the basis for their view of the nature of mind or spirit. Indeed, *ura* was one of the ancient words for 'mind', though today the mental realm is conveyed by *kokoro*. And despite the growth of secularism, the Japanese still show the influence of these traditional beliefs.

An important clue to the Japanese understanding of the mind is the fact that in Japan there has been, until modern times, no tradition of thought comparable to the Western philosophical tradition from the time of *Socrates and *Plato. The Japanese tradition is mythicoreligious. Although the origin of the Japanese as a race is still a matter of dispute, it is reasonable to suppose that Shinto developed in the Japanese archipelago, possibly from the fourth century. But during the sixth century—the key date is considered to be either AD 534 or 552—the influence of a 'higher religion', Buddhism, began to make itself felt. Buddhism was disseminated by missionary effort and by sponsored delegations from China and Korea. Despite the multiplication of Buddhist sects and a gradual accommodation with Shinto (the founder of the Shingon sect, Kukai or Kobo Daishi, maintained that the more exalted Shinto gods were incarnations of Buddhas), this faith of Indian origin influenced the Japanese character no less profoundly than did Shinto itself. For many centuries, most works of religious exegesis were written in Chinese, which, like Greek in the Occident, was preeminently the 'classic' language. Of Chinese origin likewise were Taoism and the *ethic* of Confucius, the impact of which should not be underestimated.

Finally, the Christianizing work of the remarkable Spaniard, Francis Xavier (1506–52), though later subject to pitiless persecution, proved in many respects so durable that, with the provision of a measure of freedom of belief after the Meiji Restoration of 1868—see Muraoka Tsunetsugu, *Studies in Shinto Thought* (Japanese National Commission for UNESCO, 1964), pp. 2278—many 'underground' Christians emerged into the open, especially in the Nagasaki area. Behind the Japanese tradition, therefore, lies China, and behind that India, with a distinct Christian influence first felt in the seventeenth century and renewed in the nineteenth.

It is not uncommon for a Japanese to profess several faiths at once. And even a Japanese who declares himself a total unbeliever—as a great many do today—may merely be displaying reluctance to subscribe to a particular creed or set of

Page 400

dogmas; for in any case he prefers nonverbal modes of communication. Indeed, his intense cult of aesthetic values, which has probably gained strength in an industrial society, may be his way of honouring the 'sacred' in another form. The holiness of beauty is for him a substitute for the beauty of holiness.

Interpreted philosophically, Shinto, though the least philosophical or theological of religions, implied a form of pantheism or panpsychism. Although the world of the gods (*kami*) was an invisible world outside the spatiotemporal dimension, it had 'ingression'—to employ Whitehead's term—in terrestrial affairs. Of individuality, the human being enjoyed little: there is a Japanese proverb, 'A nail that sticks out will be hit hard'. The community, possessing a kind of group mind, took precedence; and the group mind, animated by *tatema* or 'consensus', submitted at every moment to the influence and intervention of the countless divinities of the celestial hierarchy.

By contrast, Buddhism and Christianity tended to make a direct appeal to the individual conscience, where *ura* reigned; and Buddhism presupposed the existence of some kind of awareness at every level of creation. Among the voluminous Buddhist writings, one of the most attractive is that entitled *The Buddha's Law among the Birds* (trans. Edward Conze, 1955); and, according to Kukai, even trees and plants could attain to Buddhahood—the processes of budding, growing, yielding, and dying corresponded to aspiration, training, enlightenment, and nirvana. (See Sakamoto Yukio, 'On the "attainment of Buddhahood by trees and plants"'—

Proceedings of the Ninth Inter. national Congress for the History of Religions, Tokyo, 1960, pp. 41617.) In preaching the need to extinguish the blind lifeinstinct—sometimes called craving or attachment—and to discharge the accumulated burden of karma (a Sanskrit word meaning 'action' or 'fate') which had 'fed' that instinct, the Buddha was presupposing the traditional Hindu doctrine of rebirth; for only after the shedding of the karmic load was entry into nirvana possible. Where the Buddha's teaching differed from that of the tradition, and also from Western conceptions, was in his view of the mind or soul. (It is important to stress that the Buddha's sayings, as reported, are highly and no doubt deliberately ambiguous on this as on many other fundamental matters—see Bahm, A. J., *Philosophy of the Buddha*, 1958, ch. 10, 'Soul or no soul?', pp. 12230.) The so-called Wheel of Becoming started from ignorance, which gave rise to desireattachment; but although that which moved through this cycle was endowed with consciousness (*viññāṇa*), it was not an egoentity, or indeed an entity at all, but rather a psychic process (see Allen, G. F., *The Buddhist Philosophy*, 1959, pp. 403); and so the succession of rebirths was intended to lead to that form of enlightenment which entailed a total awakening from psychic sleep, with its tormenting dreams. Indeed, the word Buddha means the 'Enlightened' or 'Awakened' One. At the same time, this condition of spiritual awareness, which certain sects held to be attainable in a single lifetime, represented a final liberation from individuality and the merging in nirvana. It is often stressed that the doctrine or *dharma* preached by the Buddha was practical rather than metaphysical: 'Buddhism teaches the practical means of remolding the mind' (Kishimoto Hideo, 'The Meaning of Religion to the Japanese People', *Religious Studies in Japan*, edited by the Japanese Association for Religious Studies, Tokyo, 1959, p. 23). But in due course Buddhist teaching, especially as elaborated in the Mahayana or 'Great Vehicle', came to erect a system of metaphysical ideas of extreme refinement. No longer an atheistic creed, Mahayana theology elaborated the idea of the three bodies of the Buddha: the *Nirmanakaya*, or historical body of Gautama that existed on earth; the *Sambhogakaya*, or the transfigured body existing in paradise; and the *Dharmakaya*, or the transcendent, cosmic Buddha body, which was identical with ultimate reality itself. (Eliot, 1935, pp. 11314. Certain sects, e.g. the Kegon, distinguished ten bodies of the Buddha.) Being above or outside all categories, this Buddha of Essence was apprehensible not by reason but

by intuition (Eliot, p. 45). Such a faculty, in fact, was higher than that of reason—not supplementary or inferior to it, as in Western notions. Indeed, intuitive knowledge in this sense was identical with intellectual knowledge in the traditional sense.

Another name for it might be 'unitive' knowledge or what J. H. Newman seems to have been striving to convey by his idea of the 'illative' sense (*An Essay in Aid of a Grammar of Assent*, 1870, ch. 9). Now such knowledge, the attainment of which presupposed prolonged meditation, involved, at its highest reach, 'oneness' with its object, that is to say, identification with the Buddha nature, the concept of which is common to all the Mahayana sects except the Amidist ones.

This conception of the structure of the mind as composed of (i) psyche, (ii) reason, and (iii) (intellectual) intuition was similar at base to that of the Hindu tradition, in the context of which Buddhist theology was of course elaborated; and as scholars such as René Guénon (in his *Introduction to the Hindu Scriptures*, London, 1954) have pointed out, it was a view expounded by Aristotle in the *Posterior Analytics* and part of the *Metaphysics*. And Aristotle too believed in the final identification of knower and known. Indeed, such identification was abandoned in the West only with the disintegration of Scholastic philosophy, the exaltation of *ratio* as the highest mental faculty—the instrument of mathematicophysical science—and the loss of the concept of intellect as a spiritual faculty.

Admittedly, such considerations on the nature of mind entered hardly at all into the everyday thoughts of the ordinary man. Nor were they entertained by most Buddhist priests, who con

Page 401

cerned themselves chiefly with the performance of ritual, including the highly stylized reading of the *sutras*, and the doing of good works. Similarly, the visitor to an Indian temple, with its milling devotees and animal sacrifices, will see no obvious connection between what is going on and the recondite doctrines of the Upanishads.

And in Amidism—a simple theism in which the devotee needed merely to call upon the name of Amida for salvation—the ordinary man and woman found a nonintellectual faith which they could easily grasp. (This was *Jodo*, or Pure Land Buddhism, which began to flourish in Japan towards the end of the twelfth century.) But this is precisely where the Oriental distinction between esoteric and exoteric—inner and outer, *shruti* and *smriti*—knowledge applies. To speak of the philosophy, still less the theology, of Buddhism is misleading, since, as already implied, 'the purpose of Buddhist doctrine is to release beings from suffering, and speculations concerning the origin of the universe are held to be immaterial to that task' (Conze, 1951, p. 39). Nevertheless, the Mahayana is a metaphysical teaching of such comprehensiveness as to stand to Hinduism much as Christianity stands to Judaism; and its dependence for its basic metaphysical principles on Hinduism makes it easy to understand why many Hindus regard the historical Buddha as an *Avatara*, i.e. a divine manifestation, and in fact the ninth incarnation of Vishnu.

The Christian missions of the sixteenth and early seventeenth centuries introduced Christian theology

to many Japanese, and even to some of the Ainu aborigines of the northern island of Hokkaido; but the Meiji Restoration of 1868 opened the floodgates of Western thought. True to form, the intellectually curious Japanese seized on what was novel, iconoclastic, and supposedly scientific. Thus the French positivists and the British utilitarians were greatly in demand, and later the German idealists.

To the Japanese intelligentsia, Herbert*Spencer became as much a hero as he did to the 'interpreter' of Japan to the West, Lafcadio Hearn. (Spencer had in fact expressed the hope, in a letter to a Japanese baron, that Japan would continue her twohundredyear isolation, or *sakoku*—see the Appendix of Hearn's *Japan: an Interpretation*, 1904.) Consequently, the philosophy taught in Japanese universities is now largely Western, and some Japanese have mastered this so successfully as to be able to teach it in Europe and America. On the other hand, there have been philosophers such as Nishida Kitaro (1870-1945) who have sought to combine schools of Buddhism such as Zen (virtually a blend of the Mahayana and Taoism) with Western thought, though this has resulted in some obscurity, not least because of the inherent ambiguity of the Japanese language. (See Nishida's early work, *A Study of Good*, 1904, Japanese National Commission for UNESCO, 1960.) The Japanese founder of Zen was Eisai (1141-1215), who also originated the mindcalming tea ceremony.

Through concentrating on paradoxes or *koans*, Zen forms a technique for disciplining the mind for the purpose of attaining *satori*, or sudden illumination; and its apparent use of irrational means has endeared it to Westerners in revolt against rationalism. What its vogue seems to reflect, however, is that philosophy in the Orient is at heart not a matter of abstract speculation or analysis, but an experience, designed to bring with it enlightenment and knowledge. Whereas in the Occident the mind is treated primarily as an engine of perception and cognition, the Oriental regards his mental faculties as in need of training for the purpose of achieving, at best, a condition of what the Buddhists call 'selfluminous thought'. This condition is sometimes rather unhelpfully called 'emptiness', because the word nirvana literally means

'the extinction of breath or of disturbance'; but we should treat such a description as on a par with St John of the Cross's paradoxical 'ray of darkness': in short, nirvana is a condition of supraindividual 'fullness'. See Guénon's remarks on Buddhism in his *Man and his Becoming according to the Vedanta* (London, 1945), p.

173.

See also JAPANESE CONCEPT OF MIND: THE NEW RELIGIONS.

E.W.F.T.

The literature of Buddhism is so extensive and in many instances so recondite that a short readinglist is extremely difficult to compile. The following works are recommended for their comprehensive character:

Conze, E. (1951). *Buddhism, its Essence and Development*. London.

Eliot, Sir C. (1935). *Japanese Buddhism*. London.

Murti, T. R. V. (1959). *The Central Philosophy of Buddhism*. London.

Suzuki, D. T. (1948). *Introduction to Zen Buddhism*. London.

For Shinto, understood in its relation to Japanese culture, Tomlin, E. W. F. (1973), *Japan* (London) may be consulted.

For a general study and analysis of the Japanese character and mentality, Hajime, N. (1960), *Ways of Thinking of Eastern Peoples* (Japanese National Commission for Unesco, Tokyo) may be recommended.

JAPANESE CONCEPT OF MIND: THE NEW RELIGIONS. The catastrophic débâcle of Japan, which brought the Pacific War to an end in 1945, proved as much a psychological blow as a material disaster. According to the official 'myth', the Japanese people were descended from the gods—and ultimately from the sun goddess, Amaterasu Omikami—and they were in consequence invincible. A country accustomed to earthquakes was no stranger to physical destruction; but defeat inflicted by a people considered to be hardly less barbaric than the Mongols, who had *failed* in their onslaught on the coast of Kyushu in the thirteenth century, had been considered unthinkable. Consequently, in announcing his decision to surrender, the Emperor enjoined his people, in a familiar idiomatic phrase, to 'bear the unbearable'. Even today, the resulting shock has not worked its way out of the Japanese psyche. Moreover, the Page 402

proximate cause of the breaking of the will to fight was the use by the Allies of a weapon involving the release of a particular form of *pollution*. And pollution (*tsumi*), defilement, or taint of any sort is something to which the Japanese have a particular aversion.

Much of the ritual of Shinto was concerned with lustral purification. When in the aftermath of defeat this ancestral religion lost a good deal of its hold—for it had become virtually a state religion, and the state had been in many ways discredited—and when Buddhism, too, suffered the fate of a higher religion which had seemingly failed its adherents, a communal psychic vacuum was created. Admittedly, since adherence to Shinto was all but compulsory, and since every family was obliged to be registered at a Buddhist temple, the nominal worshippers greatly exceeded in number the true believers; but even when, after the war and in consequence of the liberal provisions of the 'American' constitution, people were free to admit their unorthodoxy or their lack of religious belief, the mental release was often less than might have been expected, because the psychological *needs* previously met by the traditional faiths were still clamant. Nor could humanism or rationalism or the pursuit of material prosperity effectively satisfy them. It was at this critical juncture that the *Shinkoshukyo*, or 'new religious cults', either spontaneously arose or came into their own.

There had been a similar uprush of religious emotion in the 1920s. Some of the cults, then and later, were quite obviously bogus. General MacArthur's Religious Bodies Law of 1945, exempting religious organizations from taxation, caused hurried registrations from bodies such as restaurants and old clothes shops purporting to have a religious 'dimension' (see Blacker, 1975, p. 336). Even so, the

number of new cults in presentday Japan runs to several hundreds (see Thomson, 1963;

McFarland, 1967).

Although it is sometimes asserted that the Japanese lack religious instinct, the facts would suggest otherwise. Such apparent indifference as there is may be due to the absence in their lives of any fixed boundary between the sacred and the secular; it is to this distinction that they are indifferent. The success of the new cults is an indication of a permanent need to 'lean on' a *guru* in the 'dependency attitude' defined by the hardly translatable word *amaeru* (noun, *amae*: see JAPANESE

CONCEPT OF MIND: TRADITIONAL, VIEWS). The *shaman* (originally a Sanskrit word) or the sibyl (*miko*) fulfilled this function in ancient society, beginning perhaps with the mysterious virgin queen, Pimiko or Himiko, who is spoken of in the ancient chronicles. And it is a role which, still openly played in certain remote regions of Japan, may be exercised under various guises in more 'civilized' regions (cf. Blacker, 1975, ch. 6). If spiritual leadership were wielded by more than one empress (for example, the eighthcentury Empress Jingo), the sacred female role—surprising perhaps in a country otherwise maledominated—could be assumed by far humbler individuals. Of these the most remarkable was undoubtedly Mrs Nakayama Miki (note that in Japanese the family name comes first), founder of the enormously successful cult of Tenrikyo (*tenri* = 'divine wisdom'). Born in poor circumstances in 1797, Miki acquired her first sense of mission in 1838 in a state of trancelike possession, during which she believed that her body had been 'occupied' by TennoShogun, god and saviour of mankind. Thenceforward so extraordinary were her actions and vatic declarations that a number of disciples, beginning with her bewildered husband, gathered round her and began to promote her teaching.

Despite official persecution, her cult grew until, when she died in 1887 at the age of 90, it was recognized as a new and flourishing religion, though classified as a branch of Shinto. Her followers maintain that she is in the world as the 'parent' of mankind, and she is ceremonially put to bed every night in the huge temple at Tenri.

Tenrikyo remains the largest and one of the most active of the Japanese new cults, with many adherents among the Japanese overseas communities and with some foreign disciples. Not long after Miki embarked upon her mission, another povertystricken woman, Deguchi Nao (1837/1918), falling into a trance and declaring herself to be possessed by the god UshitoranoKonjin, received a similar summons to lead mankind to salvation. Out of this experience. grew the Omoto ('teaching of the great origin') cult. Both Nao and Miki produced extensive 'scriptures', some of them apparently by automatic writing. Although many religious leaders were women (who nevertheless often attracted to their side a capable male administrator), the leader of the powerful Sekai Meshiakyō or 'World Messianity' sect, now about 700,000 strong, was Okada Mokichi, born in 1882. This strange man, who was at first a failure as well as a chronic invalid, announced that he was 'possessed'

by Kannon, the goddess of mercy: thereafter he developed extraordinary psychic powers as well as the gift of healing.

Another more recent clamant claimant to divine status was Kitamura Sayo (b. 1900), foundress of the so-called 'Dancing Religion' (Tensho Kotai Jingukyo), who declared in 1944 that her body was inhabited by a snake. This creature not merely gave her commands, but inspired the homilies and songs which, without her bidding, poured from her lips and also the dance which her followers still perform. These followers today number something like 350,000, and they regard Kitamura Sayo as a true successor of the Buddha and of Christ.

Many of the cults place emphasis upon happiness and contentment in this world. To that extent they diverge from 'pessimistic' religions such as Buddhism, even in the case of cults with Buddhist affiliations, such as the wellknown Soka Gakkai, with its political wing of Komeito, and also Page 403

Reiyukai, another cult founded by a woman, Kotani Kimi. Most of the others betray blends of all the higher religions, particularly Christianity. All stress the need for ritual purity. Indeed, the general aim seems to be to effect in their disciples a kind of psychic springclean, by expelling evil forces from the unconscious in order to achieve 'peace of mind'. In Japan, the extraordinary phenomenon called 'fox possession' was formerly an indication of the presence of some psychic obstruction: and just as in the field of psychiatry the patient can sometimes produce precisely the symptoms—such as dreaming the dreams—expected of him, what was formerly considered to be 'possession' by an animal might today be interpreted in terms more in keeping with psychoanalytical thinking. But even so, the Japanese psyche seems to have resisted psychoanalytical investigation more than that of the West, possibly owing to the strength of the 'dependency relationship' which would otherwise be undermined. The fact remains that psychic 'possession' of some kind, whether by another creature or by 'voices', seems a good deal commoner in Japan than in Western countries. Consequently, in the rural areas, the shaman or the ascetic is still much in demand, whereas these figures have no equivalent in the West save in the few ecclesiasticallylicensed exorcists or freelance faithhealers.

We may sum up the significance of the *Shinkoshukyo* by reaffirming that the Japanese have traditionally regarded the mind not as an engine of perception and cognition, but as the psychospiritual part of the person which seeks identification with ultimate reality. If some of the new cults strive to achieve this identification by rather superficial means—for example, by the emotional and to some extent hypnotic appeal of mass gatherings—this may be due to their simplistic view of 'the end of life'. As with Aristotle—in the *Metaphysics* at least, and in that part of the *Metaphysics* which is concerned with 'being as such'—knowledge is an experience, not the accumulation of information. Granted, there are Japanese philosophers who, following the Western empiricists in their early and latterly in their linguistic form, believe in the identity of the mind and the brain—the one being an epiphenomenon of the other—and who consider philosophy not as an experience, leading to enlightenment, but as 'linguistic analysis' (not that some analytic thinking would come amiss on occasion). But this is mainly due to the tendency for the academic world in Japan to assume an attitude of excessive veneration for whatever happens in the West, and particularly in the AngloSaxon countries. Meanwhile, the cults undoubtedly meet a psychospiritual need which the decline of the

higher religions has rendered all the more compelling. The persistence of such cults also raises for the student of mind the unsettled question of the nature of hypnotic and trance states, and of 'possession' by another 'self'—divine, daemonic, or animal—to which other contributors to this volume have addressed themselves more directly. (See, in particular, DISSOCIATION OF THE PERSONALITY; HYPNOSIS, EXPERIMENTAL; HYPNOTISM, HISTORY OF; and MESMERISM.)

JASTROW, JOSEPH (18631944). Polish perceptual psychologist, born in Warsaw and studied at John Hopkins University; became professor of psychology at Wisconsin (18881927). He contributed to psychophysical methods, and wrote *Fact and Fable in Psychology* (1900), but he is remembered for his visually ambiguous figure, the duckrabbit (see ILLUSIONS, Fig. 4a).

JENNINGS, HEBERT SPENCER (18681947). American zoologist, born at Tonica, Illinois; his studies of the behaviour of lower organisms, such as protozoa, convinced him that their reactions are too variable to find explanation in terms of mechanistic principles. He therefore promulgated the unfashionable view that mind extends to all levels of the evolutionary scale. His bestknown book is *Contribution to the Study of the Lower Organisms* (1904). Jennings's views were strongly contested by the GermanAmerican zoologist Jacques*Loeb, who advocated a strictly mechanistic explanation of animal behaviour.

JET LAG. It is common experience that lengthy journeys involving timezone changes (changes in longitude) are more disturbing than journeys of equal length where there is no local time change (journeys along one latitude). There is indeed very good evidence that disturbances of the rhythms of*sleep, digestion, and daily activity are unpleasant and impair performance, especially decisiontaking; and that it takes several days to get into phase with the new diurnal cycle. This is, of course, a problem not only for airline crews and passengers, but also for people such as nurses working on nightshifts. It is likely that the disruption is not only of the sleep cycle but also of various*biological clocks, so that they become out of phase with each other. Whether this produces longterm or irreversible bodily damage, or mental impairment, is not known.

JUNG, CARL GUSTAV (18751961). Swiss psychologist, born at Kesswil, the son of a pastor of the Swiss Reformed Church; his paternal grandfather and greatgrandfather were physicians. He enrolled at the University of Basle in 1895, where he took a degree in medicine, and then decided to specialize in psychiatry. In 1900

he went to the Burgholzli, the mental hospital and university psychiatric clinic in Zurich, where he

Eugen Bleuler. It was while working at the Burgholzli that he published his first papers on clinical topics, and also a number of papers on the use of word association tests, which he pioneered (see FREE ASSOCIATION). Jung concluded that through word association one can uncover constellations of ideas that are emotionally charged and give rise to morbid symptoms. The test worked by evaluating the patient in terms of the delay between the stimulus and his response, the appropriateness of the response word, and the behaviour exhibited. A significant deviation from normal indicated the presence of unconscious affect-laden ideas, and Jung coined the term 'complex' to describe this combination of the idea with the strong emotion it aroused.

In 1906, Jung published a study on dementia praecox, and this work was to influence Bleuler when he proposed the name *schizophrenia for the illness five years later.

Jung hypothesized that a complex was responsible for the production of a toxin which impaired mental functioning and acted directly to release the contents of the complex into consciousness. Thus, the delusional ideas, hallucinatory experiences, and affective changes of the psychosis were to be understood as more or less distorted manifestations of the originally repressed complex. This, in effect, was the first psychosomatic theory of schizophrenia, and although Jung gradually abandoned the toxin hypothesis and thought more in terms of disturbed neurochemical processes, he never relinquished his belief in the primacy of psychogenic factors in the origin of schizophrenia.

By the time (1907) that Jung first met Sigmund *Freud in Vienna, he was well acquainted with Freud's writings, and from the success of this meeting there followed a close association until 1912. In the early years of their collaboration Jung defended Freudian theories, and Freud responded to this support from an unexpected quarter with enthusiasm and encouragement. In fact, at that time Freud felt the psychoanalytic movement to be isolated and under attack, and in 1908 wrote to another colleague: 'It is only his [Jung's] arrival on the scene that has removed the danger of psychoanalysis becoming a Jewish national affair.'

In 1910 Jung left his post at the Burgholzli to concentrate on his growing private practice and also began his investigations into myths, legends, and fairytales and the light that their contents threw on to psychopathology. His first writings on this theme were published in 1911 and indicated both an area of interest which was to be sustained for the rest of his life and an assertion of independence from Freud in their criticism of his classification of instincts as either self-preservative or sexual.

Although Jung's dislike of the conceiving of the libido as essentially sexual was already apparent at this early stage, the significance became clear only much later, when he wrote about individuation. However, it was not only intellectual differences that led to the breach between Freud and Jung. Jung has recorded that he found Freud unduly concerned to preserve the tenets of psychoanalysis as articles of faith, immune from attack, and that this attitude diminished his respect for him. In fact, Jung's writings reveal that he too was prone to dogmatic assertions, but his fundamental assumptions run counter to those of Freud. Thus, while Freud, characteristically, established causal links stretching back to childhood which imply a mechanistic account of human behaviour, Jung was

concerned to place man in a historical context which gave his life meaning and dignity and ultimately implied a place in a purposeful universe. In their later writings, both men became more concerned with social questions and also more metaphysical in the way they expressed their ideas. Thus Freud balanced the life instinct against the death wish, and Jung discussed the split in the individual between the ego and the shadow.

Whatever the factors involved, Jung records that after breaking with Freud he underwent a prolonged period of inner uncertainty. Although we are given glimpses of this episode in his writings, we do not have a detailed chronological account. It is clear, however, that the inner images, which he felt almost overwhelmed him, became the major inspiration both for his writings and for his clinical practice throughout the rest of his life.

The theme which unifies the large number of writings that Jung subsequently published is individuation, a process which he saw as taking place in certain gifted individuals in the second half of life. While he felt that Freud and Alfred Adler had many valuable insights, he saw their field of interest as restricted to the problems that might be encountered during maturation. His particular concern was with those people who have achieved separation from their parents, an adult sexual identity, and independence through work, who may yet undergo a crisis in middle life. Jung conceived of individuation as being directed towards the achievement of psychic wholeness or integration, and in characterizing this developmental journey he used illustrations from alchemy, mythology, literature, and Western and Eastern religions, as well as from his own clinical findings. Particular signposts on the journey are provided by the archetypal images and symbols which are experienced, often with great emotional intensity, in dreams and visions, and which as well as connecting the individual with the rest of mankind also point towards his own peculiar destiny. In his writings on the Collective Unconscious and the archetypal images which are its manifestation, it is clear that Jung feels that cultural spread cannot wholly account for the dissemination of mythological themes in dreams and visions. He writes of many patients who, while completely unsophisticated in such matters, describe dreams that exhibit striking parallels with myths from many different traditions. Indeed, Jung records an example from the time of the resolution of his own midlife crisis. He Page 405

had taken to painting representational pictures of his experiences, but under a new impulse began to paint abstract circular designs often divided into four or multiples of four. It was only later that he discovered that similar designs were found throughout the East, and that under the name 'mandala' were used as instruments of contemplation in Tantric Yoga. He came to see the mandala as an archetypal symbol of the self, the totality of which embraces not only the conscious but also the unconscious psyche. The appearance of the mandala symbol as a spontaneous psychic event is associated with the attempt to integrate the discordant elements within the personality at a time when disintegration is threatened.

However, there does seem to be a basic ambiguity in Jung's various descriptions of the Collective Unconscious. Sometimes he seems to regard the predisposition to experience certain images as understandable in terms of some genetic model. In effect he is doing no more than pass a normative judgement about the way human beings experience the world. But he is also at pains to emphasize the numinous quality of these experiences, and there can be no doubt that he was attracted to the idea that

the archetypes afford evidence of communion with some divine or word mind. It is interesting to find that T. S. Eliot, who might himself be described as having experienced a midlife crisis, wrote, 'We take it for granted that our dreams spring from below: possibly the quality of our dreams suffers in consequence.'

The latter part of Jung's life was relatively uneventful. He lived in Zurich, where he pursued private practice and also studied and wrote. It has been regretted that he left no detailed accounts of his clinical activities, although throughout his works there are scattered anecdotes from his professional experience as a psychotherapist.

His great interest in religious questions is often treated as an embarrassment by practising psychotherapists, and certainly the problems with which he wrestles seem esoteric when compared with those encountered in a psychiatric outpatient clinic. Nevertheless, his popularity as a thinker derives from precisely this subjectmatter and from his assurance that life is a meaningful adventure. He studied Eastern religions and philosophy, but saw himself as inescapably belonging to the Christian tradition although he was in no sense an orthodox believer. In a late work, *Answer to Job* (1952), he pictures Job appealing to God against God; and concludes that any split in the moral nature of man must be referred back to a split in the Godhead. The book is often obscure, and there is no easy solution to this problem, but in a letter he wrote subsequently about the book he said, 'I had to wrench myself free of God, so to speak, in order to find that unity in myself which God seeks through man. It is rather like that vision of Symeon, the Theologian, who sought God in vain everywhere in the world, until God rose like a little sun in his own heart.' Whereas Freud said, 'I have not the courage to rise up before my fellow men as a prophet and I bow to the reproach that I can offer them no consolation', Jung in contemplating the future found himself able to view the division in man as an expression of divine conflict. 'The outcome', he wrote, 'may well be the revelation of the Holy Ghost out of man himself. Just as man was once revealed out of God, so, when the circle closes, God may be revealed out of man.'

Such darkly impressive statements are common in Jung's writings. However, in his memoirs, which were written shortly before he died, he is more detached and agnostic and denies having any definite convictions. He concludes the book: 'The more uncertain I have felt about myself, the more there has grown up in me a feeling of kinship with all things. In fact, it seems to me as if that alienation which so long separated me from the world has become transferred into my own inner world, and has revealed to me an unexpected unfamiliarity with myself.'

JUSTNOTICEABLE DIFFERENCES. Small changes of stimulus intensity (such as an increase in light or sound intensity) may go unnoticed, and in general will not be noticed unless the increase is greater than 12 per cent. The critical intensity change that is discriminated is known as the 'justnoticeable difference' (or 'j.n.d.'), and it may be called the 'threshold' of sensation. It was discovered by Ernst Heinrich*Weber that the justnoticeable difference increases in direct proportion with the stimulus intensity. Gustav*Fechner, having become interested in galvanism (see GALVANIC STIMULATION), turned to philosophy, and tried to relate physiology to psychology (in his *Elemente der Psychophysik*, 1860) by assuming justnoticeable differences to be equal units of sensations, over the entire intensity range, and so quantifying sensations as integrations of j.n.d.s. His arguments for measuring sensation, though ultimately unsound, essentially founded psychology as an experimental science.

See PSYCHOPHYSICS.

Page 406

K

KANT, IMMANUEL (1724-1804). German philosopher. Born in Königsberg, Prussia (since annexed by the USSR and renamed Kaliningrad), Kant never left the town and taught at the university there, where he became professor of logic and metaphysics in 1770. His earliest works were concerned with astronomy, and his great philosophical masterpiece, the *Critique of Pure Reason* (*Kritik der reinen Vernunft*) did not appear until 1781. This was followed by the *Critique of Practical Reason* (1788) and the *Critique of Judgement* (1790).

Kant gave the name 'transcendental idealism' to his philosophy (see IDEALISM); but in fact it is a brilliant and complex synthesis of rationalism and empiricism. On the one hand, he condemns the aspirations of the rationalists to ascend to a world of pure*a priori knowledge independently of the senses; on the other hand he rejects the empiricist notion that knowledge can be founded purely on sensory data. Kant argues that in order to experience the world at all the mind necessarily interprets it in terms of a certain structure; it is already armed with certain concepts of the understanding (*Verstandesbegriffe*). These concepts are derived from certain fundamental

'categories' (such as the category of substance and the category of causality); and the categories are a priori, not in the sense that they are independent of experience, but in the sense that they are presupposed by experience. In a complex chain of arguments called the 'Transcendental Deduction', Kant attempts to demonstrate the

'objective validity' of the categories. (See KANT'S PHILOSOPHY OF MIND).

In addition to his crucial and enduring contribution to the theory of knowledge, Kant was also highly influential in the field of ethics. In the *Groundwork of the Metaphysic of Morals* (1785), he puts forward his famous doctrine of the 'categorical imperative': 'Act only on that maxim through which you can at the same time will that it become a universal law.'

KANT'S PHILOSOPHY OF MIND. It is a commonplace that the character of our experience of the world, and hence the character of the world as *experienced* by *us*, while dependent in part on the nature of the objects we perceive, is also in part dependent on our own cognitive constitution, our physiological and psychological makeup. Experience is the causal outcome of objects affecting our constitution, and the causal mechanisms involved are matter for empirical investigation and discovery: the discovery of what it is about objects and about ourselves that makes them appear to us as they do. The distinctive feature of Kant's

'transcendental' philosophy is his transposition or transformation of this commonplace in such a way as to lift it out of the sphere of empirical investigation altogether.

Any empirical researcher, any natural scientist, takes as his field of investigation some aspect or selection of natural objects and events, located in space and occurring or persisting in time. Among these natural objects, of particular concern to biologists, psychologists, and physiologists, are our human selves. The scientist's business is to discover the laws of working which govern the behaviour and account for the characteristics of his selected objects. But those general features which constitute the very framework of such enquiries—the spatiotemporality of nature and the existence of discoverable law—are alike attributed by Kant to the constitution of the human mind; whence he contentedly draws the conclusion that empirical enquiry can yield us knowledge *only* of appearances—of the appearances that things present to beings constituted as we are. Of things as they are in themselves (including ourselves as we are in ourselves) experience and scientific investigation can yield no knowledge at all. The field of empirical enquiry is nature: but all the characteristics of natural things (including ourselves as natural objects) are thoroughly conditioned by features which

have their source in the human subject.

Kant distinguishes two primary subjective sources of these features: the *sensibility* and the *understanding*. Sensibility is passive or receptive: it is the mind's capacity so to be affected by things as they are in themselves that mental contents or representations which Kant calls 'intuitions' or 'perceptions' are thereby generated. Within this receptive faculty of sensibility Kant distinguishes between 'inner' and 'outer' sense, saying that time is nothing but the form of the one and space nothing but the form of the other. The doctrine is that the temporal character of experience in general, and of its objects, and the possession by some intuitions of the character of spatiality which

Page 407

allows of their being so ordered as to count as perceptions of objects in space are due to the constitution of inner and outer sense respectively; and that, in particular, time, the form of inner sense, is the mode of ordering which results from the selfaffection of ourselves as we are in ourselves. For, in addition to the passive or merely receptive faculty of sensibility, we have the active, affecting faculty of understanding. Understanding is the faculty which, acting on the sensibility, enables us to conceptualize our intuitions; and, more, it is the subjective source of those general principles of conceptualization (the Categories) which enable and require us so to conceptualize our intuitions as to give them the character of perceptions of a lawgoverned world of objects of which the governing laws are open to investigation by the methods of empirical science.

For this theory, as elaborated in the *Critique of Pure Reason*, Kant made great claims. He claimed that it provided the unique explanation of certain features of our empirical knowledge of nature (i.e. of the world of appearances), features which were necessary conditions of the very possibility of any such knowledge; that it supplied a salutary demonstration of the impossibility of theoretical knowledge of the supersensible realm of things as they are in themselves; and that, at the same time, it left room, not for theoretical knowledge, but for the morally based conviction that the requirements of moral responsibility and moral justice were somehow fulfilled in that realm inaccessible to our knowledge.

These claims we need not consider here. From the brief sketch given above, it seems hardly to be expected that Kant's transcendental theory of mind should have much in common with the firmly empirical theories current among psychologists and physiologists who concern themselves with the mind as a naturally given phenomenon; or, indeed, with the views of those philosophers of mind who concern themselves with the analysis or elucidation of the mental concepts which men and women employ in thinking about themselves and their fellows. When Kant speaks of the 'human mind' or of 'ourselves' as the subjective source of time, space, and the Categories, it seems that it must be of those mysteries, ourselves as we are in ourselves, that he is speaking and not of ourselves as we know ourselves; and when he distinguishes sensibility and understanding, we cannot take him as referring to such familiar objects of empirical study as sensory receptors and the daytoday workings of human intelligence.

Kant distinguishes further faculties: notably that of imagination, which serves sense and understanding

as their indispensable gobetween, synthesizing the manifold and discrete data of sense in such a way as to make possible recognition of objects as falling under empirical concepts. In this doctrine of synthesis we may be tempted to find a near or remote analogue of some findings of empirical (including physiological) psychology. But the qualification 'transcendental' standing before the phrase

'synthesis of imagination' should warn us to tread warily. The transcendental synthesis of imagination is not to be conceived as any kind of occurrent process which could be empirically studied. The doctrine is more intelligibly seen as reflecting an inescapable feature of senseperception of a world of objects: the fact that we cannot, in general, veridically characterize even a momentary perception except by acknowledging that, for example, we see what we see as a dog, say, or as a tree—

thus uniting, as it were, the instantaneous impression with other past or possible impressions (of the same object or of different objects of the same kind) which would similarly require, for *their* characterization, employment of the same general concept. This infusion or penetration of momentary senseimpressions by objectconcepts which extend beyond (and 'combine') them, Kant saw as a necessary condition of experience of a world of objects; and thus he saw imagination as a necessary ('transcendental') mediator between sense, as merely receptive, and understanding as the faculty of concepts in general and in particular as the source of those very general a priori concepts (the Categories) which necessarily found a footing in experience in the use we make of our merely empirical concepts of types of object and event. (There are instructive parallels and contrasts to be drawn between Kant's doctrine of imagination and that of Hume.) To the faculty of 'reason' Kant assigns a role which includes, but goes beyond, those merely conceptualizing, judging, and generalizing operations of the understanding whereby empirical knowledge of nature is gained and extended. Reason typically demands more than this limited knowledge which always leaves room for further questions and thus is knowledge, as Kant puts it, only of the 'conditioned'; for reason sets before itself the ideal of ultimate explanations, of final and complete knowledge which would leave no room for further questions. In so far as this 'demand of reason for the unconditioned' encourages us to push our empirical researches in the direction of more and more comprehensive theories or into everremoter regions of the physical universe or of past time, its effect is wholly beneficial. But in so far as we are encouraged to believe that the demand can be met, that we can, by pure reasoning, attain knowledge of objects answering to reason's 'ideas' of the unconditioned, its effect is simply to generate illusion; for our knowledge is necessarily confined to the realm of experience, the realm of appearances, in which no such objects are to be found.

Rather less convincingly, Kant finds for pure reason a 'practical' role as the essential source and end of morality. He further suggests that though we are denied theoretical knowledge of the supersensible realm of things as they are in themselves, yet reason in its practical role may yield moral certainties, falling short of knowledge, regarding

Page 408

that realm. He argues that our recognition of the unconditional binding force of the moral law carries with it both a belief in freedom of the will—a power of free choice which we do not possess as natural beings subject to causal determination but may possess as we supersensibly are in ourselves

— and a belief in the supersensible fulfilment of the demands of moral justice and hence in a supersensible divinity capable of securing the moral ideal.

A question naturally arises regarding the internal consistency of the 'critical' philosophy and in particular of the doctrines of 'transcendental idealism'. If the spatiotemporality and lawlikeness of nature and all that is in it are to be attributed to a subjective source in the human mind, this source cannot be identified with the human mind as a part of nature, the topic of empirical psychology—a discipline which Kant rather dismissively describes as a kind of 'physiology of inner sense'. So when Kant speaks of *our* sensibility and *our* understanding as the source of space, time, and the Categories, it must be to ourselves as we (supersensibly) are in ourselves that he is referring. But this conclusion appears to be in direct contradiction to the doctrine that nothing can be known of things (including ourselves) as they are in themselves: a doctrine he is at pains to emphasize in his criticism of 'rational psychology' which seeks to argue from the bare fact of selfconsciousness to the conclusion that the soul is a simple, immaterial, indestructible substance. The fallacies of 'rational psychology' Kant declares to be among those to which pure reason is prone in its search for the unconditioned which cannot be found in experience. It is not clear why Kant's own brand of what might be called 'transcendental psychology'—which is clearly distinguished from the empirical—does not fall under the same interdict that he places on 'rational psychology'.

These (and other) difficulties may tempt us to reconstrue, or reconstruct, the central doctrines of the critical philosophy, by (i) eliminating all reference to ourselves other than those natural selves which can be empirically studied and (ii) interpreting Kant's doctrine of the mind as concerned with certain powers and properties which we ordinary human beings (objects in nature) innately possess, and our possession of which is a necessary condition of our enjoyment of the type of experience which we do enjoy and of attainment of such knowledge of nature, including our own nature, as we do attain. Such a radically reinterpreted, such a *domesticated*, Kant would perhaps be more intellectually acceptable to us; but he would not be the great and difficult philosopher that he is in himself.

A final note may be added concerning Kant's treatment of aesthetics in *The Critique of Judgement*, where he turns his philosophy of mind to strikingly good account.

The judgement of taste, the judgement that an object of art or nature is beautiful, is subjective in so far as it necessarily involves, and rests on, a subjective feeling of pleasure; and yet it claims universal or objective validity. This claim Kant declares justified in so far as the feeling of pleasure results from the fact that the formal properties of the object are such as to excite the harmonious free play of the faculties of understanding and imagination; for these faculties are common to all men. The functioning of these faculties in this connection is described as 'free play' just because it is not under the governance of concepts such as we employ in ordinary nonaesthetic empirical judgements; i.e. our aesthetic response is not to the object as being of some general kind, but rather to it as the unique individual that it is.

P. F. S.

KATZ, DAVID (1884-1953). German psychologist, born in Kassel of Jewish extraction. He was

educated at Göttingen, where he worked under G. E. Müller, though he was also much influenced by Edmund*Husserl's phenomenology. He obtained his doctorate in 1906 and in the following year became a *privatdocent* at Göttingen. In 1911 he published his first and bestknown book, *Die Erscheinungsweisen der Farben*, abridged in English translation as *The World of Colour*. He served in the German army in the First World War and in 1919 became professor of psychology at Rostock, where he remained until 1933, when he went to England.

He worked first in Manchester and later in London until he was offered and accepted the chair of pedagogy at Stockholm, where he died.

Katz was a man with wide, and on occasion, somewhat bizarre interests. After the First World War he wrote a monograph on phantom limbs, and while a refugee in Manchester he undertook research on the tongue as a primitive sense organ and on the feeding habits of captive monkeys.

His most important books were *The World of Colour* (1935) and its companion volume *Der Aufbau der Tastwelt*, 1925 (*The World of Touch*). Other books are *Animals and Men* (1937) and *Gestalt Psychology* (1950).

O. L. Z.

KELLER, HELEN ADAMS (1880-1968). Born in Alabama, at 19 months she became deaf and blind. Educated by Anne M. Sullivan (Mrs Macy), she gradually learned to speak. She obtained a university degree in 1904, and achieved worldwide fame as a writer—a unique case of international recognition of a person with this double handicap. The story of how she discovered channels of communication and powers of expression is remarkable: see *Story of My Life* (1903, 1959, 1966).

KEPLER, JOHANNES (1571-1630). A key figure in the history of ideas, Johannes Kepler was both astronomer and astrologer to the Holy Roman Emperor Rudolf II, and later to Wallenstein, Duke of Friedland. Kepler combined medieval mysticism with the analytical power of a great scientist whose achievements encompass laws of planetary

Page 409

motion and the optics and visual functions of the eye—that it provides optical images.

In his *Mysterium cosmographicum* of 1596 he attempted a geometrical theory of the motions of the five known planets: that the five types of regular polyhedra control the planets. He was disappointed over this essentially Platonic notion, for the new highly accurate observations of Tycho Brahe did not fit this notion any better than much earlier observations. Kepler reconsidered his static geometrical models, to take into account and emphasize the importance of times and speeds. This new idea of relative speeds led to his *Harmonie mundi* (Harmony of the Universe) in 1619, which included the mathematical statement known as his third law: that the square of a planet's periodic time is proportional to the cube of its mean distance from the sun. Here by heroic arithmetic from the new data he discovered, with no prior hypothesis, an entirely surprising key to the universe; and he justified his astronomy with the aesthetics of music, believing that the harmony of the universe, which

we may appreciate by science and by art, is in God's mind. Kepler in his account recognized seven good chords: octave, major and minor sixths, the fifth, the fourth, and the major and minor thirds. These musical ratios he conceived in terms of a vibrating string, thought of as bent round the sides of a polygon, so that each polygon is a musical conception based on Pythagoras's discovery that musical pitch is inversely related to the length of a vibrating string. Enjoyment of music is not just pleasurable stimulation of the ear, for 'the souls of men rejoice in those very proportions that God employed (in the Creation), wherever we find them, whether by pure reflection, or by the intervention of the senses . . . (or exercise of reason) by an occult, innate instinct'. So the astronomer should learn to match the harmony of the heavens with the harmony within his mind. Kepler applied this also to astrology, holding that the earth is an animated being. How the soul of the body perceives planetary influences was for him no more mysterious than how retinal images in our eyes give us conscious perceptions. And yet he wrote (in a letter to Herwart): 'My aim is to show that the heavenly machine is not a kind of divine, live being, but a kind of clockwork (and he who believes that a clock has a soul, attributes the maker's glory to the work), in so far as nearly all the manifold motions are caused by a most simple, magnetic, and material force, just as all motions of the clock are caused by a simple weight.'

Kepler's first law, that planets move in ellipses, and his second law, that planets describe equal areas in equal times, were both published in 1609. The notion that planets move in ellipses took a great deal of working out, and it was not intuitively likely or aesthetically acceptable. The ellipse was seen as inelegant, as only one focus is filled—by the sun—the other being empty. Kepler could not even be sure that the planets revolve with constant angular (or rather swept area) velocity round the sunfilled focus, rather than the empty focus, and indeed there were rival claims that the empty focus was the key to planetary movements, rather than the massive sun. It still seems amazing that *conic sections* provide a master key to the heavens!

In his strange book, which is fanciful science fiction while also providing thinking tools, *Somnium* (A Dream, or astronomy of the moon; first draft 1611), Kepler wrote an allegory in which he protected himself against attack for holding the Copernican notion of the earth moving round the sun. He described what things would look like from the moon, which was well known to be in motion. He was able to point out that the stars would seem to move from a moving base, and thus to imply that, against appearances, the earth may be moving and so produce the movements of the 'fixed' stars. He had heard of Galileo's discoveries with the telescope in 1610, of lunar craters and the four bright moons of Jupiter, and he very soon had the use of a telescope to which he added optical improvements. He supposed that as the lunar craters are circular, they must have been made by intelligent moondwellers, to shield them from the heat of the sun; but he also supposed that as the lunar mountains are irregular, they are natural and not constructed by intelligence. This criterion for extraterrestrial intelligence was also accepted by NASA in the early years of space exploration with planetary probes; they looked for circular or straightline structures as evidence of intelligence. It was the reason also for the American astronomer Percival Lowell believing there to be intelligent life on Mars, as he saw straight 'canals'; these turned out to be, a not yet fully understood, visual illusion.

The *Somnium* portrayed Kepler's own mother as an enchantress; it may have contributed to the calamity of her being prosecuted for witchcraft. (She died a year after being released from custody.) Be that as it may, he describes, in this first science fiction, how to get to the moon and suggests that

the best space travellers would be

'dried up old crones who since childhood have ridden over great stretches of the earth at night in tattered cloaks on goats or pitchforks'. To avoid being shrivelled by the great heat of the sun they must travel during the four brief hours of a lunar eclipse, in the shadow of the earth, and be pulled up to the moon by the sun's power that raises the tides of the sea. From prehistoric times tides had been seen as evidence of the harmony of the universe with life on earth. This strange work has been translated by Edward Rosen as *Somnium: the dream, or posthumous work on lunar astronomy* (1967; Madison, Milwaukee, and London).

KIERKEGAARD, SØREN AABY (1813-55). Danish philosopher, founder of existentialism. He read theology but did not take orders. Suffering ill-defined guilt, he broke off his engagement to Regina Olsen and lived as an obsessive bachelor, on capital which was exhausted the day he died. Rejecting philosophical systems, he argued that subjectivity is truth. He attacked official Christianity; he also attacked his own books in anonymous reviews. His principal works are *Either/Or* (1843), *Philosophical Fragments* (1844), and *The Concluding Unscientific Postscript* (1846).

KINDI, AL (803-73), Arab philosopher. See ALKINDI.

KLEIN, MELANIE (1882-1960) née Reizes, British psychoanalyst, was born in Vienna. Marrying early, she moved to Budapest. Her interest was aroused by the writings of Sigmund*Freud, and she underwent analysis with Sandor Ferenczi, later working in his children's clinic. In 1921 she moved to Berlin for further analysis with Karl Abraham and continued her work with children. She decided to move to London in 1926 and was naturalized.

She was much influenced by Abraham's object-relations interpretation of Freud's theories (see FREUDIANISM: LATER DEVELOPMENTS). Her own particular contribution to psychoanalysis,

however, lay in her work with children. She believed that emotions—love, fear, hate, concern—were present in children from very early infancy and that it was possible to interpret the child's behaviour and the emotional states to which it could not give coherent expression by observing it play. She therefore undertook the analysis of children at a much earlier age than others had thought possible, and gradually built up a picture of the inner world and emotional needs of both normal and abnormal children. She was also noted for her work with paranoidschizoid and manicdepressive adults.

Much of Klein's work has aroused fierce controversy, but many of her ideas have been absorbed into the greater understanding that now exists of mental states. Her publications have been collected in *The Writings of Melanie Klein* (London, 1975).

KLÜVER HEINRICH (1897-1979). German-American psychologist, born in Schleswig-Holstein and educated at the universities of Hamburg and Berlin. He emigrated to the United States in the 1920s and obtained his doctorate at Stanford in 1925. A great admirer of Karl Lashley, he went to the University of Chicago in order to work with him. Although Lashley soon moved on, Klüver remained in Chicago for the rest of his life.

Klüver's best known work is his monograph on *Behaviour Mechanism in Monkeys* (1933), which owes much to Lashley, who wrote the Introduction. He is also known for his description, with P. C. Bucy, of the Klüver-Bucy syndrome, observed in monkeys after bilateral excision of the temporal lobes. This syndrome is marked by failure to recognize objects by sight, hypersexuality, compulsive oral behaviour, and a striking diminution in fear and aggression. In so far as this last is concerned, it is now known to result from damage to the amygdala, a part of the limbic system lying deep in the temporal lobes.

O. L. Z.

KNOWLEDGE may be described as representations of facts (including generalizations) and concepts organized for future use, including problem-solving. There is

'useless' knowledge, such as which is the third, or the thirteenth, longest river in the world; on the other hand there is also knowledge that far transcends even what is necessary for immediate survival. It is on this latter that civilization's future depends, and in our possession of it we are, surely, outside the biological stream of natural selection.

It is useful also to distinguish 'knowing how' from 'knowing what', for knowledge includes the skills of knowing how to make effective use of individual facts and generalizations. When appropriately organized, it allows us to transfer experience from the past to the future, to predict and control events, and to invent new futures.

It is, thus, a crucial component of intelligence.

KNOWLEDGE: NATURALISTIC ANALYSES. Philosophers have generally, if not invariably, held that to know that something is the case entails a true belief that that thing is the case. If A knows that *p*, then it is entailed that A believes that *p* and that *p* is the case. However, it is not possible to maintain that every case of true belief is a case of knowledge. A paranoiac might believe, without good grounds, that a certain person was trying to injure him. But even paranoiacs have enemies, and it might be that in this particular case the paranoiac's belief was correct. Such a case of true belief would not be a case of knowledge. The question arises, therefore, what further condition or conditions must be added to true belief to yield knowledge?

A traditional answer to this question is that A *knows* that *p* if, and only if, his true belief that *p* is supported in his mind by the possession of sufficiently good evidence.

A difficulty for this traditional answer is that this evidence, to be sufficiently good, will itself have to consist of a proposition or Page 411

propositions, *q*, which A *knows*. (For suppose it be given that A's evidence is *q*, but it is not the case that A knows *q*. We will hardly think that A's true belief that *p* is sufficiently supported for A to know that *p*.) Now, however, the problem arises of what it is for A to know that *q*. If the same traditional answer is given, still further knowledge will be required to back up A's true belief that *q*, and so *ad infinitum*. The traditional analysis appears to be involved in a vicious infinite regress.

This difficulty has exercised philosophers for a long time and various remedies have been proposed. In recent years, various *naturalistic* accounts of knowledge have been suggested which show promise of evading the difficulty. The general outline, if not the detail, of a naturalistic account of *belief* is rather easy to discern. Beliefs will be some sort of complex structure, a structure purporting to represent reality, found within the minds (brains?) of human beings and, presumably, higher animals.

These structures will stand in various naturalistic relations to the states of affairs which they purport to represent. Some of these relations may be such that, if a belief has such a relation to the world, it is not simply belief but is knowledge. Three suggestions about the nature of these relations are worth consideration.

(i) *The 'Proper channels' account.* It is clear that we are equipped by nature with certain reliable 'channels' for the receipt of information. We gain knowledge of the current state of the physical world, including our own bodily state, by means of our senses. We gain knowledge of our own current state of mind by means of introspection. We do not *acquire* knowledge by memory, but memory is a reliable means of conserving it. If we restrict ourselves to simple, 'selfevident' steps we can by reasoning acquire knowledge in such fields as logic and mathematics. These facts lead up to the suggestion that knowledge is simply a true belief acquired (and/or conserved) through such channels.

This suggestion has to meet the difficulty that it is possible to have cases of true belief acquired and/or conserved in these ordinarily satisfactory ways, but for these beliefs not to be cases of

knowledge. Consider, for instance, a person who begins by knowing that a certain telephone number is 3286693. At a later time, as a result of alterations in the person's memorytrace, he comes to believe firmly but falsely that the number is 3826963. The memorytrace continues to alter, but, by sheer chance, the next alteration happens to reinstate the original (true) belief: that the number is 3286693. Here we have a case of true belief, yielded by memory, which we would not account a case of knowledge.

(ii) *The Causal account*. A second suggestion is that when a state of affairs brings it about that we believe that that state of affairs obtains, then and only then do we have knowledge. This is what generally happens in perception. There is a bird in the tree; this state of affairs acts upon my sense organs; and, as a causal consequence, I come to *know* that there is a bird in the tree.

The Causal analysis has this advantage over the previous suggestion: it requires no independent stipulation that the belief be true. If the state of affairs, *p*, brings it about that A believes that *p*, then, automatically, the belief is true. The definition is, however, a limiting one. For instance, it makes it impossible to have knowledge of *future* states of affairs except under the difficult and perhaps selfcontradictory supposition of 'backward causation': that such states of affairs can have effects upon our minds at an earlier time.

It may be possible to sophisticate the Causal analysis in such a way as to bypass this objection, but the analysis also faces a difficulty similar to the one brought against the 'Proper channels' account. Cases can be conceived where a state of affairs brings about a belief that that state of affairs obtains, but where we would deny that the case was one of knowledge. Consider a man whose nervous system is so deranged that any sharp sensory stimulus makes him believe that he hears a loud sound.

Bright light, a cut, a strong smell, a blow, all have this one effect. Now let the stimulus be a loud sound. He will believe that he hears a loud sound, but it is clear that he does not know it.

(iii) *The Reliability or Nomic (Lawlike) account*. A final suggestion is this. If A believes that *p*, and if it is impossible, given the natural laws which govern the world and the situation which A is in that his belief should be false, then his belief constitutes knowledge. A reliable thermometer or a watch in good working order supplies a good model for this situation. If such a thermometer or such a watch, placed in a normal environment, gives a certain 'reading' (which corresponds to a belief), then, given the actual laws of nature, it must be the case that this reading is correct. One who knows is one whose belief stands to the world in the same way that the thermometerreading stands to the actual temperature or the watchreading stands to the actual time.

A major advantage of this particular approach is that it can be extended to cover beliefs which fall short of knowledge, but which are nevertheless reliable to a high degree. If the laws of nature make it objectively very probable that a certain belief held on a certain occasion is true, then that belief, even if not knowledge, will still be a reliable belief. It is possible to hold that no belief ever reaches the very high (but not logically unreachable) standards which the Reliability approach sets for knowledge. The biological value of beliefs with a high degree of reliability of the sort indicated is obvious enough.

It may be objected to this account that it can give us no practical help in deciding in actual cases whether a particular belief is or is not a case of knowledge. However, this is a complaint that can be directed against all naturalistic definitions of knowledge, indeed, against all definitions of knowledge whatsoever. It is in fact a misguided complaint. No definition can be expected by itself to

Page 412

pick out actual instances falling under the definition. No definition of knowledge can answer the sceptic who doubts the existence of knowledge. It can only tell us what knowledge is like *if* there is knowledge.

A more legitimate complaint against the Reliability account of knowledge is that it may turn out to be too restricted. It can perhaps give an account of knowledge of particular, spatiotemporally limited, states of affairs. But what of knowledge of laws of nature, or knowledge of logical and mathematical truth? A lawlike connection between a belief in an individual mind and such general states of affairs as arsenic being poisonous, or $7 + 5$ being equal to 12, is not easy to understand. This difficulty is one which may threaten any naturalistic account of the nature of knowledge.

KNOWLEDGE BY ACQUAINTANCE, AND KNOWLEDGE BY DESCRIPTION. This distinction was made by Bertrand*Russell (see especially Russell, 1914, p. 151). Knowledge by acquaintance is 'what we derive from sense', which does not imply 'even the smallest "knowledge about" ', i.e. it does not imply knowledge of any proposition concerning the object with which we are acquainted. For Russell knowledge is primarily—and all knowledge depends upon—the

'knowledge by acquaintance of sensations'; but when this is expressed in language, and organized by common sense or science, we have knowledge by description. It is a deep question how we learn to name objects of common experience (stones, tables and chairs, etc.) from our private 'knowledge by acquaintance'.

More recently, theories of*perception have blurred Russell's distinction by suggesting that there is no *direct* knowledge by the senses, but that perceptions are essentially descriptions (though by brain states rather than language) of the object world. This follows from the view that perception is knowledgebased and depends upon (unconscious) inference, as suggested in the nineteenth century by Hermann von*Helmholtz and now very generally, if not quite always, accepted. Clearly this philosophical issue is bound up intimately with theories of perception, though it is central for

epistemology.

Russell, B. (1914). *Our Knowledge of the External World*. London.

KOFFKA, KURT (1886-1941). *Gestalt psychologist, born in Berlin. With *Wertheimer and *Köhler, Kurt Goldstein, and Hans Gruhle, he founded the journal *Psychologische Forschung*. This survived for 22 volumes, until 1938 and the rise of Hitler. Koffka spent much of his academic life after 1924 in America. His main works are *The Growth of the Mind* (1924), and many important papers on *perception.

KOHLER, WOLFGANG (1887-1967). Cofounder and leading member of the Gestalt school of psychology, Köhler was born in Reval on the Baltic and educated at Tübingen, Frankfurt, and Berlin. While at Frankfurt, he became acquainted with Max *Wertheimer, and both he and Kurt *Koffka acted as subjects in Wertheimer's classical experiments on apparent visual motion. Between them, they evolved what became known as *Gestalt theory.

In 1913, Köhler went to Tenerife to study the behaviour of anthropoid apes and was perforce obliged to remain there for the duration of the First World War. His celebrated book describing his observations and experiments appeared in German as *Intelligenzprüfungen am Menschenaffen* (English translation *The Mentality of Apes*, 1925). In this book, Köhler developed the important thesis that problemsolving involving detours or simple toolusing comes about through sudden insight, and does not depend on fortuitous trial and error as E. L. *Thorndike had contended. (This controversy was further reviewed by Koffka (1921), who strongly defended Köhler's standpoint.)

Although the Gestalt view of *problemsolving as due to sudden insight has often been questioned, the idea of a 'restructuring' of the field of perception to enable key features previously hidden or unnoticed to be literally 'seen', undoubtedly describes aptly some types of problemsolving—in particular visuospatial—in both higher animals and man. Köhler further laid stress on the ways in which differences of size or brightness might apparently be perceived directly, irrespective of the actual value of the differences themselves.

Köhler was appointed to the chair of psychology at Berlin in 1921, largely on the strength of an important work on aspects of modern physics which he held to be relevant to psychological issues (*Die Physische Gestalten in Ruhe und Stationären Zustand*; translated in abridged form by W. D. Ellis, *A Source Book of Gestalt Psychology*, 1938, pp. 1755). Though exhibiting high intellectual quality, this work is often dismissed as a *synthèse manquée*; none the less, Köhler believed implicitly that the road to scientific advance in psychology is by way of physics, and he attempted to justify this view in many of his later books and papers (cf.

The Selected Papers of Wolfgang Köhler, ed. by Mary Henle (New York, 1971)). All his books are essentially inspired by Gestalt thinking. The most important are: *Gestalt Psychology* (New York, 1929; London, 1930; rev. edn. 1947); *The Place of Value in a World of Facts* (New York, 1938);

Köhler felt obliged for reasons of conscience to abandon Hitler's Germany in 1934 and emigrated
Page 413

to the United States, where he found a congenial home at Swarthmore College, where he remained for nearly all the rest of his long life.

O. L. Z.

KONORSKI, JERZY (1903-73). Polish neurophysiologist and behavioural scientist, born in Lodz. After studying medicine at the University of Warsaw, he visited Ivan*Pavlov's laboratory before returning to Poland to work at the Nencki Institute of Experimental Biology. At the time of his death he was both the director of the Nencki Institute and head of its department of neurophysiology.

Konorski's studies of the relationship and interaction between classical and instrumental*conditioning in the 1930s antedated comparable research in the West by more than a decade. Unfortunately, even the belated English publication of his first monograph, *Conditioned Reflexes and Neuron Organization* (1948), was largely ignored in the West at the time. This book attempted to provide an interpretation of Pavlovian and instrumental conditioning in terms of Sherringtonian neurophysiology. Although his second book, *Integrative Activity of the Brain* (1969), in which he extended his ideas to cover perception and motivation, received more attention, Konorski's full influence on Western psychology became apparent only after his death. The influence of his work and ideas on current research on conditioning and related areas is secondary only to that of Pavlov himself. A.D.

KORSAKOFF SYNDROME. Sergei Korsakoff (1854-1900), a Russian neuropsychiatrist, published in 1887 the first of several papers on a special form of psychic disorder which occurs in conjunction with peripheral neuritis. He mentioned as characteristic such symptoms as irritable weakness, rapid fatiguing, sleeplessness,*memory disturbance, preoccupation with fantasy, and fearfulness. In its modern use the term 'Korsakoff syndrome' refers to a group of symptoms—

known alternatively as the amnesic syndrome—which includes inattentiveness, memory defect for recent events, retrograde*amnesia and other disorders of recall and recognition, and disorientation in time, place, and situation. Confabulation, grandiose ideas, and an inappropriate cheerfulness are prominent symptoms in some cases.

The syndrome can occur without peripheral neuritis, for example as a stage in recovery after trauma to the brain. When it is combined with peripheral neuritis, the term Korsakoff psychosis tends to be used.

The Korsakoff syndrome develops most often in chronic alcoholics who fail to take an adequate diet. This may cause an acute deficiency of thiamine (vitamin B), 1

which produces an acute delirious illness known as*Wernicke's encephalopathy. When or if the patient recovers he will probably be left with the typical features of the Korsakoff syndrome. The

syndrome has seized the interest of neurologists and psychologists because it throws light on normal processes of recall and recognition, although many of the questions it raises have yet to be given precise answers. The memory defect is revealed in the difficulty the patient shows in finding his way about, his forgetfulness in simple matters, and especially his failure to retain information. Also, presented with an object he has been shown a few minutes before, he tends to respond to it as not identical or as in some manner changed. A learning disability can readily be demonstrated in such tests as 'paired associates' and in the delayed recall of pictures of everyday objects. There is a tendency to persist in giving wrong answers, and to fail to 'unlearn'. The deficiency in recalling recent events has been attributed to partial or total derangement of the consolidation of sensory impressions as a permanent memory trace, or entrain, or, to put it another way, to a failure to transfer information from a shortterm to a longterm memory store. Explanation along these lines has to be qualified by the observation that the patient sometimes recalls after a few hours what he has not recalled after a few minutes.

Some of the symptoms have been attributed to lack of insight or lack of selfcritique. A patient with severe memory loss will generally confabulate when questioned about recent activities. That is to say, he will answer incorrectly by describing events that could not possibly have happened. This may give the impression that he is fabricating replies to cover the gaps in his memory. In fact he is doing nothing of the kind. His replies are often accounts of occasions in his more distant past life which are now transposed into the immediate past. He is unaware of the absurd nature of his replies as he is unconscious of the fact that he is answering incorrectly. As Barbizet so neatly put it, 'Confabulation is due to the patient's inability to remember that he can't remember'. If his memory improves he ceases to confabulate and merely replies that he does not know the correct answer to the question which has been put to him.

The lack of selfcritique is shown too when he 'entertains incompatible propositions'. He says, for instance: 'I am fiftytwo years old. I was born in 1920. It is now 1975.' The item most likely to be correct is the year of birth. He does not apply tests to check the correctness of what he has said, as a healthy person tends to do.

One reason may be indolence or passivity. However, by insisting on the incompatibility of the propositions the observer may provoke a 'catastrophic reaction', and this suggests that false propositions are held to as a defence against*anxiety.

Neuropathological studies of patients who have shown the syndrome have contributed to knowledge of the brain structures concerned in memory processes. The floor of the third ventricle is usually affected. The lesion tends to be localized in subcortical structures. The hippocampal region and the mamillary bodies are involved, it has been claimed, in all cases. Recent work has shown that

damage is not confined to these structures. There is also evidence of atrophy of the frontal lobes and dilatations of the cerebral ventricles. This structural damage of the brain has been reported not only in chronic alcoholics but also in young heavy drinkers and may help to explain why it is so difficult for

these subjects to learn new ways of dealing with their drinking problems.

KORTE'S LAWS. A. Korte was a student of the Gestalt psychologist Kurt Koffka, who with Max Wertheimer and others described various kinds of 'apparent movement' elicited by lights switched alternately. The following kinds of movement were distinguished.

movement: pure movement from pairs of flashing lights.

movement: movement of an object from one position to another.

movement: change of size with successive presentation (e.g. of the two arrow figures in the Müller-Lyer illusion).

movement: expansion or contraction with, respectively, increasing or decreasing illumination.

movement: 'reversed' movement occurring when the later stimulus is much brighter than the earlier. This movement is in the opposite direction to the order of presentation.

Korte's laws refer to the time interval and separation of alternating pairs of stimuli for giving optimal apparent movement. Perhaps, though, 'laws' is too strong a word for such variable effects.

Boring, E.G. (1942). *Sensation and Perception in the History of Experimental Psychology*, pp. 596-7. New York.

KRAEPELIN, EMIL (1856-1926). German psychiatrist, educated at Würzburg, who became professor of psychiatry at Dorpat (1886), Heidelberg (1890), and Munich (1903). He was probably the only psychiatrist of his day to study with Wilhelm Wundt, thereby acquiring considerable understanding of experimental methods. This he passed on to many of his early students of psychiatry, some of whom carried out experiments with their patients, in particular, studies of reaction times and mental disorders. Kraepelin is best known for the fundamental distinction which he drew between manic-depressive psychosis and schizophrenia (then known as dementia praecox). His textbook of psychiatry, which went into several editions, was for many years the standard text.

O. L. Z.

KRAFFT-EBING, RICHARD VON, Baron (1840-1902). German neurologist, born at Mannheim and educated at Prague; he became professor of psychiatry at Strasbourg in 1872, at Vienna in 1889. He established that general paralysis of the insane can be a late manifestation of syphilitic infection. This

was one of the first clear examples of severe personality change and, finally, loss of mental abilities and behaviour from a specified organic brain disease. It led to identifying the effects of chronic intoxication with alcohol, lead, and other substances which may be pollutants.

KRETSCHMER, ERNST (1888-1964). German psychiatrist, educated at the University of Munich, where he studied under Emil Kraepelin. He worked at Tübingen and then at Marburg, where he was appointed professor of psychiatry and neurology. He is best known for his books *Körperbau und Charakter* (1921;

English trans. *Physique and Character*, 1925) and *Geniale Menschen* (1929; English trans. *The Psychology of Men of Genius*, 1931). Although his attempts to correlate body build with types of psychosis proved to have little importance in psychiatric diagnosis, Kretschmer's work did much to reawaken interest in the relations between body build and qualities of temperament or personality.

O.L.Z.

KÜLPE, OSWALD (1862-1917). German philosopher and psychologist born at Kandau in Courland, at that time part of Russia and later Latvia, where he had strong German connections. He was educated at the universities of Leipzig and Berlin, where he studied history, but his major interests soon turned to philosophy and psychology, in large part due to the influence of Wilhelm Wundt. After studying experimental psychology for a time with G. E. Müller, Külpe returned to Leipzig, where he obtained his doctorate under Wundt. Thereafter he divided his interests more or less equally between philosophy and psychology, both of which he taught for the rest of his life, first at Würzburg, where his most important work in experimental psychology was done, and later at Bonn and Munich.

Külpe produced a large number of books, of which the best known are his *Grundriss der Psychologie* (1893) of which an English translation was published in 1905, and *Einleitung in die Philosophie* (1898), which was likewise translated into English and became highly popular in its day. His *Vorlesungen über Psychologie* was published posthumously in 1922. In addition he published a book on Kant and wrote widely on issues in aesthetics and ethics and even wrote a book on *Psychology and Medicine* (1912).

It was as a professor at Würzburg that Külpe established what came to be known as the Würzburg School of Experimental Psychology, which offered a strong challenge to Wundt's contention that the thought processes lie beyond the scope of experimental study. As an example of the Würzburg method one may, for instance, refer to an experiment in which the subject was asked to

Page 415

read a series of unrelated words and in each case to produce a spoken word logically related to the stimulus word—e.g. 'bird': 'wing'. Reaction times were measured and introspective reports recorded in detail. In such an experiment it was found that the subject invariably made a kind of generic preparation for the task in hand. The preliminary instruction orientated him towards the general theme, e.g. that of subordination, which produced a kind of preselection from among all possible

responses available to the subject. In Würzburg jargon, what came to be called the 'determining tendency' was released by the task (*aufgabe*) which enabled a preexisting reproductive tendency to be raised to supraliminal strength. It was further supposed that the determining tendency was seldom represented directly in consciousness, and that a selective and facilitating influence on certain preexisting associations took place, leading to what is essentially an act of constructive recall.

Although this interpretation of a very simple act of reproduction might sound unduly elaborate, it does provide an advance on the classical conceptions of association by continuity or similarity which were taken over from the philosophy of mind; indeed it may be said that Külpe's thinking had some of the originality—as well as the obscurity—which characterized the work of Sigmund*Freud.

A second advance which we owe to Külpe is likewise reminiscent of Freud in his insistence on the reality of so-called 'imageless thought'. Again and again in the experiments of Külpe and his colleagues, states of mind were reported in which no images could be detected, in spite of the fact that most of the subjects, including Külpe himself, were highly intelligent and well practised in introspective selfobservation. It was alleged by almost all these subjects that no amount of introspective sophistication enabled such states as confidence or doubt to be brought under the rubric of sensation, image, volition or feeling which, in the view of Wundt and others of his time, were regarded as primary and irreducible.

The question of whether or not thought without images really exists became one of the most controversial issues in experimental psychology. A number of ingenious experiments, which it was hoped would settle the matter for good, were reviewed by George Humphrey (1951) without any clearcut solution being found. All the same, Humphrey was right to conclude that the fundamental thesis of the Würzburg School had been well sustained by a majority of the experimentalists working on the problem. Moreover, as Humphrey pointed out, among the great names of philosophy it would be hard to find one, apart from Hume, who states unequivocally that thinking can be described in terms of images.

L

LABORATORIES OF PSYCHOLOGY. The first laboratories for carrying out experiments under controlled and isolated conditions were devised by the alchemists, and much of their apparatus is to be found almost unmodified in modern chemical laboratories. The first laboratory of experimental psychology was founded by Wilhelm*Wundt at Leipzig in 1879, in an old building which has not been

preserved. Many celebrated psychologists received their training at this first laboratory: A. Lehmann and O.*Külpe; and from America G. Stanley*Hall, J.*Cattell, E. W. Scripture, Frank*Angell, E. B.*Titchener, G. M. Stratton (famous for his inverting spectacles experiment), and C. H. Judd, also a pioneer in the study of visual*perception.

In America, William*James, although not himself much of an experimenter, introduced physiological psychology to Harvard in 1875. He persuaded Harvard to spend \$300 on 'physiological' apparatus and to set aside two rooms in the Lawrence Scientific School, where he held a class on 'the relations between physiology and psychology'. In 1877 he added space in Harvard's Museum of Comparative Zoology.

In Russia, Vladimir Bekherev (1857-1927) founded a laboratory at Kazan, where learning, psychopathology, and alcoholism were investigated. The first officially recognized institute of psychology, at Moscow University, was not, however, founded until 1911, and this was based on German psychological theory of the 1880s.

The first psychological laboratory in Britain was founded at Cambridge in 1879, under the direction of W. H. R.*Rivers. It became effective under C. S.*Myers from 1913, and was directed by Sir Frederic*Bartlett from 1931 to 1952 and by Oliver Zangwill until 1981, then by Nick Macintosh.

The Oxford Institute of Experimental Psychology was founded in 1936. It is now the largest psychological laboratory and teaching department of psychology in Britain. Only three years before its foundation, William Brown (then the Wilde Reader in Mental Philosophy) wrote, in the *Oxford Magazine* of 11 May 1933:

'Psychology has encountered more difficulty breaking away and finding its own level in Oxford than in any other university . . . Oxford is the only great university in the world which still has no laboratory in experimental psychology.'

The post of Wilde Reader in Mental Philosophy was founded by Henry Wilde in 1898. It was first held by G. F. Stout, then by William*McDougall—who violated the original stricture that no experiments were to be undertaken. It has been suggested that this bizarre restraint reflected the comment of a Cambridge mathematician, that it 'would insult religion by putting the human soul in a pair of scales'. However this may be, Wilde's bequest required that: 'The Reader shall from time to time lecture on illusions and delusions which are incident to the human mind. He shall also lecture, as far as may be practicable, on the psychology of the lower races of mankind . .

.' This statute has since been changed.

The present laboratory owes its creation to a student of McDougall's, Mrs Hugh Watts, who in 1935 donated £10,000 to the University for this purpose, thus inspiring the university to action. The Second Chair of Psychology—which was held by Jerome Bruner, and then by Peter Bryant—is named after Mrs Watts.

Experimental psychology was not a subject for undergraduate teaching in Oxford until 1947. The first

professor was George Humphrey, who came to Oxford from Queen's University, Ontario. (He said that he first learned of Oxford's interest in him when he read of his appointment in *The Times*.) He was succeeded by Carolus Oldfield. The institute was housed in a medley of small buildings (the professor's office was a converted lavatory) in Banbury Road; then in a large Victorian house in South Parks Road. It changed its name from 'Institute' to 'Department' upon moving into its present magnificent specially designed building, which is shared with zoology, in South Parks Road. The professor and head of the department, Laurence Weiskrantz, who moved from America to Cambridge before his appointment at Oxford, supervised this vast expansion and built up a wideranging department which is internationally in the top league for teaching and research.

R.L.G.

Boring, E. G. (1950). *A History of Experimental Psychology*. 2nd edn. New York.

LABYRINTHS (OF THE EAR). A complex organ for attaining balance, provided by a fluid in three orthogonal circular tubes (the semicircular canals; see HEARING), which moves beads of calcium carbonate suspended on hairs, and so activates special nerves sending signals to the brain of movement of the head. In Ménière's disease, these signals occur inappropriately, through damage of the hair cells, to produce dangerous unpleasant dizziness. The condition is most frequent in middle life and it generally subsides of its own accord.

Page 417

LADD, GEORGE TRUMBULL (1842-1921). Pioneer American psychologist whose lifelong interest lay in the relations between the nervous system and mental phenomena. A professor of philosophy at Bowdoin College and later at Yale, his principal work was *Elements of Physiological Psychology* (1887).

LAING'S UNDERSTANDING OF INTERPERSONAL EXPERIENCE. The British psychiatrist R. D. Laing's contribution to the understanding of the mind operates in a field that can be broadly characterized as empirical interpersonal phenomenology, which is a branch of social*phenomenology. The field of social phenomenology has been cultivated from the standpoints of anthropology, sociology, psychology, and philosophy. Any work of social phenomenology from any one of these points of view has implications for all the other perspectives which are knit together by the common discipline of phenomenology.

At present there is no overall definition or system of phenomenology agreed upon by all self-styled phenomenologists, and even someone who disclaims phenomenology, such as the French historian Michel Foucault, may nevertheless be regarded as embodying much phenomenology in his theory and method.

Laing has been mainly concerned to see and to describe what goes on in people's experience, as mediated by their interactions.

Everyone knows that our feelings are affected by how our nearest and dearest feel about us. But this

is a devilishly difficult area to study for many reasons. 'Galilean'

natural science, in which we are all brought up, is a theory especially and explicitly designed to see the world without reference to personal passions. This theory and method is as irrelevant to the study of interpersonal experience as interpersonal experience is to it. But what then shall be our method? Is such a project possible by any method?

The philosophy, anthropology, sociology, and psychology of interpersonal relations are all in an unsatisfactory state despite the *aperçus*, insights, and intuitions of*Hegel, Dilthey, Buber, Goffman,*Husserl, Sigmund*Freud, Schultz, Marx,*Nietzsche, Scheler, Heidegger,*Sartre, Foucault, MerleauPonty, Bateson, MacMurray, and others, in and out of phenomenology, who have influenced Laing's work.

The philosophical foundations of a 'dialogal knowledge' have not so far been comprehensively and systematically laid down. The epistemological status, for instance, of the nature of the knowledge we derive from the study of how we affect each other remains unclarified; and, within some current ways of seeing and modes of thought, the very possibility of persons is hardly conceivable other than as the ghost of a category already *dépassé*.

Not only is there an absence of such desirable philosophical foundations but the problems of method are as vexing as they are unresolved. In some respects they have not yet even been explicitly formulated. Nevertheless, Laing has studied various facets of very disturbed and disturbing personal relations.

These studies grew out of, and have moved away from, his work as a psychiatrist and psychoanalyst. From the beginning he did not look at what he saw as a psychiatrist from the usual psychiatric point of view. The attribution of the absence in the other of the capacity to form good enough personal relationships is the basis for the diagnosis of*schizophrenia. This diagnosis is both an attribution (he is incapable of forming a personal bond; he is cut off) and a causal theory to account for this attribution (the reason he is cut off is because he is suffering from a mental or physical illness).

In *The Divided Self* Laing construed this attribution as a function of an extremely disjunctive relationship between the person who is in the role of a depersonalized—

and depersonallizing—diagnosing psychiatrist and the person who has become a depersonalized, and sometimes depersonalizing, diagnosed patient. This construction is a contribution towards a personal understanding (* *Verstehen*) of what is going on between psychiatrist and patient, in contrast to a scientific explanation of what is going on in the patient alone. In fact, he offered a personal understanding of the psychiatrist's scientific explanation and construed it as, unwittingly, a way of cutting off the cutoff person from the possibility of reunion and renewal.

The psychiatric, diagnostic look is itself a depersonalized and depersonalizing cutoff look. It is an application of a highly sophisticated scientific look that is culturally deeply conditioned. It is a way of seeing *things*, and the relation between things, by subtracting all personal experience. However, a

person is not a thing, nor is a thing a person. It is a look which is cultivated with the express intention of not seeing intentions out there. Things have no intentions. It is the exact opposite of a sensibility cultivated with the express intention of recognizing and sympathetically understanding the intentions of others, and their interconnections.

The scientific, psychiatric, and medical look is an acquired technique, adapted to the elimination of the conditions of the possibility of understanding. To understand what is going on in and between people it is necessary to place the interpersonal happenings within their social context.

In a series of studies, Laing investigated the family contexts of diagnosed schizophrenics. The theory behind this work was largely influenced by Sartre's *Critique of Dialectical Reason*; in particular, the distinction made there between praxis and process, and the relation between them. There is an interplay between the dynamic structure of any human multiplicity and the intentions and actions of its members. When the psychosocial interior of the families of schizophrenics was looked at from the twin perspectives of praxis and process, instead of looking at the schizophrenic alone, it appeared that those experiences and actions which are Page 418

regarded as the signs and symptoms of a pathological process within one individual were much more socially intelligible than they had been taken to be by most psychiatrists.

This claim is quite uncontentious and nonexclusive, but it has led to a lot of controversy, and to a lot of contentious misunderstanding. It does, however, keep open the rationality of a response to a quintessentially personal type of suffering, with its confusions, terrors, mystifications, and disarray, based on a personal understanding of it.

As Chairman of the Philadelphia Association, London from 1965 to 1982, Laing was involved in the provision of social contexts where people in disturbed states of mind could live, at their own choosing, on their own discretion, in their own way. Some of the experiences that emerged in these contexts were very unusual. In contemporary psychiatric practice they had never been allowed to happen. A notable feature of some of the accounts is the way some people's minds go through transformations which, if they are allowed to continue and if they do not lose their own momentum, seem to eventuate in a clear, balanced state of mind. Reports of similar experiences from comparable contexts, suggested in the first place by the London experiment, point in the same direction. Reports from the National Institute of Mental Health and elsewhere have shown that when these transformations are allowed free rein, in a socially facilitating, endorsing, validating, encouraging context, the

'results', viewed from the objective statistical standpoint, look as good as or better than those of conventional psychiatric treatment.

In the years since 1970 Laing's work has been concerned with all aspects of *biopolitics*: namely, the issues of power which cluster and accrue to all phases of the human lifecycle, from conception to death. Who makes and whence comes decisions about who can, must, cannot, must not, do what to whom, and in what circumstances? By what diktat is it determined what may or may not be done to us

before we are born, when we are giving birth, or being born? Who says, of mothers and babies, who can be with whom? What can or cannot be done to us when we are in a state of mental, emotional, or physical collapse? How do we treat each other when we are helpless? Who says how and where and in what company we must, or may, or may not die? What happens between us at the interface of maximum and minimum power, as during a surgical operation?

There is so much that goes on between us which we can never know. The necessity of this ignorance, and the impossibility of any satisfactory criteria of decidability when it comes to the validation of particular attributions of a personal and interpersonal order, have led those who wish to cultivate the art of the soluble to abandon this area of uncertainty and enigmas. However, this domain does not evaporate because the objective look does not see it. The great divide between fact and feelings is a product of our own schizoid constructions.

In reality, the reasons of the heart and the physiology of the brain coexist and must be interdependent. We cannot construe this reality, however. We cannot explain it, much less can we understand it.

Many people recognize themselves in Laing's descriptions, but when they feel his constructions are correct it may simply be that they share with him their illusions.

Those who disagree with his constructions and do not recognize his descriptions (of psychiatrists and patients, husbands and wives, parents and children, lovers, and others) regard his work with reserve and suspicion. There has been a lot of confusion.

However, it has always been part of Laing's method to attempt to depict his way of seeing as a contribution to the understanding of what comes into view or not, is seen or not, from whatever point of view. This methodological reflexivity is necessarily reflected in his own style of depiction. It therefore may turn out that the main significance in Laing's work lies in what it discloses or reveals of a way of looking which enables what he describes to be seen.

Laing's principal works include: *The Divided Self* (London, 1960); *The Self and Others* (London, 2nd edn., 1969); *Knots* (London, 1970); *Sanity, Madness and the Family* (with A. Esterson, Harmondsworth, 1970); *The Politics of the Family* (London, 1971); *The Politics of Experience* (London, 1978); *The Voice of Experience: Experience, Science, and Psychiatry* (Harmondsworth, 1983); and *Wisdom, Madness, and Folly: the Making of a Psychiatrist* (London, 1985).

R.D.L.

LAMARCK, JEANBAPTISTE DE (1744-1829). Born at Bazantin, he joined the French army in Germany at the age of 17, and while stationed at Toulon and Monaco became interested in Mediterranean flora. He resigned after an injury and worked on botany, publishing a *Flore française* in 1778. He became Keeper of the Royal Garden—the nucleus of the Jardin des Plantes—where he lectured for a quarter of a century on invertebrate zoology. He began to consider the origin of species about 1800; the result was his *Philosophie zoologique* (1809), and his *Histoire naturelle des animaux sans vertèbres* (1815-22). By stressing the variation of species he was a pioneer,

before*Darwin, of an evolutionary account. His view that characteristics acquired by individual experience can be inherited was popular politically, and educationally, even though variation of species was opposed to religious belief in special creation. Darwin accepted*Lamarckianism (inheritance of acquired characteristics), but apart from occasional claims it has now been abandoned. Lamarck's evolutionary views were opposed particularly by Cuvier, who effectively destroyed him. Lamarck became blind, and died in poverty. Shortly after his death he was honoured by a vast monument, which still stands.

Page 419

LAMARCKIANISM is the doctrine that what is learned by individual experience can be inherited by the offspring. It is named after the distinguished French anatomist JeanBaptiste de*Lamarck, whose books had considerable influence. Charles*Darwin accepted the Lamarckian thesis, even to the extent of advising young women to learn as much as they could (including manly skills!) before starting their families (in *The Descent of Man*, 1888).

Inheritance of acquired characteristics appeared highly unlikely following the acceptance of Mendel's laws of inheritance, first appreciated in 1900, and with the development of the gene theory of inheritance in the 1920s. Many experiments have been conducted to test the issue, but none have convincingly shown inheritance of memories or learned skills. The collapse of Lamarckianism has consequences for accounts of ethics which may be upsetting—for, however hard one struggles to be good or wise, one's virtue as acquired by one's own efforts dies with one. Possibly the neoDarwinianism which rejected inheritance of acquired characteristics—

arguing that evolution depended entirely upon random genetic variation and selection of the fittest to survive and procreate—was resisted largely because of its moral implications: it might reduce motivations towards good behaviour. (See EVOLUTION: NEODARWINIAN THEORY.) Lamarckianism was the basis of Russian agricultural policy under Lysenko, though with unfortunate results. It is still not dead: every few years claims are still made of inheritance of acquired characteristics, and to a limited extent it just might be possible.

LA METTRIE, JULIEN OFFRAY DE (170951). French philosopher and army surgeon. His courageously expressed mechanistic ideas became so unpopular that he lived in exile in Leiden, where he published perhaps the first clear account of man as a machine: *L'homme machine* (1748); English version, Gertrude C.

Bussey, *Man a Machine* (1953).

LAND COLOURS. The American inventive genius Edwin Land (inventor of 'instant' photography, and polaroid filters) discovered (following some early experiments by C. H. Judd) that although, as Thomas*Young showed in 1801, three spectral colours are required to match any spectral hue (see COLOUR VISION), a remarkable range of colours is produced by only two colours, for patterned or picture displays. Thus, a pair of photographs taken one with a red and the other with, say, a yellow or a green filter, or even white with no colour, give almost perfect colour pictures when combined with

a pair of slide projectors each fitted with its appropriate filter. This led Land to develop his Retinex theory of colour vision, which suggests that colours are seen by ratios of different intensity regions, which may be quite widely separated, rather than only from the relative stimulation of neighbouring 'red', 'green', and 'blue' cone receptor cells. These Land effects are related to the wellknown colour contrast phenomena, which were investigated by*Goethe, but they are gradually forcing a revision of understanding of colour vision. See RETINEX THEORY AND COLOUR CONSTANCY.

Land, E. H. (1977). The Retinex theory of color vision. *Scientific American*, 237, 6, 10828.

Matthaei, R. (ed.) (1971). *Goethe's Colour Theory*. London.

LANGE, CARL GEORG (1834-1900). Danish psychologist and materialist philosopher working in Copenhagen. Independently of William*James, he arrived at an almost identical theory of*emotion, i.e. that emotion consists of the bodily changes evoked by the perception of external circumstances. Lange, however, placed far greater stress on the role of the cerebrovascular system in the genesis of emotion than did James. None the less, their views are so similar that the theory has always been known as the JamesLange theory of emotion. Lange's principal work first published in Denmark in 1885 became widely known in German translation as *Über Gemustsbewegungen* (1887). The respective contributions of James and Lange were brought together in a book entitled *The Emotions* (ed. K. Dunlap, 1922).

O. L. Z.

LANGUAGE, CHINESE EVIDENCE FOR THE EVOLUTION OF. See CHINESE EVIDENCE FOR THE EVOLUTION OF LANGUAGE.

LANGUAGE: CHOMSKY'S THEORY. In undertaking the study of mind, it is useful to consider the less controversial question of how we study a complex physical system such as the human body. We assume that the species is characterized by a certain biological endowment. The embryo grows to the adult as its genetic programme unfolds, under the triggering and controlling effect of the environment. The organism does not 'learn' to grow arms or reach puberty. Rather, the general course of maturation is genetically determined, though the realization of the genetic plan depends in part on external factors. The result is a system of interacting organs—the heart, the visual system, etc.— each with its structure and functions, interacting in largely predetermined ways.

It is fortunate that we have such a refined and specific innate endowment. Were this not so, each individual would grow into some kind of amoeboid creature, merely reflecting external contingencies, utterly impoverished, and lacking the special structures that make a human existence possible. Naturally, the same innate factors that permit the organism to transcend environmental factors, reaching a remarkable level of complexity of organization that does not 'mirror' the limited environment, rule out many possible courses of development and limit drastically the final states that can be reached in physical growth.

Little is known about how any of this happens, but no one seriously doubts that something of roughly this sort is true. Why? Because of the vast qualitative difference between the impoverished and unstructured environment on the one hand, and the highly specific and intricate structures that uniformly develop, on the other.

Turning to the human mind, we also find structures of marvellous intricacy developing in a uniform way with limited and unstructured experience. Language is a case in point, but not the only one. Think of the capacity to deal with abstract properties of the number system, common to humans apart from gross pathology, and, it seems, unique to humans. The essence of this system is the concept of adding one, indefinitely. The capacity is not 'approached' by the ability of some birds to match patterns of n objects for some finite (and small) n , just as human language with its discrete infinity of meaningful expressions constructed by abstract rules crucially involving operations on phrases is not simply 'more' than some finite system of symbols imposed on other organisms— or, for that matter, just as the ability of a bird to fly, though finite, is not simply an extension of the human ability to jump; whatever the evolutionary history may have been, quite different mechanisms are involved. The capacity to deal with the number system or with abstract properties of space—capacities that lie at the core of what we might call the human 'scienceforming faculty'—are no doubt unlearned in their essentials, deriving from our biological endowment. One can think of many other examples.

These systems have many of the relevant properties of physical organs. We might think of them as 'mental organs'. Thus the human language faculty might well be regarded on the analogy of the heart or the visual system. It develops in the individual under the triggering effect of experience, but the mature system that grows in the mind (that is 'learned', to use the standard but misleading term) does not 'mirror' the contingencies of experience, but vastly transcends that experience. True, there are differences among individuals contingent on experience; some know English, others Japanese. Similarly, onset of puberty varies over some range, as does body size, or the ability to pole vault, or the distribution of cells of the visual cortex specialized to respond to lines of particular orientation in the visual field. But the pole vaulter will never fly like a bird (even a chicken), and the human language faculty will never grow anything but one of the possible human languages, a narrowly constrained set.

In brief, our genetic endowment provides for the growth and maturation of special mental organs, the language faculty being one. The development of these systems is essentially uniform among individuals. Two people from the same speech community can converse freely on some topic new to them despite substantially different experience, despite the fact that the sentences they produce and understand bear no direct analogy to anything that they have heard. Their minds contain roughly comparable rule systems of highly specific structure determined in general character by some property of the human species. These rule systems cannot be derived from the data of experience by 'induction', 'abstraction', 'analogy', or 'generalization', in any reasonable sense of these terms, any more than the basic structure of the mammalian visual system is inductively derived from experience.

As in the case of the physical body, we are fortunate to have this rich innate endowment. Otherwise, we would grow into 'mental amoeboids', unlike one another, merely reflecting properties of the impoverished environment, lacking the finely articulated structures that make possible the rich and

creative mental life that is characteristic of all humans who are not severely impaired by individual or social pathology. These same innate factors provide the basis for a social existence in common with others whose capacities are not unlike our own despite accidents of individual history. We live in a world of shared understanding that extends far beyond the limited experience that evokes cognitive structures in the mind.

Again, the very same innate factors that provide for the richness and variety of mental life, shared with others comparably endowed, impose severe bounds on what the mind can achieve. Scope and limits are intimately related. Our inability to fly like birds derives from the same innate properties that enable us to become humans rather than amoeboid creatures. Comparably, the fact that there are many imaginable languages that we could not develop through the exercise of the language faculty is a consequence of the innate endowment that made it possible for us to attain our knowledge of English or some other human language. Similarly, the fact that there are no doubt many systems of musical organization that we simply could not comprehend or enjoy should be a source of satisfaction, because it reflects the same innate endowment that enables us to appreciate Bach and Beethoven. And the fact that many possible branches of science lie beyond our cognitive reach should cause no dismay when we realize that it results from that innate scienceforming capacity that permits the construction of intelligible explanatory theories on weak and limited evidence in at least some domains of thought. And so on.

This talk of 'mental organs' should not mislead. We can discuss a physical organ—say the visual system—in terms of its abstract properties, knowing little about its physical realization. Nothing more than this is implied when one speaks of the mind as a system of mental organs, or when one studies these organs and their interaction as systems of mental representation and mental computation.

How can we proceed to gain insight into the specific properties of particular mental organs?

Page 421

Consider the case of language. There are three basic questions that arise: (i) What do we know when we are said to know a language? (ii) What is the basis for the growth of this knowledge? (iii) How is this knowledge put to use?

The answer to the first question seems to be that knowledge of a language is mentally represented as a 'grammar'—that is, a finite system of rules and principles that interact to determine ('generate') an infinite class of expressions, each with a phonetic form, meaning, and associated structural properties (for example, an organization into words and phrases). As for (ii), it seems that many of the fundamental properties of these grammars are part of innate endowment, so that the child in effect knows in advance what kind of grammar he must construct and then must determine which of the possible languages is the one to which he is exposed. Study of (iii) leads to the construction of 'performance models' that have access to the grammar—the knowledge of language—represented in the mind.

To illustrate with a simple example, consider the reciprocal construction in English: such sentences

as 'The men saw each other', 'I asked them about each other', 'We shot arrows at each other', etc. The rule of grammar governing these constructions specifies that the expression 'each other' requires a plural antecedent. Once the antecedent is found, we apply the dictionary rule of interpretation to fix the meaning: roughly, that each of the men saw the other men (or man), etc. However, it is not always so easy to select an antecedent. Sometimes it lies in a different clause, as in 'The candidates wanted [each other to win]' or 'The candidates believed [each other to be dishonest]'. In these sentences the bracketed expression is a subordinate clause with 'each other' as its subject, just as in 'John wants [Bill to be successful]'

'Bill' is the subject of 'be successful' in the bracketed subordinate clause. The antecedent of 'each other' lies outside the clause. But we cannot always select an antecedent outside of the subordinate clause. Consider 'The candidates believed [each other were dishonest]' (compare 'The candidates believed [their opponents were dishonest]') or 'The candidates wanted [me to vote for each other]' (compare 'The candidates wanted [me to vote for them]').

Such facts as these are known to all speakers of English, and analogues appear to hold in other languages. The facts are known without experience, let alone training.

The child must learn that 'each other' is a reciprocal expression, but nothing more, so it seems. No pedagogic grammar would mention such facts as those described above; the student can be expected to know them without instruction. The principles that determine selection of an antecedent, it seems reasonable to assume, belong to 'universal grammar', that is, to the biological endowment that determines the general structure of the language faculty. From another point of view, these principles form part of a deductive, explanatory theory of human language.

Proceeding in this way, we can attempt to construct grammars that answer question (i), a theory of universal grammar that in part answers question (ii), and performance models that incorporate grammars, answering question (iii). In so far as it succeeds, this quest provides the theory of a particular mental organ. Others can be studied in the same way, and in principle we should be able to proceed to the study of the interaction of such systems—a central topic as soon as we turn to the study of word meaning, for example.

This seems to be a reasonable paradigm for the study of mind, one that has achieved a certain measure of success and holds much promise for the future.

LANGUAGE: LEARNING WORD MEANINGS. It may seem at first sight easy to tell when a child knows what a word means. When a little girl of thirteen months sees a ball, says 'ball', and then

at once goes to pick it up, the obvious conclusion may appear to be that the meaning of the word is now known to her. But if, during the next month or so, she is heard to say 'ball' on seeing a balloon, an Easter egg, a small round stone, and so on, doubts must begin to arise; and it may then seem wiser to replace the first conclusion by the more guarded one that the word 'ball' has now entered her lexicon and that her knowledge of its meaning has begun to grow.

The above example is not invented. It is provided by Bowerman (1978) from a study of her daughter, Eva. And many similar instances have been recorded by Bowerman and others. So it is clear that, even in the case of 'simple' words like 'ball', the acquisition of word meaning is not an all-or-none affair. Word meanings grow and change—a fact stressed by Vygotsky (1962), who regarded it as central to an understanding of the development of thought and language. Thus it is by no means so easy as one might suppose to give a straightforward answer to the question: how large is a child's vocabulary, on average, at different ages? Differences in the manner of collecting and handling the data (whether, for instance, the past tense of a verb is to be treated as a separate word or not) have led to widely differing estimates. However, normal children certainly have several thousands of words which are in some sense in their vocabulary by the age of 5. This means that some very rapid and efficient learning must go on.

Although nouns which name familiar objects—or people—are frequently among the earliest words that a child produces, the vocabulary, even in the beginning, need not be limited to words of

Page 422

this kind. Expressions such as 'all gone', 'more', and 'byebye' are common. Nelson (1973) reports marked individual differences in this respect among the children she studied: some used many object names, others were more inclined to use words expressing feelings and needs. However, some later studies (e.g. Benedict, 1979) suggest that children have early vocabularies that represent all word classes. It is in any case a problem to know how to classify words in this stage of a child's development, since even a common noun, when used by a very young child, appears to function not just as a label but rather as a substitute for some more complex utterance (expressing a limited range of communicative acts such as interest, desire, intention, etc.) of which the child is not yet capable.

Commonly, when a young child begins to use a word, the meaning is 'overextended', as in Eva's use of 'ball': that is, the range of referents to which the child applies the word is wider than in normal adult usage. Sometimes the extension is to objects all of which share with the original referent some common perceptual feature. All Eva's

'balls' have rounded contours. But the rule that governs extensions need not be of this straightforward kind. Vygotsky (1962) reports a principle of grouping known as a 'chain complex', where each new referent has a feature in common with some other, but where no single feature is common to them all. Thus the word 'quah' may be used first of a duck in a pond; then of any liquid; then of a coin with an eagle on it; then of any round object resembling the coin.

Bowerman did not find that chaining was common in the speech of her daughters; but she reports

frequent occurrence of a kind of extension, also noted by Vygotsky, where the first referent serves as a nucleus or 'prototype', so that later referents all have some feature in common with it, though, as in 'chaining', they may not have any feature in common with one another. Thus for Eva the word 'close' had as its nucleus the act of closing a drawer or a box and was later used for the act of folding a towel (shared feature: bringing two parts into close contact) and of turning the knob on the TV set till the picture darkens (shared feature: hiding or concealing something).

Some theorists have suggested that a prototype or central exemplar may function as a kind of unanalysed image or 'schema'. But, as Bowerman and others have pointed out, there is no reason to think that the existence of prototypes makes featural analysis unnecessary; and there is every reason to think that such an analysis must actually occur on some level even at very early stages in language acquisition.

A second kind of departure from Eva's overextension of 'ball' involves extension to objects which share with the original referent not some perceptual feature but some function. Thus the word 'ball' might be applied not to other round objects but to other objects able to be bounced or thrown. Nelson (1974) argues that, when the children are developing their first word meanings, function is more important than form. But this claim has been disputed and is certainly not proven. What is clear is that, from a very early stage, a child may use either perception of similar form or knowledge of common function (or both) as the basis for a generalization of word meaning—a generalization which may go beyond the limits of the accepted adult norm.

There is nothing surprising in the fact that children initially make such mistakes. It would indeed be astonishing if they were to arrive at a knowledge of the limits of adult usage by one simple assimilative move. It is much more reasonable to think of them as entertaining hypotheses—though these are unlikely to be consciously articulated—and modifying them progressively as more evidence is obtained.

So far we have considered only evidence that comes from observation of a child's use of language. However, knowledge of word meanings must also manifest itself in understanding. The problem is that when one considers both the evidence of how young children use language and the evidence of how they understand it, there is often a lack of accord between the two.

For instance, though children are apt to overextend meanings when they produce words, they do not consistently do the same thing when they interpret the words of others (Huttenlocher, 1974). If anything, a child may initially interpret a word more narrowly than an adult would do. Thus Reich (1976) reports that his son, Adam, in response to 'Where's the shoes?' would crawl only to the shoes in his mother's shoe cupboard, bypassing shoes on the floor to get there. Later he would also crawl to shoes in his father's cupboard; then to shoes on the floor, but not to shoes on someone's feet; and finally to shoes wherever they happened to be.

The assumption that there is a single 'word store' drawn on in the same way for comprehension and for production is thus called in question; and a related challenge arises when one considers evidence about the interpretation of words in longer utterances by older children. If a child understands an

utterance, it may seem obvious that the words which compose it are 'known' and that, in the process of making sense of the utterance, each of these words is given 'its meaning'. But this is to suppose that a child interprets the language in isolation from its immediate context, which is not what typically happens. Macnamara (1972) argues that it is only to the extent that children understand *situations* that they are able to begin to work out the meaning of the language that is used in them; and this view is now widely accepted. Thus a child can begin to learn the meaning of 'Do you want some milk?' because when someone picks up a jug and holds it over a cup the intention to offer milk is understood. On this view it is to be expected that for a long time the interpretation of language should remain, for the child, embedded in, Page 423

and powerfully dependent on, the context of occurrence.

There is now clear experimental evidence that this is so. What a child takes an utterance to mean is liable to be determined not just by knowledge of the language but also by an assessment of what the speaker intends (as indicated by nonlinguistic behaviour) and by the impersonal context in which the language is being used. In one study, Donaldson and McGarrigle (1974) found that children aged between 3 and 5 who correctly judged that a row of five cars contained more cars than a row of four might reverse this judgement a moment later when the four cars were enclosed in a row of four garages (so that this row was 'full') while the five cars were enclosed in a row of six garages (so that one garage was left empty). One is tempted to say, then, that these children gave 'more' a different meaning on the two occasions; and yet to put it this way is probably to suggest a more analytic, wordbyword, interpretation than actually occurs, at any rate at the level of the child's conscious awareness. (It seems that children have only a limited awareness that the flow of language is broken up into words at all; and yet of course if they did not break it up this way, at some level, how could they produce, in their turn, words organized into new utterances which they have never heard before? Much that goes on in language learning is clearly not conscious.)

Attempts have been made to study children's ability to arrive at word meanings by giving them 'nonsense words' in linguistic contexts so devised that inferences as to meaning are possible. A classic study by Werner and Kaplan (1950) used such sentences as

A corplum may be used for support.

A wet corplum does not burn.

You can make a corplum smooth with sandpaper.

Children proved to be very bad at deriving the meanings of isolated words from a series of examples of this kind. (See also Campbell and Bowe, 1978.) It seems clear, then, that nonlinguistic contexts are essential for the early stages of the growth of wordmeaning. And recent work has emphasized also the early importance of *conversational* contexts, within which the child's use of singleword utterances gradually shifts from a limited to a wider range of communicative acts, and eventually to the *predicative* function (as in uttering a comment on an adultintroduced topic) that appears to mark the threshold into early word combinations (Dore, 1985; Griffiths, 1985). But it is perhaps only with the

advent of literacy that language starts to become sufficiently 'disembedded' to be considered and reflected upon as a system in its own right (cf. Donaldson, 1978 and Perera, 1984), so that linguistic contexts alone can begin to provide the basis for additions to the mental lexicon.

LANGUAGE: NEUROPSYCHOLOGY. In the psychological analysis of the breakdown of language and speech in neurological disorders the main emphasis is on acquired*aphasia (disorders of language in patients braindamaged as adults, although there are also studies of patients with acquired*dyslexias (disorders of reading), dysgraphias (disorders of writing), and*dementias, as well as children (and adults) with the corresponding developmental disorders. The studies have centred around two main aims: the development of models of language processing that will account for the observed patterns of language breakdown, and the identification of the neural substrates of language processing.

Since H. C. Bastian (1869) and Carl*Wernicke (1874) demonstrated that, as well as problems in language production, some aphasic patients have problems in language comprehension, it has been evident that there is no single problem of aphasia. At the same time, the close relation between language and thought has led some theorists to maintain that underlying the language deficit was a more general impairment of cognitive function, in particular of symbolic thinking (Head, 1926), or of abstract reasoning (Goldstein, 1948), or of the

Page 424

ability to form propositions (Hughlings Jackson, 1878). Although many aphasic patients perform poorly on nonverbal tests of intellectual function, some do not (Zangwill, 1964); demanding nonverbal tasks may be performed quite adequately—there are cases of aphasic musicians, bridge players and painters.

The earliest comprehensive theory to account for aphasias was proposed by Lichtheim (1885); he showed that a model with three centres—one for storing auditory word images, one for motor word images, and one for the word concepts—could predict a number of distinct subtypes of aphasia.

In the second half of the twentieth century, advances in linguistics that emphasized the relationships between thought and language brought a renewed interest in aphasia and especially awareness of its linguistic dimensions. The WernickeLichtheim classification system was revived and extended by Geschwind and Goodglass working in Boston, USA (for a summary see Albert, et al., 1981). They suggested that there are five main types of aphasia, together with some less frequent forms.

These are classified in terms of the characteristics of their spontaneous speech, and the degree to which language comprehension and sentence repetition are impaired.

Each of the types is believed to be associated with lesions in particular parts of the dominant cerebral hemisphere, and to represent a disruption at a different level of linguistic description. In *Broca's aphasia* spontaneous speech is nonfluent and sometimes dysarthric (slurred), with short sentences consisting mainly of nouns and main verbs; comprehension is relatively well preserved except with sentences which can only be understood with syntactic analysis. The underlying disorder is said to be

(mainly) syntactic, and Broca's aphasia is associated with lesions in the inferior part of the left frontal lobe. In *Wernicke's aphasia* speech is fluent with many correctly used grammatical structures, but some inappropriate nouns and main verbs; auditory language comprehension is severely affected. The deficit is thought to be mainly at a semantic level, and the lesion usually involves the superior part of the left temporal lobe. *Conduction aphasics* have poor repetition despite relatively well preserved comprehension and fluent language production, although phonemic errors may be common in their spontaneous speech. It has been argued that their problem is (primarily) phonological, and the lesion responsible may lie on the borderline of the frontal and temporal lobes. In *anomic aphasia*, language comprehension and repetition are good, but spontaneous speech shows difficulty in finding words, and circumlocutions despite normal syntactic structures. Anomic aphasia, which is not associated with any well defined areas of damage, is considered to be a disruption on a lexical level. In *global aphasia* all aspects of language are severely affected due to large lesions in the left hemisphere.

While this classification scheme is widely used in the English speaking world, in other countries somewhat different approaches have been adopted. In the Soviet Union, A. R. *Luria (1947) developed a classification system based on his analyses of the aphasias of men with bullet wounds to the head, adopting the linguistic theories of the Prague School. In France and Germany the more classical theories of Wernicke and Lichtheim were maintained and developed.

Attempts to localize the lesions causing different types of aphasia have met with several criticisms. *Hughlings Jackson (1878) argued that aphasic symptoms were not the result of a missing, or damaged portion of the brain, but were rather the consequence of the activity of the whole of the undamaged part. He pointed out that language which might appear to be lost in purposive, propositional speech, could still be accessible in more 'automatic' uses (e.g. swearing and singing). Language functions could not be localized to one area of the brain without considering the operation of the rest of the brain as a whole. This dispute—between localizationists (e.g. Kleist and Nielson) and antilocalizationists (e.g. Pick, Head, and Goldstein) has been a recurring theme. Earlier studies relied for information on the localization of lesions by postmortem examination of the brain. Since 1970, advances in techniques for examining the location of damage in the brains of living patients—e.g.

computerized axial tomography (CAT scan) and positron emission tomography (PET scan)—have allowed many more patients to be examined. While different aphasia types can be shown to have a general correspondence to areas of damage, in large scale studies there may be no single part of the brain that is affected in every one of a group of patients with aphasia of a particular type. (See IMAGES OF THE BRAIN IN ACTION.) Systematic psychological testing was first introduced by Weisenburg and McBride (1935). They established test norms to enable comparisons to be made between aphasic patients and normal subjects on a range of verbal and nonverbal tasks, and also between the different aphasic patients. Modern test batteries used to classify patients into the diagnostic subtypes of the kind described above have depended on this methodological innovation.

Since the 1950s most investigations in the neuropsychology of language have used groups of patients with aphasia of these types in attempts to characterize their basic problems. But there is increasing evidence that the aphasia types of the Boston School are not unitary syndromes. For example, there

are Broca's aphasics who are nonfluent but have no problem with grammar, and others who cannot generate syntactic structures but have no dysarthria; there are conduction aphasics who have problems in list and sentence repetition but do not make phonemic errors in their speech, and others who make many phonemic errors, but have no particular difficulties in list repetition.

One response to these problems is to reject the presupposition that proper, homogeneous aphasia
Page 425

types can be found, and instead to investigate single patients. This has led to the development of a cognitive approach to the neuropsychology of language; this approach, whose primary focus was disorders of reading and writing, has recently extended to other aspects of aphasic language, as well as developmental language problems in children. Workers in this field have adopted detailed information processing models of language drawn from investigations of normal people, and applied these to the analysis of aphasic language by identifying the defective components of the processing system in individual patients. They have argued that, at best, questions of localization are secondary; they can only be approached once models have been developed that are rich enough to account for the language behaviour of every aphasic patient (see, e.g., Coltheart, Patterson, and Marshall, 1980).

LANGUAGE AREAS IN THE BRAIN. The study of the neurological basis of language began in 1861 when Paul*Broca published his findings from the brain of a patient who had suffered from one form of*aphasia. The superiority of one side of the brain for a particular function is called *cerebral dominance*. Each half of the brain is dominant for several functions—for example, the left side is usually dominant for language, the right side for certain musical and spatial abilities (see also NEUROPSYCHOLOGY). Dominance has usually been regarded as a unique biological feature of humans, but it is now known to be present in other species. Thus birdsong is much more severely affected after damage to one side of the brain.

The basis of dominance was unclear for many years. It has recently been established that certain areas of the cortex are much larger on one side of the brain. In particular, one of the major speech areas has been found to be usually of greater extent on the left than on the right. This anatomical asymmetry is found in the foetus at thirtyone weeks of intrauterine life, suggesting that dominance is genetically determined. Lefthanders show less anatomical asymmetry than righthandera, a finding concordant with other data showing that functional dominance is less marked in lefthanders. (See HANDEDNESS.) Asymmetries have also been observed in the brains of great apes, a finding of interest since recent studies support the thesis that chimpanzees have certain capacities for language. (See PRIMATE LANGUAGE.) The human skull is also asymmetrical since its shape is moulded to that of the underlying brain. The longrejected ideas of the*phrenologists are thus partially justified.

Skulls of ancient humans (dating back as much as 300,000 years) exhibit similar asymmetries, so that cerebral dominance for language was probably present early in human evolution.

Our knowledge of the speech areas and their functions has been based on several techniques: postmortem study of brains of aphasic patients; electrical stimulation of the exposed brain during neurosurgical operations; recording of changes in the electrical activity of the brain during language activities; and injection of radioactive substances into the bloodstream which permits measurements of changes in bloodflow in localized brain regions during speech. (See IMAGES OF THE BRAIN IN ACTION.)

The major language areas, named after two of the great pioneers in the study of aphasia, lie along the lateral (or Sylvian) fissure of the left side of the brain. We do not know the full extent of these areas. Broca's area lies in the frontal lobe above the lateral fissure. It is just in front of the region of the cortex, stimulation of which leads to movements of the muscles involved in speech. Broca's area may be thought of, as a simple first approximation, as the region which contains the learned programmes for control of the musculature of speech. After destruction of this region, speech is slow and hesitant and the sounds of language are badly produced. In addition the speech is agrammarie, i.e. prepositions, conjunctions, and auxiliary verbs are often omitted, and incorrect endings may be used in verbs or nouns (for example,

President live Washington'). These findings suggest that Broca's area has a major role in the production of grammatically correct language. The Broca's aphasic also produces defective writing which is agrammatical. His comprehension of spoken and written language may be excellent. Although the Broca's aphasic produces defective speech, he usually sings melodies well. The programmes for production of musical sounds appear Page 426

to lie elsewhere in the brain, probably on the right side. In a few cases, singing actually facilitates the production of words and this has been used as the basis of an experimental method of speech therapy.

The second major speech area lies in the left temporal lobe below the lateral fissure and is named after Carl*Wernicke. This area lies adjacent to the primary auditory cortex, which is the endstation for auditory input to the brain. The speech of the Wernicke's aphasic is quite different from that of the Broca type. The patient may speak very rapidly, with good articulation and melody and a normal grammatical structure. He has, however, great difficulty in finding the correct word and uses imprecise words (such as 'it' or 'thing') and circumlocutions. He may use words incorrectly. Such improperly used words are called paraphasias and may bear a close relation in meaning to the desired word (for example, 'knife' for 'fork') or no obvious relation at all (for example, 'Argentinian rifle' for 'coin'). He may use nonexistent words, which are called neologisms (for example, 'flieber').

There are other areas involved in language functions, damage to which may lead to other distinctive language disorders. Furthermore, there are bundles of nerve fibres (called tracts) which connect the language areas to each other and to other parts of the cerebral cortex on the same or the opposite side of the brain. The corpus callosum is the largest and most obvious collection of such tracts. Destruction of a group of connecting fibres may prevent intact portions of the brain from communicating with each other. The resulting disorders are called disconnection syndromes. They demonstrate the fact that different portions of the brain may carry on complex functions without the awareness of activities in other portions.

A great variety of other aphasic syndromes can result from damage to the language areas or their connections. 'Pure alexia', 'pure wordblindness', and 'alexia without agraphia' are synonyms for a nearly isolated loss of the ability to understand written language while other language capacities are intact. 'Pure worddeafness' is an isolated loss of the ability to comprehend spoken language. 'Pure agraphia' is the isolated loss of the ability to write correct language (in the absence of paralysis).

'Apraxia' is the loss of the ability to carry out movements to verbal command despite good comprehension, and despite preservation in most cases of correct movements in response to nonverbal stimuli. Some remarkable patterns of loss of function are often seen. Thus, the pure alexic may fail to read words and to name colours, but he may read numerals and name objects without difficulty. A patient with callosal damage may write correct language with the right hand, but with the left hand he may produce legible but aphasic, i.e. linguistically incorrect, language. The mechanisms of many of these dissociations of function are well understood, but others still remain obscure. They are of course important clues to the intellectual processes of the brain. (See LANGUAGE: NEUROPSYCHOLOGY.) In the adult, extensive damage to one of the primary language areas leads in most instances to permanent disability. However, children who sustain gross damage to the left

hemisphere before the usual age of language acquisition will go on to acquire language. The right hemisphere thus has the potential to become the major seat of language. Similar findings are found in birds who sustain unilateral damage on the dominant side before song appears.

If the left hemisphere is damaged after the appearance of language but before the age of 8 or 9, the child nearly always recovers language in a period ranging from a few months to three years. The mechanisms of this plasticity or recovery by means of the right hemisphere are not clearly understood. Their elucidation may help to lead to more effective means of therapy for that majority of older patients who do not recover adequate function spontaneously.

N. G.

LANGUAGE DEVELOPMENT IN CHILDREN. How does a child acquire his native language? Perhaps this question presupposes a more basic one: what is it that a child has to know in order to be said to have acquired his native language? All the current answers to this question suggest that the child has to have competence. Some claim he needs linguistic competence, others that he needs cognitive as well as linguistic competence, and others again that he needs communicative competence, which adds a strong social component to the other two. Before we discuss these three alternative theoretical approaches, we must first clarify the notion of competence.

What does it mean when we say a person has competence? The first aspect of competence is that it is abstract knowledge. An example of linguistic competence is the general rule that to form a plural in English you add an 's' to the noun. Of course, you do not need to be consciously aware of this rule in order to use it—children aged 2 or 3 use it reliably, but cannot describe it. The fact that they *are* using a general rule is, however, clear from their errors. They are highly unlikely to have heard of

'sheeps' or 'roans' from someone else, so it is clear they are constructing these words themselves from a rule they have overgeneralized.

This brings us to the second feature of competence—it is generative. That is, knowledge of general rules means that we can generate new examples, new instances of those rules. 'Sheeps' and 'mans' are, for the child who spoke them, completely new instances, his own creations. The sentence I am writing now is a completely novel one, based on my knowledge of the rules whereby one constructs sentences.

But when we consider a child speaking, or, for that matter, an adult writing a sentence for *The Oxford Companion to the Mind*, we are unwilling Page 427

to attribute these performances simply to linguistic competence. Putting it crudely, we know that the child has to have something to say before he expresses it, and that, hopefully, so does the adult. In other words, a certain cognitive competence as well as a linguistic competence is a necessary condition for successful linguistic performance; we have to mean something when we speak, and we have to go some way towards understanding what the other person means when he speaks to us.

This feature was somewhat underemphasized until the late 1960s and early 1970s. During the early

1960s, Noam Chomsky's account of generative linguistics dominated the research scene (see LANGUAGE: CHOMSKY'S THEORY). Investigators audiotaped young children in dialogue with their parents, transcribed the tapes, and analysed the transcripts linguistically. That is, they performed a *structural* analysis, whereby they treated the child's utterances as though they were a novel language. This analysis resulted in a description in terms of classes of words which did not correspond to adultform classes (such as noun, verb). Children might say

'car gone', 'Daddy gone', 'lettuce gone', 'that red', 'that bowwow', 'that man', demonstrating use of a class of pivot words (gone, that), which each occur frequently in one position only in a twoword sentence, and upon which other, openclass words are hung. Generative psycholinguists tried to extend these findings both back and forwards in the child's development. First, they suggested that these twoword utterances embodied the linguistic universals with the knowledge of which the child had been innately endowed. That is, every infant is preprogrammed, they maintained, with the capacity for using features which are common to all languages, such as the distinction between subject and object or that between qualifier and noun. The generative psycholinguists also tried to trace the ways in which the early twoword sentences subsequently develop into full linguistic performance. They attributed this development to the acquisition of more and more complex transformation rules—

that is, rules that transform the deep underlying structure into the surface structure.

Soon dissatisfied with a purely linguistic approach, investigators started to videotape as well as audiotape the child's conversations with his mother. When they did so, they found that a *functional* analysis was appropriate for the data collected. It is only from a videotape that one can discover whether, when a child said 'Mummy shoes', he was meaning 'Those are mummy's shoes' (possessive) or 'Mummy, put my shoes on' (actor, action, object). Clearly, the child has meanings he wishes to express, and functional analysis soon revealed a corpus of about a dozen or fifteen other such relationships which were expressed in the utterances of children aged 2.

From this point of view, language development lags behind cognitive development—the child has to understand what he wants to say before he can say it. Or, as Dan Slobin has put it more elegantly, 'New forms first express old functions, and new functions are first expressed by old forms'.

In some cases, though, linguistic development lags far, far behind cognitive development. The fouryearold child has long since acquired the notion of himself as an individual. Yet the linguistic forms he Uses to refer to himself develop painfully slowly. He may use his own name all the time to begin with—'Adam go hill', 'Pick Adam up'. Next he uses 'I' in the initial sentence position only, 'me' in all other positions—'I Adam do that', 'Why me spilled it?' Finally, he grasps the subject and object functions of I and me—'That what I do' and 'You want me help you?' This example shows that while a certain level of cognitive development is a necessary condition for linguistic performance, it is not a sufficient condition: there are certain specifically linguistic competences which also have to be acquired. What is more, some languages make it very hard to be linguistically competent—how does the French child acquire the right gender for all his nouns?

The mechanisms by which linguistic competence develops, and the nature of its dependence on

cognitive development, have been the subject of much speculation;

little, however, is really known. *Piaget and his followers suggest that the grammatical expression of such structures as actionobject and actoraction is dependent upon the sensorimotor development of the child. The child has to act upon his own environment before he can conceive of the notions of actor, action, and object and subsequently express them.

More recently, psychologists have stressed the social context of the precursors to language. At a very early stage of his life indeed the child can direct his mother's attention to something in his environment simply by focusing his gaze upon it. Subsequently in his development he may make grasping movements towards it, and later still gesture or point towards it. Jerome Bruner suggests that it is by this manipulation of his *social* environments that the child is laying the foundations for competence.

And it is *communicative* competence that is being acquired; he is acquiring the rules relating to how we refer.

LASHLEY, KARL SPENCER (1890-1958). American neuropsychologist, educated at Johns

Page 428

Hopkins University, Baltimore. While still relatively junior he began to work with Shepherd Ivery*Franz, a pioneer in the application of physiological methods to the study of brain mechanisms and intelligence in animals. Lashley later worked closely with J. B.*Watson and may indeed be regarded as a cofounder of*behaviourism.

Indeed his understanding of neurology was a good deal more sophisticated than that of Watson and he soon abandoned Watson's reliance on*reflexes and conditioned reflexes (see CONDITIONING) as the building blocks of behaviour. At the same time, he held strongly to Watson's insistence on objective methods and the abandonment of consciousness in the explanation of behaviour.

Lashley's bestknown work involved study of the effects of lesions of the cerebral cortex on intelligence and learning in the rat and monkey. He was a most competent experimenter and the first to apply statistical methods to the analysis of the results of brain lesions and to ascertain their locus and extent by postmortem anatomical study. He published two important groups of studies, the first concerned with cerebral function in learning (192035) and the second on the neural mechanisms of vision (193048). His important monograph on *Brain Mechanisms and Intelligence* appeared in 1930.

Lashley's work convinced him that although sensory and motor functions are in some sense localized, the effects of cerebral lesions involving the so-called association areas do not indicate clearcut functional*localization. Indeed it was far more in keeping with his experimental findings to denote the association cortex as substantially equipotential as regards the acquisition and retention of habits and to view the impairment of learning and memory which resulted from cerebral lesions as dependent on the extent rather than the locus of the excision. This relationship has become known as the law of mass action, and although it has been much criticized in recent years, it remains an important principle of cerebral organization.

Lashley was a figure of high standing in the field of physiological psychology and although, unlike his early colleague Franz, he never extended his studies to brain injury in man, he had great influence on the evolution of contemporary*neuropsychology. Among his students were Donald O. Hebb and Karl Pribram. He was a Foreign Fellow of the Royal Society of London.

LATERAL THINKING. There may not be a reason for saying something until after you have said it. That statement does not make sense in the world of logic, where each step has to rest securely on the preceding step: reason must come before a conclusion, not after it. Yet the statement makes perfect sense in the world of lateral thinking, of perception, of patterning systems, of poetry, and of hypothesis. Philosophers and scientists have always complained that we have no logical way of generating hypotheses. We do have such a way, but it cannot be logical for logic involves analysis of what we know. Instead of analysis we need provocation, and that is what lateral thinking is about.

Suppose we are looking for a new idea for a cigarette product. We use one of the more provocative lateral thinking techniques and we bring in a random word as provocation. The word can be picked

from a dictionary with a table of random numbers so that no unconscious selection takes place. Does this mean that any word whatsoever may be used as a provocation with any problem whatsoever? It does. There is no connection at all between the random word and the problem. The word is 'soap', and from this comes the idea of freshness, and of spring, and of putting flower seeds in the butt of cigarettes so that when the butts are thrown away a flower will grow from each one and beautify the surroundings instead of polluting them. It is very difficult to see how such an idea could ever come purely from *analysis* of a cigarette since there is no part of it which would suggest this type of idea. Another time the provocation is 'trafficlights' and from this comes the idea of putting a red band round the cigarette about two centimetres from the butt end to indicate a danger zone and so give the smoker a derision point. Now this idea is very logical in hindsight and could possibly have come through analysis. In hindsight it is often difficult to tell how an idea actually came about since the aim of lateral thinking is to produce ideas that are logical in hindsight.

The first stage of thinking is the perception stage: how we look at the world; the concepts and perceptions we form. The second stage of thinking is the processing stage: what we do with the perceptions that have been set up in the first stage. Logic can only be used in the second stage since it requires concepts and perceptions to work upon. So what can we do about the first or perception stage? We can rely on chance, circumstance, experiment, or mistake to change our perceptions, or we can try to do something more deliberate. That is where lateral thinking comes in.

A perception is a particular way of looking at some part of the world. It is the grouping together of certain features or the isolation of a certain relationship. Perceptions are the patterns which form in our minds after exposure to the world at first or second hand. These patterns are only some among the *many possible patterns* that could have formed. Moreover, because of the nature of patterning systems, we may be unable to use one perception because we are led away along another. So the type of processing we want to do in the first stage of thinking is concerned with *changing perceptions*. It is concerned with forming new perceptions and with uncovering the perceptions we have but are unable to use.

If we accept that the mind is a patternmaking

Page 429

and patternusing system, at least in the perception stage (and all the evidence suggests it is), then we need to develop some deliberate habits of provocation if we are to move from established patterns to open up new ones. Our usual mode of thinking is, quite properly, based on judgement. But judgement only serves to reinforce existing patterns, not to change them. Instead of judgement we need something more provocative. Instead of judgement we need movement, and that is what lateral thinking is about.

There is nothing mystical or magical about lateral thinking. As soon as we accept that perception is based on patterns (rather like the streets in a town) then we need some method for getting out of the familiar patterns—some jolting or provoking system. If our ideas are only a summary of what we already know, then how are we to get new ideas? Certainly we can get some by analysing more fully the implications of what we do know, but the really new ideas depend on new hypotheses, on new

conceptual jumps. In a patterning system it is perfectly logical to be illogical. In the example given earlier there is no connection between a cigarette and soap, but one quickly forms along one of the many association pathways we have. Our ideas about cigarettes can now start to move out along this track—and it is a different track from the one they would otherwise have moved along. So the reason for juxtaposing cigarette and soap only appears after the juxtaposition has been made and has proved useful.

We need some indicator to show that we are not operating in the usual judgement system. Otherwise, if we make a statement like 'The hands of a watch should move backwards', we would be judged as unhinged. So from *po*etry, *hy**po*thesis, and *sup**po*se we extract the syllable *po* which indicates that we are using an idea in a provocative manner in order to open up new ideas. So we now say, 'Po the hands of a watch should move backwards', and using that as a steppingstone we might come to consider the idea of having the numbering of the hours running from twelve down to one so that by glancing at our watch we can tell how many hours are *left* to the day rather than how many have passed.

The use of random juxtapositions and provocative steppingstones is only part of the process of lateral thinking—there are many other techniques, some of which are more analytical than provocative. With all the techniques the aim remains the same: the changing of concepts and perceptions. Occasionally the changed perception gives a solution or a valuable new idea. More often lateral thinking only gives a new startingpoint which has then to be developed in the usual logical manner. For instance, in a fishprocessing plant the startingpoint that it might make more sense to take the bones away from the flesh instead of the more usual method of taking the flesh away from the bones led to a new process which saved a great deal of money.

In general our mental tools for judging and processing and analysing are very good. But we have been very poor at generating new ideas and hypotheses because we have failed to realize that in a patterning system provocative methods are required. It was necessary to invent the term 'lateral thinking' because creativity is too vague a word, simply meaning the production of something new. Lateral thinking is concerned with changing concepts and perceptions. Some of artistic creativity has to do with lateral thinking but much of it does not. The term 'divergent thinking' only covers a small part of lateral thinking: that is to say the generation of alternatives as a method for changing perceptions. Indeed some of the lateral thinking processes are not divergent at all. Lateral thinking is concerned with the changing of concepts and perceptions by provocative and other means.

A young toddler is upsetting granny's knitting by playing with the ball of wool. One suggestion is to put the child into the playpen. Another suggestion is to leave the child outside and put granny into the playpen.

LAUGHING GAS (nitrous oxide). The effects of breathing nitrous oxide were first investigated by the distinguished chemist Sir Humphry Davy (1778-1829). In Bristol, as a young man, Davy joined the Pneumatic Institute, which was run by Dr Thomas Beddoes (1760-1808). Here experiments were undertaken on the effects of breathing gases. They were frequently dangerous, but were an important step towards the discovery of anaesthetics. The 'subjects' included some of the most famous men of letters of the day, for example Robert Southey and Samuel Taylor Coleridge, who wrote: The first time I inspired the nitrous oxide, I felt a highly pleasurable sensation of warmth over my whole frame, resembling that which I remember once to have experienced after returning from a walk in the snow into a warm room. The only motion which I felt inclined to make, was that of laughing at those who were looking at me.

Davy first tried the experiment on 11 April 1799, when he obtained nitrous oxide in a pure state. He describes a later experiment in these words: A thrilling, extending from the chest to the extremities, was almost immediately produced. I felt a sense of tangible extension highly pleasurable in every limb; my visible impressions were dazzling, and apparently magnified, I heard distinctly every sound in the room, and was perfectly aware of my situation. By degrees, as the pleasurable sensations increased, I lost all connection with external things; trains of vivid visible images rapidly passed through my mind, and were connected with words in such a manner, as to produce perceptions perfectly novel. I existed in a world of newly connected and newly

Page 430

modified ideas: I theorized, I imagined that I made discoveries. When I was awakened from this semidelirious trance by Dr Kinglake, who took the bag from my mouth, indignation and pride were the first feelings produced by the sight of the persons about me. My emotions were enthusiastic and sublime, and for a minute I walked round the room perfectly regardless of what was said to me. As I recovered my former state of mind I felt an inclination to communicate the discoveries I had made during the experiment. I endeavoured to recall the ideas: they were feeble and indistinct; one collection of terms, however, presented itself; and with a most intense belief and prophetic manner, I exclaimed to Dr Kinglake,

'Nothing exists but thoughts! The universe is composed of impressions, ideas, pleasures and pains!' (Kendall, 1954, pp. 445).

Davy realized that the gas might be useful as an anaesthetic, for he wrote in 1800: 'As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place.' It was not, however, until 1844 that Horace Wells, an American dentist, first employed nitrous oxide for this purpose—for the extraction of one of his own teeth. (See ANAESTHESIA.) Kendall, J. (1954). *Humphry Davy, Pilot of Penzance*. London.

LAW OF EFFECT. The law of effect is a kind of hedonism of the past: actions that lead immediately to pleasure are learned, remembered, and repeated as habits;

whereas actions leading to pain are not remembered, or are suppressed so that later painful behaviour is avoided. This is a reversal of the moralist's hedonism which suggests that we seek pleasure in the future. The concept of the law of effect is a basic tenet of *behaviourism, which eschews *purpose or *intention. It is now held to be correct, although not to be accepted as accounting for all learning and behaviour.

The concept derived from E. L. *Thorndike's experiments with cats placed in puzzle boxes, from which they escaped by trial and error behaviour. The escape was the reward that produced the learning, though without understanding.

Thorndike, E. L. (1898). *Animal Intelligence*. New York.

LAW OF MASS ACTION. See HANDEDNESS.

LAWS OF NATURE. Perhaps the most mysterious issue in the whole of science is the origin and logical status of the laws of physics. Why do they continue to hold without change? Did physical laws 'exist' before matter? Do they change, through the history of the universe? Are they, even, derived by a kind of natural selection of the inorganic world—as suggested by the American philosopher Charles Sanders *Peirce? These impossibly deep questions are discussed in the works listed below.

LAWS OF THOUGHT have traditionally been linked with, and sometimes identified with, laws of logic. (This tradition was challenged by, among others, Sigmund *Freud, who held that there are highly irrational, powerful laws determining behaviour and how we perceive the world and ourselves.) The English mathematical logician George Boole (1815/64) was perhaps the first, since *Aristotle, to develop the idea that laws of logic are rules by which the mind works. Thus, that which renders Logic possible, is the existence in our mind of general notions—our ability to conceive of a class, and to designate its individual members by a common name. The theory of Logic is thus intimately connected with that of language. A successful attempt to express logical propositions by symbols, the laws of whose combinations should be founded upon the laws of mental processes which they represent, would, so far, be a step toward a philosophical language (Boole, 1847, Introd.).

For Boole, it seemed possible to discover how the mind works by looking at rules of logic. This idea is remarkably similar to Ludwig Wittgenstein's account of the procedures of language as generating

concepts according to the chosen 'language games'. Language, for Wittgenstein, is a kind of machine which by operating generates understanding—and sometimes confusions, which need to be made explicit and sorted out by philosophers. (See WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE.)

A deep question is how far laws of thought are innate (and, together with this, how far the structures of language are innate, as Noam Chomsky holds with his Deep Structure theory of language: see LANGUAGE: CHOMSKY'S THEORY) and how far they are learned, and are products of particular cultures, societies, and technologies. Here there is an enormous range of opinion, from Immanuel**Kant's* notion that our ideas of space and time are innately given, to the extreme empiricism of**Helmholtz*, for perception, and the earlier empiricist philosophers, who believed, following**Locke*, that all we have to start with is the ability to associate sensations to generate ideas and understanding.

If laws of thought are*innate—inherited—it now appears that they can be modified: there are few, if any, limits to how or what we may think.

At present, it seems that we shall not be able to specify effective laws of thought in detail before there are adequate computer programs for solving problems—

including problemsolving that is not strictly and explicitly logical. (See ARTIFICIAL INTELLIGENCE.) R. L. G.

Boole, G. (1847; repr. 1948). *The Mathematical Analysis of Logic: being an essay towards a calculus of deductive reasoning*. Oxford.

LEARNING AND LEARNING THEORY. The study of learning has been prominent in psychology

Page 431

for more than eighty years. Since the pioneering work of Ivan**Pavlov* and E. L.**Thorndike*, its importance has consistently been reflected empirically through experimental investigations and conceptually through interpretative theories.

Pavlov demonstrated empirically the ways in which dogs develop acquired**reflexes*, and thus identified the basic phenomena of what is now termed classical**conditioning*. As the result of a temporal association with a stimulus which already elicits a response, a previously neutral stimulus comes to elicit a similar, conditioned, response. Thus, for example, a bell paired with food elicits conditioned salivation. At an empirical level, *Pavlov's* extensive research was remarkably effective in producing robust data relating to a psychological phenomenon. At a theoretical level, *Pavlov* introduced an important element of plasticity into the Russian reflexological tradition which interpreted all behaviour, including that of humans, as the result of environmental stimuli. *Parlor* regarded conditioned behaviour as a reflection of higher nervous activity set in train by stimuli.

Thorndike also used experimental methods and animal subjects, studying 'intelligence' by investigating, for example, how cats learned to escape from a puzzle box to obtain food. He too obtained pleasingly orderly behavioural data which indicated gradual changes in behaviour rather than sudden 'insightful' changes. Thorndike argued that the gradual changes occurred because the 'satisfying state of affairs' which followed the correct response made it progressively stronger or more probable.

Through his *law of effect Thorndike emphasized that patterns of behaviour can be selected by their consequences, rather as advantageous taxonomic form is selected by evolutionary pressures on species. In both cases, apparent purpose can be reinterpreted in terms of the effects of consequences. Thorndike originally believed that behaviour followed by an 'annoying state of affairs' became weaker; but his own research, here largely with human subjects, did not demonstrate this. Thorndike therefore retained a truncated form of his law of effect which emphasized the selective strengthening effects of what are now termed reinforcers in instrumental conditioning.

The impact of subsequent empirical studies of learning was for some time largely reflected by theories which were in effect general theories in psychology. This is illustrated in J. B. *Watson's writing. He exploited his familiarity with early empirical studies which related changes in behaviour to environmental conditions in order to advocate that psychology as a whole should be reformulated as the science of behaviour rather than of mental life and experience. Watson's *behaviourism has contributed to the widespread adoption of behavioural studies in psychology, but his more negative views about the relevance of mental life to the refocused discipline of psychology have been less influential. Like subsequent theorists, Watson used the empirical data of studies of learning as a platform for his approach to psychology in general. In particular, he extended the principles of classical conditioning to emotions in humans through his famous studies with 'little Albert', and emphasized environmental influences on behaviour to the neglect of inherited differences.

Edward *Tolman carried out ingenious experiments on learning in animals, and demonstrated patterns of behavioural change which were not so readily interpreted in simple stimulus-response terms. For example, he showed that rats learned to run to a particular place for food rather than to make a stereotyped response such as turning right at a choice point. He also investigated latent learning, shown through savings when animals were allowed simply to explore a maze before being required to run through it to a specific goal box. Tolman used the methods of behavioural investigations, but extended the complexity of the environmental arrangements whose effects on behaviour were studied. He was drawn to use intervening concepts, such as expectancies or cognitive maps, to deal with the relationships he observed between environment and behaviour. In this regard, Tolman was a precursor of contemporary cognitive psychology.

The most detailed and systematic account of learning yet developed was that of Clark *Hull. Yet again based on controlled experiments with animals, Hull's theory was presented in formal terms, with postulates giving rise to precise behavioural predictions expressed in quantitative terms through equations with intervening variables.

These variables, which in Hull's theory were such concepts as drive, habit strength, and reaction

potential, were more tightly tied to empirical measurements than were Tolman's more cognitive terms. Hull's theory is often cited as the best example in psychology of the hypothetico-deductive method of scientific enquiry, and in this sense it is a further example of a learning theory which has implications for psychology reaching far beyond the empirical studies of learning on which it is based. The theory also strove for a general explication of learning, emphasizing similarities between classical and instrumental conditioning and across species, though incorporating quantitative differences.

In the thirty years 1950-80 the emphasis on formal global theories of learning diminished. Empirical research on conditioning and learning has continued to flourish, however. The methods of free-operant conditioning developed by Skinner have been extremely beneficial in this respect, making it possible to study more effectively the effects of intermittent reinforcement, discriminative control, punishment, and so on. Indeed operant conditioning has become a technology for the experimental analysis of behaviour. One systematic use of the data of operant conditioning has

Page 432

been to support the general behaviouristic approach to psychology favoured by Skinner, with its emphasis on explanations of behaviour couched in terms of its relationships with environmental events in applied contexts with humans as well as with animals in the laboratory (functional analysis of behaviour). (See BEHAVIOURISM, SKINNER ON.) However, the behavioural data obtained from operant conditioning may be evaluated in terms of other theories.

In recent years a number of trends have emerged from empirical studies of conditioning. First, conventional distinctions between classical and instrumental conditioning have been further challenged. One important factor here has been the suggestion that activities of the autonomic nervous system such as heart rate and blood pressure, previously thought to be affected only by classical conditioning procedures, can be modulated by instrumental reinforcement, a possibility that encouraged the use of so-called *biofeedback techniques with patients in clinical practice. Secondly, greater interest has been shown in biological or phylogenetic influences on conditioning and learning. It seems that some patterns of behaviour are more readily affected by conditioning procedures than others: animals appear, for example, to be biologically prepared to associate novel tastes and nausea, no doubt because of the implications of such preparedness for survival. Similarly, species-characteristic patterns of behaviour may intrude even in the controlled environment of the conditioning laboratory. These findings have raised some doubts about the generality of the laws of learning established thus far, but they emphasize that behaviour must be interpreted in terms of interactions between inheritance and experience. Thirdly, the increasingly complex relationships between environment and behaviour studied in conditioning experiments have led some contemporary learning theorists (e.g. N. J.

Mackintosh) to reintroduce cognitive explanations even of animal behaviour.

The field of learning has consistently been one of the most active areas of experimental psychology. The empirical data which have been produced have consistently demonstrated the power of experimental and comparative methods in psychology. In turn they have given rise to theories which,

though designed primarily to accommodate the phenomena of animal learning, have implications for psychology in general, in terms of human as well as of animal behaviour. These theories have therefore reflected (or perhaps led) changing perspectives in psychological science. Learning and learning theory can be said to offer an insight into the empirical and theoretical development of psychology as a whole.

See also MEMORY: BIOLOGICAL BASIS.

D. E. B.

LEAST EFFORT, PRINCIPLE OF. This asserts that minimal energy will be expended, sufficient for survival. As a 'complacent cow' description of behaviour, this is not true even for complacent cows! Some degree of more or less random searching—apparently having a basis of curiosity—is characteristic of virtually all organisms, and is exceedingly highly developed in man. We by no means take least effort as our maxim for behaviour: hence the ziggurats of Babylon, the pyramids of Egypt, the temples, statues, and paintings as well as the philosophy of Greece, and the science which has come to mould Western civilization. The effort involved in building a city—be it Athens or New York—is truly remarkable. It provides the clearest evidence that behaviour is not passive, initiated by stimuli, and that we are not organisms content to exist with least effort. On the other hand, least effort *is* a criterion for the intelligent planning of an enterprise: we set up goals difficult to achieve, and with intelligence reach them without wasted effort.

LEFTHANDEDNESS. See HANDEDNESS.

LEIBNIZ, GOTTFRIED WILHELM, FREIHERR VON (1646/1716). Born in Leipzig and trained as a lawyer, Leibniz depended for his livelihood on the patronage of German princes, for whom he worked as a counsellor, diplomatist, and historian. Much of his life was spent as librarian to the Electors of Hanover;

George I, who disappointed him by not taking him to England when he became king in 1714, called him a 'living encyclopaedia'. There were few areas of learning to which he did not make important contributions.

He is best known as a philosopher and mathematician. He shares with*Newton the honour of discovering the calculus; their discoveries were effectively independent, though Leibniz was bitterly attacked by Newton's followers, who accused him of plagiarism. He attempted to apply the mathematical type of reasoning as widely as possible, and in so doing can be said to have invented symbolic logic; though because he did not publish his work it had to be invented again 150 years later. He wanted to create a perfect language, which would reflect in its grammar and wordstructure the full logical complexity of what we say; this idea has been very fruitful in recent philosophy, especially through the work of Bertrand*Russell, who was much influenced by Leibniz. But Leibniz was also interested in how actual languages worked, and was a pioneer of systematic philology.

He was a leading critic of the physics of*Descartes, which left no place for the force he considered to

be inherent in matter; this was one of the things that led to his remarkable philosophical theory of matter as built up out of little minds (monads). He was heavily influenced by Descartes and*Spinoza, who are usually classed with him as rationalists; he in turn was to be a major influence on*Kant. Popularly he was perhaps best known for maintaining that this is the best of all possible worlds, a view Voltaire satirized in *Candide*. But

Page 433

Voltaire was unjust in treating him as a shallow optimist: he did not believe this world is obviously perfect, but only that because a good God exists this *must be* the best world possible, however evil it may seem.

He invented a calculating machine, and a machine for pumping water out of mines. He founded the Academy of Sciences at Berlin, and had Peter the Great found one at St Petersburg. Himself a Protestant, he did his best to achieve a reunification of the Churches, though without success. He worked extremely hard, and carried on an enormous correspondence on intellectual matters; but his life seems to have lacked an emotional side. He did write poetry, which was admired at the time, but it was dreary, formalistic stuff. He never married; it is said that he proposed at the age of 50 but changed his mind before it was too late.

LEIBNIZ'S PHILOSOPHY OF MIND. Although he never published it in complete form,*Leibniz's philosophy is a closely knit system of speculative metaphysics, with a neatness and storybook attractiveness which led*Kant to say that Leibniz had built 'a kind of enchanted world'. Subsequent philosophers have generally found the system as a whole too strange to be taken seriously, but some of the individual ideas have been extremely influential.

It could all be described as philosophy of mind, for it is Leibniz's opinion that only minds exist. There are endlessly many of them, all different, and what we take to be inert matter is made up of nothing but minds of a rather stupid variety. There is no difference of kind between them and ourselves, only a difference of degree. They can be thought of as coming low on a scale of gradually increasing intelligence, with microbes and insects and animals and men above them. Above men come angels, and right at the top, God. God is rather a special case, being infinite and the creator of everything

else; all other minds are finite minds, of more or less intelligence.

Leibniz calls them 'monads'.

Monads have perceptions and desires; according to Leibniz, when mental states are analysed it turns out that fundamentally they all come down to these two kinds.

Each monad continually seeks its own improvement, which consists in coming to perceive things more clearly and distinctly. The awareness that one's perceptions have become more clear and distinct is called pleasure, while the awareness that the opposite has occurred is called pain. This leads to so implausibly intellectual a view of the feelings and emotions that only a philosopher could have adopted it. Leibniz probably derived it largely from Spinoza, and does not work it out in much detail, but he does provide a few analyses—love, for example, is pleasure at the pleasure of another, pleasure itself being defined as above.

Perceptions may be more, or less, clear and distinct; it is in respect of the clarity and distinctness of their perceptions that minds differ. What makes one mind more intelligent than another is just that it can perceive things better. Leibniz includes as perceptions both thoughts and senseexperiences, for he sees no essential difference between them; senseexperiences are one variety of clear but not very distinct perception. A perception is clear when one understands what one is perceiving, but distinct only to the extent that one can analyse the concepts involved. Many of our thoughts are obscure and confused perceptions, but a few are clear and distinct: the thought that $2 + 2 = 4$, for example, and our apprehension of the two principles Leibniz thinks fundamental to all reasoning: the Principle of Contradiction ('No proposition can be both true and false at once') and the Principle of Sufficient Reason ('Nothing occurs without adequate reason'). These things are not learned from senseexperience, as Locke and the empiricists maintain; our knowledge of them is innate, though experience is required to bring them to consciousness. Leibniz also rejects Locke's claim that all our concepts are acquired from experience by abstraction. No experience could give us concepts like those of God or of mathematical equality, and these must be inborn in us in the same way. Recently the defence of innate knowledge has been taken up by Noam Chomsky (see LANGUAGE: CHOMSKY'S THEORY); but it is one of the things that mark Leibniz off as a rationalist, and it leaves him with the perennial problem of rationalist philosophers: why should an inborn propensity to believe certain things be any guarantee of their truth?

Leibniz was the first to introduce the idea of the *unconscious*. He points out that one can often recall having perceived something—some detail of a familiar scene, perhaps—although one did not notice it at the time: clearly one must have perceived it without being aware of doing so. And in listening to the sea breaking, one is conscious only of the sea and not of each individual drop of water; yet the sound of the sea is made up of the sounds of the drops, so that one must in some way be perceiving each of them. Such unconscious perceptions he calls 'little perceptions'; they differ from conscious perceptions only in degree—degree of clarity and distinctness. Unconscious perceptions are highly obscure and confused, and Leibniz thinks we have far more of them than we might ever suspect; for each monad continually perceives the entire universe, though we are never conscious of more than a small part. Those monads which come very low on the scale, so low that we

Page 434

normally fail to recognize them as minds at all, have only unconscious perceptions, and there are times when we are in this state ourselves—in*sleep, for example, and in death. For when someone dies his mind loses its clearer and more distinct perceptions, but does not cease to exist or lose its identity; it sinks down, temporarily at least, to a lower position on the scale.

No monad wants its perceptions to become less clear and distinct; on the contrary, all its actions are directed towards moving further up the scale. Leibniz regards an action as an event directly caused by the will of a monad, and this is much too crude an account of action. But it is over freedom that Leibniz gets into particular difficulties; he is anxious to defend free will against the determinism of Spinoza, yet it is hard to see how he can. Since every monad must will its own improvement, it can exercise*choice only over how to achieve this. But it is bound to choose whatever means seem the best available—the Principle of Sufficient Reason guarantees that no choice can be made without adequate grounds. So the choice is completely determined by the monad's beliefs about what the best means are. Leibniz ties himself up in knots over this, and attempts various solutions, but he usually says that its beliefs *incline* it, without *necessitating* it, to make the choice it does. Since they incline it quite irresistibly this constitutes a memorable attempt to have your cake and eat it.

The difficulty is made even more acute by a further part of his theory. For he holds that God programmed into every monad at the creation the whole course of its future development, including every action and every thought. We would hardly describe as free, a robot all of whose behaviour had been determined in advance by its designer.

Leibniz actually holds that created monads never produce effects in one another. They only appear to. They are like different clocks, which strike the hours together.

God has so designed them that whenever an event we regard as a cause occurs in the career of one monad, the events we think of as its effects will occur in the histories of the others. So the monads keep time with one another, and appear to act on one another, but really do not: there is a 'preestablished harmony' between them. In virtue of the harmony there is a correspondence between each monad's perceptual states and how things are outside it, so that it can be said to 'mirror' the universe even though its perceptions are not caused by the things outside.

Leibniz's reason for this remarkable theory is that if monads could act on one another he thinks they would not be genuinely independent things, substances. Indeed, he goes so far as to maintain that monads cannot really stand in any relations to one another at all. This leads him to deny the reality of space, for he thinks that space can only be a system of relations between things. Things do appear to be spatially related, but really there are no relations between them and therefore no space.

Nevertheless, the appearance is 'well founded' in the perceptual states of the individual monads; for they each differ in the clarity with which they mirror different parts of the universe, and our idea that they have positions in space is a confused awareness of these differences. Roughly speaking, I appear closest to those things I most clearly perceive. But one cannot do other than speak roughly here, for the theory is not properly worked out, and could not be. I can perceive the Pleiades, after all, more clearly than the back of my head.

Clarity and distinctness are being given too much work to do. They cannot provide the reality behind our awareness of spatial relationships, nor is it really our sole aim in life to get more of them. Leibniz's overvaluation of them is characteristic of an age intoxicated with the recent successes of rational thought and its apparent capacity to solve every problem; it does not detract from the brilliance and originality of many of his ideas.

R. C. S. W.

LEONARDO DA VINCI (1452-1519). Italian sculptor, painter, architect, and engineer-inventor, born at Vinci near Florence, the natural son of a notary. He was apprenticed to Verrocchio (about 1470) in Florence and in 1482 settled in Milan, working with Lodovico Sforza. In 1502 Leonardo entered the service of Cesare Borgia, as architect and engineer. The *Mona Lisa* was painted about 1504.

Leonardo's *Notebooks* are of great interest in describing his work and ideas on hydraulics, the casting of statues, and many inventions, as well as in giving his advice to painters and clear accounts of perspective and the use of shadow. He did not, however, appreciate that the two eyes give perception of depth (by stereopsis); and he wrongly thought that light must cross twice in the eye to produce a right way up retinal image, for perception to be noninverted. He was also confused on why mirrors normally reverse left and right but not up and down—see MacCurdy (1938), vol. 1, ch. 9. Leonardo recognized, however, many properties of the eye, such as

'irradiation'—bright objects appearing larger than dark ones; and his anatomical drawings are masterpieces, even though they sometimes incorporate features which he believed present when in fact they are not. Leonardo is generally recognized as the most universal genius of all time. (See MIRROR REVERSAL.) A feature of Leonardo's *Notebooks* of particular psychological interest is that these manuscripts were consistently written in mirror-script. As is well known, mirror-writing is not an altogether uncommon accomplishment, particularly among the left-handed. Although Leonardo's handedness is not reliably known, some experts have claimed that careful study of the detail and shading of his marginal sketches indicate that—at all events before he sustained a partial left-sided paralysis in later life—the pen was held in his left hand. It appears probable, therefore, that Leonardo was naturally left-handed and, like some other left

Page 435

handed individuals, had a particular facility in mirror-writing.

LEUCOTOMY. The removal of small regions of the frontal lobes of the brain, for extreme depression. The operation is now seldom, if ever, performed. See also PSYCHOSURGERY.

LEVITATION. A*paranormal phenomenon which has been claimed to occur in the open air (at a garden party and witnessed by perhaps a hundred guests), and, by the nineteenth-century medium Daniel Dunglas*Home, at a party when he was reported as gliding out of an upstairs window and into another without material support.

There appear to be no recent reports of levitation.

An interesting party game is to press down on the head and shoulders of someone blindfolded and seated in a chair, and then to release the pressure. He will then (with some added verbal suggestion) feel that he is floating up to the ceiling. The experience can be extremely convincing, and frightening, though of course he remains seated in the chair.

LIBIDO. For Sigmund*Freud, the libido was essentially the sexual drive, which could be sublimated into the great variety of human creative expressions. The evidence that all*creativity beyond*least effort is sexual in origin is now generally regarded as too narrow, and Freud probably exaggerated the sexual basis of creativity. See FREUD ON MENTAL STRUCTURE.

LIE DETECTOR. See ELECTRODERMAL ACTIVITY.

LIMBIC SYSTEM. The term 'limbic system' derives from the concept of the 'limbic lobe'. It was first used by the French anatomist Paul*Broca in 1878 to describe that part of the brain surrounding the brainstem and lying beneath the neocortex. A generally accepted modern definition of the 'limbic system' has, however, never been given. Some neuroanatomists believe that the term should be abandoned. Nevertheless it is a widely used 'shorthand' term and most authors would include the following structures within its definition: the hippocampal formation, olfactory regions, hypothalamus, and amygdala.

Functionally, the limbic system is generally said to be concerned with visceral processes, particularly those associated with the emotional status of the organism. Both experimental and clinical data indicate that the amygdala is involved in emotional experiences and reactions, particularly those associated with fear and anger, flight and defence. Stimulation of the amygdala in conscious animals can give rise to quite integrated response patterns evolving over time and involving a wide variety of motor and autonomic responses which are integral parts of the overall behaviour pattern. Although the amygdala would therefore appear to be involved in these responses, it may not be the only such area. Thus changes in aggressiveness can be obtained by stimulation or ablation of septum, certain areas of cerebral cortex, and the grey matter of the mesencephalon. This emphasizes the importance of considering the interaction of connected brain areas rather than the activity within particular 'centres', as effectors of functions.

The hippocampus has been the object of much experimental work, and theories about the nature of its function have multiplied. One possibility which has attracted attention from*behaviourists is that it may be involved in*memory. However, at present no clearly formulated results can be stated. This is in consequence partly of the anatomical complexity of the region and partly of the semantic difficulties surrounding the words 'memory' and 'learning'. Since the hippocampus is richly connected

to many other brain regions, it is, as in the case of the amygdala, probably misleading to think of such a structure as a 'centre' of such a function. Physiologically one of its most striking properties is seen in relation to activity in the cerebral neocortex. When the neocortex is 'desynchronized' (i.e. shows lowvoltage rapid potentials) the hippocampus becomes 'synchronized' and shows rhythmic sinusoidal waves of 47 per second ('theta waves': see ELECTROENCEPHALOGRAPHY). When the neocortex is synchronized, on the other hand, the hippocampus is desynchronized. The functions of this reciprocal relationship are not understood, but it appears to be related to the activity of the reticular formation and the state of attentiveness of the subject. Recent work strongly suggests that serotonin and noradrenaline are closely involved in the switching of mechanisms between these two states.

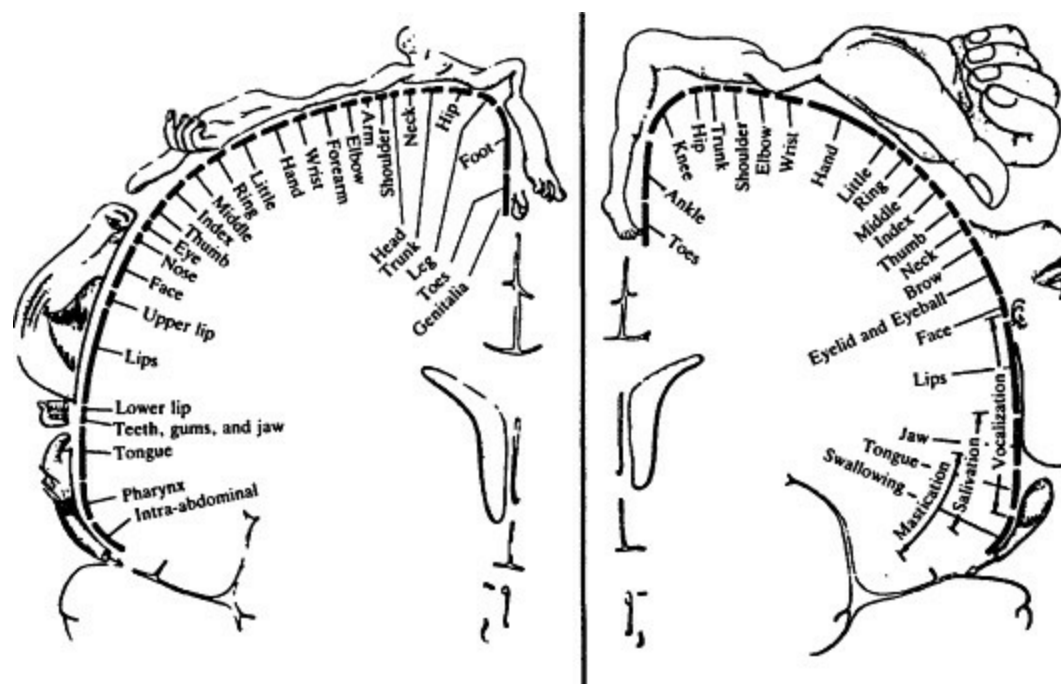

Another division of the 'limbic system', the entorhinal area, is closely related anatomically to the hippocampus, providing its main cortical source of afferent fibres.

Recent anatomical work has shown that it also receives fibres from the frontal, temporal, and cingulate neocortex as well as the olfactory cortex, indicating that it is the final cortical link between the sensory systems of the neo and transitional cortex on the one hand and the hippocampus and dentate gyrus on the other. It would seem from an anatomical point of view that the sensory information arriving at the entorhinal area is probably highly refined (see DOPAMINE NEURONES IN THE

BRAIN).

The information derived from the entorhinal area interacts with hippocampus and amygdala. These structures deliver further messages both directly (from amygdala) and via septum and nucleus accumbens to regions of the hypothalamus concerned with motivational and rewarding mechanisms.

Thus interaction of all the structures in the complex, from the entorhinal area to hypothalamus, is probably of great importance in deciding the final

actions of an organism in a particular environment, and in the formation of adaptive behaviour patterns.

O. T. P.

LOBACHEVSKI, NIKOLAI IVANOVICH (1793-1856). Russian mathematician, founder of nonEuclidian*geometry. This was extremely important in epistemology as it showed that*Euclid's axioms are not known with certainty, a priori, but are hypotheses which may or may not correspond to physical space. His work is published in *Über die Principien der Geometrie* (1829-30).

LOCALIZATION OF BRAIN FUNCTION AND CORTICAL MAPS. One of the echoing controversies in psychology concerns localization of function, the notion that the control of different aspects of behaviour resides in different parts of the brain. Although it is difficult to say exactly when the dispute arose, it certainly became prominent with the work of*Gall in the early nineteenth century. From first observing at school that the mental characteristics of his friends appeared to be related to the shape of their heads, Gall believed that traits like cautiousness and mirthfulness were localized and that their degree of development was indicated by the size and shape of the overlying part of the skull. Gall's*phrenology enjoyed a brief ascendancy until about 1820 when*Flourens, noting that damage to different parts of the brain often had similar and diffuse effects on behaviour, concluded that the brain acts as a whole. It was only after 1861, when*Broca first showed that speech impairment followed damage to a restricted part of the left frontal lobe, that localization of function acquired scientific respectability. And the dispute seemed settled in 1870 when Gustav Fritsch and J. L. Hitzig reported their observations on the effects of electrically stimulating different parts of the exposed brain, first in soldiers with head injuries and then in animals. They found that stimulating discrete parts of what is now known as the motor cortex produced movements of different regions of the body. Eighty years later, in 1950, W. G.*Penfield and Theodore Rasmussen published the results of similar observations made on fully conscious patients awaiting brain surgery under local anaesthetic. By electrically stimulating small regions along the central fissure, they showed that there was a map of bodily movements in front of the fissure and a map of sensation from the skin behind it (see Fig. 1). Meanwhile, in the intervening years, Gordon*Holmes had discovered that the eye is mapped on to the back of the brain. His method was to look for small areas of blindness in the visual field of patients with gunshot wounds at the back of the head. He found that the part of the

Fig. 1.

The diagram on the left shows a slice through one side of the brain, roughly between the ears and through what is called the somatosensory cortex. There is a map of the body surface here. Note that some areas, like face and fingers, have a much larger cortical representation than others, i.e. the map is distorted. The diagram on the right shows the map of the muscles in the motor cortex on a slice of the other side of the brain and at a more anterior portion.

eye that was blind depended on the part of the visual cortex that was damaged.

Despite this apparently irrefutable evidence of regional specialization in the brain in connection with speech, movement, seeing, and the sensations from the skin, *Lashley produced abundant evidence in the 1930s and earlier that Flourens' position was not untenable with respect to some forms of behaviour. By studying maze learning in rats, Lashley showed that the deleterious effects of removing parts of the cerebral cortex depended on the amount of tissue removed rather than on its exact location, a finding enshrined in the principles of mass action and equipotentiality. Lashley's views struck a sympathetic chord with many psychologists of the following generation, who likened the brain to a computer which can become increasingly unreliable as more of its components are damaged, but which rarely suffers a severe breakdown when a small number of specific localized components are removed.

With hindsight we can see that the often bitter controversy was unnecessary. The view that the brain acts as a whole stems from investigation of complex phenomena, such as learning and remembering complicated tasks involving several of the senses. It is small wonder that a good deal of the brain is involved in such behaviour and therefore that damage to any part of it has some effect. The evidence for regional specificity came, by contrast, from investigations of relatively simple actions such as moving a finger, seeing a light in one part of space, or detecting that a particular part of the skin had been touched. The latter are all examples of sensory discrimination or voluntary movements, the former of higher level cognitive and intellectual behaviour. To return to the analogy with a computer, we can say that the circuit controlling one of the bulbs on its visual display, or part of the keyboard used to type a program, is localized. But the function the computer performs, from arithmetic to guiding a spaceship, is not so localized.

The resolution of the apparently contradictory evidence concerning localization of function had one particularly interesting but unfortunate effect. It came to be taken for granted that the senses of touch and vision were mapped on the surface of the brain and that there was a similarly orderly representation of the muscles, as shown in Fig. 1. But why there is a map at all ceased to be recognized as a question of fundamental importance, despite the fact that nature had to go to a great deal of trouble to evolve a set of genetic instructions which ensured that the retina of the eye and the surface of the body are represented on the surface of the brain in an orderly map and not higgledy-piggledy. Furthermore, a computer programmed to recognize patterns does not need within its components anything like a map of the original scene. So why does the brain have one?

It became increasingly difficult to avoid the question with the demonstration from 1970 onwards of multiple maps of the retina in the brain. A map is usually demonstrated by recording the electrical activity of single nerve cells or clusters of them, determining where a visual stimulus must lie on the retina for it to excite these particular cells, and then moving the recording electrode to another group of cells. Using this procedure in anaesthetized animals, it has been shown that the retina is mapped not once but over and over in the cortex. The cat has at least thirteen mapped representations of the retina, the owl monkey at least eight, and the rat has six.

As shown in PRIMATES, EVOLUTION OF THE BRAIN IN, Fig. 8, the posterior third of the

cerebral cortex in the owl monkey is concerned with the multiple mapped representations of visual space.

What is the possible purpose of such an arrangement, which is not confined to vision for there are now known to be several topological representations of the surface of the body and the musculature in monkeys? The most plausible explanation concerns a wellknown physiological phenomenon called lateral inhibition. In the eye itself, adjacent differences in the brightness of the image are given prominence in the nerve signals that leave the eye. This is accomplished by a system of lateral inhibitory connections in the retina which ensure that nervecells tend to inhibit their immediate neighbours. In an area of uniform illumination, all cells are equally excited by the light and equally inhibited by their neighbours. But where there is a sharp difference in illumination, as at the image of a contour, the highly illuminated cells exert a powerful inhibition on their neighbours in the shade, and the difference in signals sent by the two groups of cells is enhanced. Lateral inhibition cannot create something out of nothing, but it can enhance one feature of the visual image at the expense of another. Lateral inhibition of the kind just described ensures that edges and contours are prominently coded in the signals from the eye.

There is now excellent evidence from physiology and anatomy that lateral inhibition works in the brain as well as in the eye, and this provides the major reason for the existence of a map of the retina on the cortex of the brain. If the differences in illumination of adjacent parts of the eye are to be given further note in the cortex, then the sensory connections between the nervecells concerned with the two adjacent parts of the image should be close together. In a map they are as close together as possible, and lateral interactions will be maximally efficient. If there were no map at all, so that nervecells concerned with adjacent parts of the image were often far apart in the brain, the problem of interconnecting the cells would be formidable and the average length of a connection could be much greater. In a map of the sensory surface the lateral interconnections between cells can all be local, and anatomy has shown this to be so.

But why are there many maps rather than just one? The answer is really the same. Inhibitory connections between neighbouring nervecells of the cortex are now believed to be involved in

Page 438

coding many attributes of the visual image, such as colour, movement, disparity, orientation, size, and spatial periodicity. If all of this were to be attempted within one map, the local interconnections would again have to be longer and the problem of interconnecting the right cells would increase. By having many maps, each of which is small and contains nervecells concerned only with one or a few of the stimulus attributes just mentioned, the lateral interconnections can be kept as short as possible and the problem of interconnecting the right type of cell is minimized.

This simple idea has much to support it. First, although there are long fibre connections from one part of the brain to another, electron microscopy has shown that the connections within a particular map are very short and predominantly inhibitory. Second, physiology has shown that nervecells within a particular cortical representation of the retina tend to be concerned with a restricted range of stimulus

qualities, such as orientation and size, or colour, or movement. Different representations deal with different stimulus qualities. Third, there are many examples of very selective effects on visual perception of localized brain damage. Although they are rare, some patients suffer a highly selective disturbance of the perception of colour or position or depth, as would be expected when the damage is occasionally restricted to one of the visual maps.

Although the different sensory qualities of the visual scene may initially be coded in separate visual areas, our visual perception is unitary not fragmented, which means that the timing of the activity of cells in different visual areas must be precisely coordinated. If we look at a moving, spinning coloured object and the nervous signals in one visual area were to be out of phase with all the others, some distortion should occur in what is seen. Indeed, fever, toxicosis, and brain damage may all lead to temporary visual perceptual dislocations. For example, in one part of the visual field objects may appear too large or too small, smooth movement may look jerky, contours may be multiplied, position and orientation be greatly misperceived.

Multiple brain maps of sensory and motor systems are now established. They permit the maximum efficiency and economy in the myriad interconnections between nerve cells responsible for analysing sensory signals. Their existence also throws light on what is now seen as an unwarranted controversy about localization of function. The cortical representations of the sensory attributes of some stimuli, such as colour, may be confined to a few areas. The cortical events underlying complex and cognitive actions are probably so widely dispersed that no brain damage, however great, can either destroy them entirely or leave them wholly unimpaired.

A. C.

LOCKE, JOHN (1632-1704), born at Wrington, Somerset, the first son of a lawyer whose father was a clothier. He was educated at Westminster School, where he was a King's Scholar, and Christ Church, Oxford, where he obtained a scholarship in 1652. His first published work was a complimentary poem for Oliver Cromwell, written while he was an undergraduate.

He took degree courses in logic, metaphysics and classical languages, but he was dissatisfied with the peripatetic philosophy he was taught. Even so, he developed an interest in experimental philosophy which led him to the study of medicine and the foundations of empirical philosophy. Through this he met Robert Boyle, probably the strongest influence on him, and became his close friend, student and unofficial assistant. He graduated as an MA in 1658 and was elected a Senior Student of Christ Church and then a lecturer in Greek.

After a brief excursion into diplomacy in 1665/6 he returned to Oxford to study medicine and collaborated with the great physician Thomas Sydenham. In 1667 he left Oxford to become personal physician to Lord Ashley, later first Earl of Shaftesbury, whose life he was credited with saving by an operation. He was elected Fellow of the Royal Society in 1668. On the third attempt he gained a doctorate in medicine in 1674 and was appointed to a medical studentship at Christ Church. In the 1670s he spent periods in France and drafted his first *Letter Concerning Toleration* and *Essay Concerning Human Understanding*.

In 1682 he met Damaris Cudworth, daughter of the Cambridge Platonist Ralph Cudworth. They became close friends and wrote poems and love letters to one another, but their romance never blossomed and in 1685 she married Sir Francis Masham and went to live at Oates in Essex. They remained firm friends and Locke spent his last years at Oates.

Under the influence of Ashley and his friends, Locke's political views became more liberal and he was involved in Whig and Protestant struggles against the power of the king. The first of his *Two Treatises of Government*, probably written in 1681, may be seen as a justification of Shaftesbury's revolutionary movement for a Protestant succession. Shaftesbury fled to Holland in 1682 and, after the Rye House Plot to kidnap the king in which a number of his friends were implicated, Locke followed in 1683. A year later, at the command of Charles II, he was deprived of his studentship at Christ Church.

While in Holland Locke worked at his *Essay*, sending it for publication in 1686. He also wrote letters, later published as *Thoughts Concerning Education*, to his cousin Mary Clarke, wife of Edward Clarke, about the upbringing of her son. He also had contact with William Penn, of whose constitution for Pennsylvania he had criticisms. In 1688 Penn secured a pardon for Locke from James II, which Locke rejected, but he returned to London on the accession of William III in 1689.

William offered him more than one ambassadorship, which he refused partly because of his inability
Page 439

to drink as deeply as such a post demanded. Instead he became a commissioner of appeals. His *Essay* was published in 1689 (dated 1690) by Thomas Bassett, who paid him £29 for the privilege. Locke met Isaac*Newton in 1689 and corresponded with him for the rest of his life, mainly on theological matters.

Finding that the London air was bad for his asthma, a lifelong complaint, he went to live with the Mashams at Oates, but his appointment as a commissioner for trade and plantations in 1695 involved him in much work in London, including the appointing of governors for New York and other American colonies, and the preparation of some vicious proposals, fortunately not accepted, for the combating of pauperism. He also worked on new editions of the *Essay*, and corresponded with admirers and critics, especially Edward Stillingfleet, bishop of Worcester. Perhaps his greatest mistake was to dismiss*Leibniz's criticisms as trivial. In 1698 the king offered him an important diplomatic post in Paris, possibly the one later held by David*Hume, but he refused. From 1700 until his death he lived in retirement at Oates. He is buried in the churchyard at High Laver in Essex. In spite of his many close friendships with beautiful women he had remained a bachelor.

Among his lesser known works were his editing of Boyle's *General History of the Air*, published in 1692, an edition of Aesop's *Fables* designed to help children to learn Latin, a book on money and interest rates, and the invention of a truss.

Cranston, M. (1957). *John Locke: a biography*. London

LOCKE ON THE MIND. In an early scholarly book on Locke, James Gibson (1917, p. v) said that it is too often assumed that the *Essay Concerning Human Understanding* 'can be understood without being studied and that its full significance can be summed up in a small number of simple propositions'. This assumption is still made in spite of recent efforts by scholars. Locke is often spoken of as a precursor of modern psychology, but his view of the mind and its influence is seldom studied in detail. It is said that for Locke the mind was a mere passive receptor of sensations, that he espoused a crude*faculty psychology, and that he was an important initiator of associationist psychology. When these allegations are not plainly false they are seriously misleading.

Locke begins by saying (*Essay*, I.i.1, 2) that the understanding, like the eye, makes us 'see and perceive all other things' but takes no notice of itself; 'Art and Pains'

are required to discover its nature. However, he says that he does not intend to enquire into the physical concomitants of the mind or to 'examine wherein its Essence consists'. What he does propose to examine is the relations between the mind and its objects.

A central conception of Locke's philosophy is that of *ideas*. This word is used to refer to various different things, including sensations or sensedata, memories, and concepts: when I see a yellow daffodil I am having, *inter alia*, an idea of yellow, when I remember the colour I am having a memoryidea of it, and when I think about democracy I am operating with an idea (i.e. concept) of democracy. None of these ideas should be thought of as mental *images*, but an idea may be an image. It is usually clear from the context which of these meanings is intended. The term 'idea', Locke says, stands for 'whatsoever is the Object of the Understanding when a Man thinks' or 'whatever it is which the Mind can be employ'd about in thinking' (*Essay*, I.i.8).

All ideas originate in experience. Locke devotes the whole of Book I to arguing directly against the conception of*innate ideas, and then says that the whole of the rest of the *Essay*, based as it is on the hypothesis that there are no innate ideas, shows that we can do without this conception.

There are two sources of ideas: sensation and reflection. Ideas of sensation occur when we observe external objects, and ideas of reflection when we observe the operations of our minds. Thus we come by ideas of yellow, cold, square, sweet, and of perceiving, believing, willing (II.i.24).

Ideas may be simple or complex. Complex ideas are analysable into, or constructed out of, simple ideas, but simple ideas are unanalysable and unconstructed. The mind is passive in its reception of simple ideas; it cannot prevent simple ideas from being impressed on the mind, or alter them, or choose to have a particular simple idea in the absence of the appropriate stimulus. However, this passivity is limited, and in the reception of simple ideas the mind may be active in attending to, or noticing, different things. The reception of simple ideas is not regarded by Locke as a purely physical process but involves also a mental element, logically distinct from the physical elements. He says that 'in bare naked *Perception*, the *Mind* is, for the most part only passive' (II.ix.1), but he also says that 'whatever impressions are made on the outward parts, if they are not taken notice of within, there is

no Perception' (II.ix.3). If we are concentrating on a difficult book we may fail to notice even a loud noise and so not receive the idea even though our sense organs are stimulated (II.ix.4). It is similar with simple ideas of reflection (II.ix.7, 8).

However, the mind is active in operating upon its ideas as it does in remembering, discriminating, comparing, combining and enlarging, and abstracting them. By *combining* simple ideas the mind makes complex ideas, by *comparing* the mind arrives at ideas of relations, and by *abstracting* them from other ideas with which they occur it makes general ideas (II.xii.1).

Locke refers to thinking and willing, 'the two great and principal Actions of the Mind', as 'faculties' (II.vi.2), but he warns us against thinking of them as 'real Beings in the Soul, that perform[ed] those Actions of Understanding and Volition'. They are not separate mental agents Page 440

each with its own task to perform; it is *the mind* that performs all these actions (II.xxxi.6).

Locke devotes a whole chapter to 'the association of ideas'. If it is true that this chapter was an important influence on the creators of associationist psychology then it is likely that those creators were among the many who have misunderstood Locke. This chapter, the last in Book II, was included only in the fourth and fifth editions of the *Essay* and the central conception is put to a very limited use: that of explaining one of the ways of going wrong in thinking, which Locke describes as 'a sort of madness'.

The sort of unreasonableness shown by a person who argues obstinately for his view in the face of all the 'evidence of reason' is often thought to result from education, presumably faulty, and prejudice. Locke, says,

Education is often rightly assigned for the Cause, and Prejudice is a good general Name for the thing it self: But yet, I think, he ought to look a little farther who would trace this sort of Madness to the root it springs from, and so explain it, as to show whence this flaw has its Original in very sober and rational Minds, and wherein it consists (II.xxxiii.3).

Locke calls this 'Madness' because it is 'opposition to reason', which he sees as one, but not the only, form of madness. What particularly concerns him includes arguing from false premisses provided by the association of ideas;

Some ideas are 'naturally' connected. An example that he might have given is the ideas of shape and size, which are essential properties of matter. However, besides this 'natural connexion',

there is another Connexion of Ideas wholly owing to Chance or Custom; Ideas that in themselves are not at all of kin, come to be so united in Mens Minds, that 'tis very hard to separate them ... and the one no sooner at any lime comes into the Understanding but its Associate appears with it ... (II.xxxiii.5).

Locke then proposes a possible explanation for this which resembles a 'braintrace' theory (see ENGRAM). Custom may 'settle' trains of motion in the 'animal spirits',

'which once set a going continue on in the same steps they have been used to, which by often treading are worn into a smooth path, and the Motion in it becomes easy and as it were Natural' (II.xxxiii.6). Thus two ideas may be connected by accident and then, by the strength of the original impression or frequent repetition, appear to be necessarily connected. If an adult is surfeited with honey, the very idea of honey may call up the ideas of dislike and vomiting. He can trace this association to its origin. However, if this happens to a very small child the cause may not be noticed and the child may be thought to have a 'natural antipathy' to honey (II.xxxiii.7). We should, in educating children, strive to prevent the undue connection of ideas that are in themselves 'loose and independent' of one another. Children may, for example, become afraid of the dark because goblins are, unnaturally, associated with darkness.

Associationism, seen primarily as the attempt to reduce all mental activity, including rational thinking, to the association of ideas, or sensations, is very far from Locke's conception of association. However, other aspects of Locke's philosophy of mind, and matter, might be more plausibly related to one idea of 'mental chemistry'

espoused by some associationists. He was greatly influenced in his discussion of physical phenomena by chemistry and the corpuscular hypothesis of Robert Boyle.

Locke accepted that physical objects are composed of minute corpuscles having just a few simple, intrinsic, 'primary' qualities, and that the more complex 'secondary'

qualities of the physical objects may be explainable in terms of the primary qualities of the constituent corpuscles in their many different arrangements. There are suggestions in Locke's works that if he had gone on to consider mental phenomena in more detail he would have arrived at a view similar to his view about physical phenomena, namely that complex mental states or activities could be analysed into, or explained in terms of, simple mental entities. He does appear to have supposed that there is mental as well as material substance, and he might well have distinguished between primary *mental* qualities (simple) and secondary *mental* qualities (complex). There is a parallelism between the concepts of simple physical corpuscles combined to form complex physical bodies—primary qualities so arranged as to produce secondary qualities—and simple ideas combined to form complex ideas. Applied to mental as well as physical phenomena, this suggests a form of 'mental chemistry', according to which mental compounds may be analysed into simple mental elements, such as sensations (Woodworth, 1931). Locke does not, however, show any signs of attributing the combining of ideas involved to *his* conception of the association of ideas; he reserved that for the explanation of the involuntary connecting of ideas and held that the *reliable* connections of ideas were the result of natural or chosen connections (*Essay*, II.xii.2). There are, of course, problems about what 'natural' means, about how the ideas of natural connections and voluntary connections would relate to one another and to the combining of primary mental qualities to give secondary mental qualities, and how far the analogy with the corresponding physical combinings would hold.

LOEB, JACQUES (1859-1924). German biologist, born in Mayen. Educated in Berlin, Loeb emigrated to America in 1891, and finally became head of the general physiology division of the Rockefeller Institute for Medical Research (1910-24). He worked on comparative physiology, and on artificial parthenogenesis, but he is perhaps best known for his elegant experiments on the 'forced movements' of tropisms in simple animals and for his 'tonus hypothesis' to explain this highly ordered behaviour. The tonus hypothesis is that paired receptors, such as the eyes, send signals to paired muscles which when in balanced tension make the animal move in a straight line either towards the source of the stimulus (positive tropism) or away (negative tropism). Loeb's work on quantifying tropisms, and combining and opposing them to find their relative strengths and interactions, is important in its own right, and it is historically a basis of behaviourism, as it suggested that there might be simple laws for the behaviour even of higher animals. The tonus hypothesis is now abandoned for even simple animals, and the behaviour of higher animals is not stimulus determined.

Loeb's books include *Dynamics of Living Matter* (1906); *Artificial Parthenogenesis and Fertilisation* (1913); and *Forced Movements, Tropisms, and Animal Conduct* (1918).

LOGICAL POSITIVISM. Philosophical school, based on linguistic analysis (to clarify the meanings of statements and questions) and on demands for criteria and procedures of empirical verification (for establishing at least in principle truth or falsity of statements, by observation or experiment). Logical positivism is essentially a systematic attack on metaphysics by demanding observations for conferring meaning. Metaphysics is rejected as nonsense. Many positivists (such as

Bertrand*Russell) were influenced by the doctrines of 'logical atomism', which claimed that the world is a collection of atomic facts describable by simple propositions, the truth of which is independent of the truth of all other propositions. The positivist analogue of this doctrine is the idea that every basic statement must, in order to be meaningful, be verifiable in isolation. This argument has, however, largely been abandoned, as many clearly important statements in science are not individually verifiable; and it has proved impossible to formulate consistent criteria of verification which are not either too 'weak' (failing to reject metaphysics) or too

'strong' (rejecting important statements in science or other knowledge). See also VERSTEHEN.

The book which introduced and most clearly formulated logical positivism in the English language is A. J. Ayer, *Language, Truth and Logic* (1936).

LUNACY. The term was originally used to denote an individual subject to intermittent bouts of insanity thought to be influenced by the phases of the moon. According to Hugh Farmer (1775), in Greek and Roman times it was synonymous with epilepsy, and the evangelist St Matthew also appears to have considered lunacy and epilepsy as one and the same condition (Matt. 17:15).

In English law, lunacy implied such mental unsoundness as interfered with civil rights and transactions. The word was used in Britain throughout the nineteenth century in titles of the numerous Bills and Acts brought into Parliament for the regulation of persons suffering from mental illness. The general currency of lunacy and lunatic is shown in the title of a book published in 1850, *Familiar Views of Lunacy and the Lunatic Life*. If, as is probable, the author was Dr John Conolly of Hanwell Asylum, a man with the deepest concern for the welfare of patients committed to his care, evidently he did not consider the book's title to be derogatory but simply an apt description of conditions in his hospital. As time has gone by the words 'lunacy' and 'lunatic' have dropped out of medical parlance, to be replaced by mental illness and mental disorder in the last two 'Lunacy' Acts, the Mental Health Acts of 1959 and 1983.

LURIA, ALEXANDER ROMANOVICH (1902-77). Soviet psychologist, probably the only one to become generally known outside the USSR after the Second World War. Born in Kazan of Jewish extraction, Luria was educated at the University of Kazan and graduated in social sciences in spite of his father's wish that he should qualify in medicine, which in fact he did several years later when his career in psychology underwent an unexpected check. His interest in psychology developed rapidly and while still a student he had the temerity to found a psychoanalytic circle in Kazan which he brought to the attention of Sigmund*Freud himself—

though later he repudiated psychoanalysis.

In 1925 Luria was appointed to a junior post at the Moscow Institute of Psychology, where, under the direction of N. K. Kornalov, he carried through an ambitious research programme on the effects of emotional stress on human motor reactions recorded under experimental conditions. This work owed something to Ivan*Pavlov's work on experimental neurosis in dogs, though it should be stressed that while Luria had the highest regard for Pavlov as a physiologist, he never accepted his view that

complex human behaviour could ever be satisfactorily explained in terms of reflexes and conditioned reflexes. (His adherence to this view Page 442

caused him great difficulty in later life and nearly brought his career to an untimely end.) Luria wrote up his experimental findings in a massive book which was published in English translation as *The Nature of Human Conflicts* (1932).

In 1924, Luria had made the acquaintance of Leo Semionovich*Vygotsky, originally a language teacher who deviated to psychology and came to exert a remarkable influence on the younger generation of Soviet psychologists. Although a convinced Marxist, Vygotsky was far from doctrinaire and had wide interests in human development and the role of education and culture in shaping it. Also he developed a lively interest in the effects of nervous disease on human intellectual capacities and was almost certainly responsible for redirecting Luria's interests towards*neuropsychology. He agreed strongly with Luria in deploring Pavlov's rejection of mind and consciousness in the human sciences.

Partly as a result of Vygotsky's influence, Luria successfully qualified in medicine, and in 1941 he was pressed into service as a medical officer with special responsibilities for the assessment and rehabilitation of braininjured servicemen. His background in psychology, together with a more recently acquired knowledge of linguistics, enabled him to devise some simple, yet effective, methods of assessing deficits in higher psychological capacities and of retraining the patients whenever possible. This work was later transferred to the Institute of Neurosurgery in Moscow, and Luria continued to work there until 1950, when he was summarily dismissed from his post, apparently for ideological reasons, in particular his somewhat feeble enthusiasm for Pavlovian methods and theory. Fortunately, he was restored to his post some years later and was able to return to his neuropsychological studies virtually until his death.

Luria was a prolific writer, many of whose books and scientific papers were translated into English. He visited Britain and the United States on many occasions in the 1950s and 1960s to attend conferences and give lectures, and he made numerous friends in psychological and neurological circles, many of whom visited him in Moscow on occasion and came to know him well. His posthumous autobiography, *The Making of Mind: a personal account of Soviet psychology*, edited by Michael and Sheila Cole (Harvard, 1979), provides a brief but evocative account of his life and work.

Luria's principal books in English translation are *The Nature of Human Conflicts* (trans. W. H. Gantt, 1932), *The Role of Speech in the Regulation of Normal and Abnormal Behaviour* (1961), *Traumatic Aphasia* (trans. Basil Haigh, 1970), *Basic Problems in Neurolinguistics* (trans. Basil Haigh, 1976), and *Higher Nervous Functions in Man* (2nd edn. trans. Basil Haigh, 1980).

O. L. Z.

LYCEUM. The name of the gymnasium and covered garden adjacent to the temple of Apollo Lyceus in Athens where Aristotle taught his students.

LYING. Deliberate falsification of the truth in order to confuse or mislead. This is an essential weapon for selfprotection; and for societies, especially in war, to put an enemy off his stroke. Although condemned by moralists, lying can have high survivalvalue.

Page 443

M

McCULLOCH, WARREN STURGIS (18991969). American neurophysiologist, cybernetician and philosopher of mind. Born in Orange, New Jersey, his first degrees were from Yale (1921) and Columbia (1923), and his MD was from Columbia in 1927, where he was an instructor in physiological psychology following an internship at Bellevue Hospital in New York. He did his classic work with Dusser de Barenne at Yale, which led to the book *The Isocortex of the Chimpanzee*.

Moving to the University of Illinois in 1941, he started the collaboration with Walter Pitts, which provided two of the foundation papers of brain theory, 'A logical calculus of the ideas immanent in nervous activity' and 'How we know universals: the perception of visual and auditory forms'.

From 1952 he was a member of the Research Laboratory of Electronics at the Massachusetts Institute of Technology, where he devoted himself fulltime to leading a research group working on models of neural networks. This was the period that produced the work (with Jerry Lettvin and Humberto Maturana) 'What the frog's eye tells the frog's brain', a series of papers (with Jack Cowan, Sam Winograd and Manuel Blum) on the construction of reliable neural networks from unreliable components, and an interest (largely stimulated by the philosophy of C. S.*Peirce) in the construction of a logic of triadic relations.

See also MCCULLOCH'S CONTRIBUTIONS TO BRAIN THEORY.

M. A. A.

McCULLOCH'S CONTRIBUTIONS TO BRAIN THEORY. Warren*McCulloch was a central pioneer figure of cybernetic and computational models of brain function. The year 1943 saw the publication of 'A logical calculus of the ideas immanent in nervous activity' by McCulloch and Walter Pitts, in which they offered their formal model of the neurone as a threshold logic unit, building on the neurone doctrine of*Ramon y Cajal, and the excitatory and inhibitory synapses of*Sherrington.

A major stimulus for their work was the*Turing machine, an imagined device which could read, write and move upon an indefinitely extendible tape each square of which bore a symbol from some finite alphabet. Alan Turing (1936) had made plausible the claim that any effectively definable computation (i.e. anything that a human could do in the way of symbolic manipulation by following a finite and completely explicit set of rules (in 1936 the referent of 'computer' was still a human!) could be carried out by such a machine equipped with a suitable program. What McCulloch and Pitts demonstrated was that each such program could be implemented using a finite network, with loops, of their formal neurones.

In another classic paper 'How we know universals: the perception of auditory and visual forms', Pitts and McCulloch (1947) sought 'general methods for designing nervous nets which recognize figures in such a way as to produce the same output for every input belonging to the figure'— just as we recognize a figure such as a square, despite changes in position or size.

Thus they sought to explain how we know universals. Lettvin, Maturana, McCulloch, and Pitts (1959) turned to the frog for experimental answers to the questions set by the earlier paper, noting that the frog is normally motionless, and that its visually guided behaviour can be adequately described in terms of recognition of two universals, *prey* and *enemy*. (Subsequent research has complicated this picture considerably—Fite, 1976.) Lettvin et al. (1959) found that the majority of the axons of the frog's retinal ganglion cells could be classified into one of four groups, on the basis of their response to visual stimuli, and that moreover the axons of the four groups ended in four distinct layers of the tectum (part of the frog's midbrain), with the four layers being in registration, in that vertically arranged cells in the tectum would signal the presence or absence of the four features in the same region of the visual field. The four feature detectors described in this celebrated paper, 'What the frog's eye tells the frog's brain', were:

- (i) *Sustained contrast detectors* yield a prompt and prolonged discharge whenever the sharp edge of an object, either lighter or darker than the background, moves into its receptive field and stops there (or appears there when light is turned on).
- (ii) *Net convexity detectors* respond to a small or convex edge of a large dark object passed through the visual field; the response does not outlast the passage; a smooth motion across the visual field has less effect than a jerky one.
- (iii) *Moving edge detectors* respond to any distinguishable edge moving through its receptive field.

(iv) *Net dimming detectors* respond to sudden reduction of illumination by a prolonged and regular discharge.

The essential point of this is that 'the eye speaks to the brain in a language already highly organized and interpreted, instead of transmitting some more or less accurate copy of the distribution of light on

Page 444

the receptor' (Lettvin, et al., 1959, p. 1,950). Further, the encoding is such as to aid the frog in finding food and evading predators—in recognizing the universals *prey* and *enemy*.

We now turn to McCulloch's consideration of the question 'How is the central nervous system structured to allow coordinated action of the whole animal when different regions receive contradictory local information?'. McCulloch suggested that the answer lay in the *principle of redundancy of potential command*, which states, essentially, that command should pass to the region * with the most important information. He cited the example of a naval fleet, where the behaviour of the whole (First World War) naval fleet is controlled at least temporarily by signals from whichever ship first sights the enemy—the point being that this ship need not be the flagship, in which command normally resides. McCulloch suggested that this redundancy of potential command in vertebrates would find its clearest expression in the reticular formation (RF) of the brainstem. W. L. Kilmer and McCulloch then made the following contributions toward building a model of RF. Firstly, they noted that at any one time an animal is in only one of some twenty or so gross *modes* of behaviour (e.g. sleeping, eating, grooming, mating), and they suggested that the main role of the core of the RF (or at least the role they sought to model) was to commit the organism to one of these modes. Secondly they noted that anatomical data (of the Scheibels, 1958) suggested that RF need not be modelled neurone by neurone, but could instead be considered as a stack of 'poker chips', each containing tens of thousands of neurones, and each with its own nexus of sensory information. Thirdly they posited that each module ('poker chip') could decide which mode was most appropriate to its own nexus of information, and then asked: 'How can the modules be coupled so that, in real time, a consensus can be reached as to the mode appropriate to the overall sensory input, despite conflicting mode indications from local inputs to different modules?'

In this framework, Kilmer et al. (1969) designed and simulated a model, called SRETIC, of a system to compute mode changes, comprising a column of modules that differed only in their input array, and that were interconnected in a way suggested by RF anatomy, as the anatomy was at that time described.

The overall effect of the scheme is to decouple the modules initially, after an input change, in order to accentuate each 'poker chip's' evaluation of what the next mode should be, and then through successive iterations to couple them back together, in order to reach a global consensus. Computer simulation showed that SRETIC, at least with the coupling patterns they studied, would converge for every input in less than 25 cycles, and that once it had converged it would stay converged for a given input. When the inputs strongly indicate one mode, convergence is fast; but when the indication is weak, initial conditions and circuit characteristics play an important role. Although the anatomical

picture of SRETIC has now changed, this is the start of the important concept of 'cooperative computation' for brain function.

Let us now briefly examine the general implications of these papers for brain theory. For Pitts and McCulloch, the point of their model of the superior colliculus (the mammalian analogue of the frog's tectum) was that it gave an implementation of their conceptual scheme that did justice to neurophysiological data. However, the scheme has far greater significance than this, for it shows how to design a* *somatotopically organized network in which there is no 'executive neurone' that decrees which way the overall system behaves; rather, the dynamics of the effectors, with assistance from neuronal interactions, extracts the output trajectory from a population of neurones, none of which has more than local information as to which way the system should behave*. In other words, the Pitts and McCulloch model of the superior colliculus showed how 'the organism can be committed to an overall action by a population of neurones none of which had global information as to which action is appropriate'. This is the organization (and sometimes disorganization!) of a democracy. The study of cooperative computation in somatotopically organized networks now provides a central paradigm of brain function.

McDOUGALL, WILLIAM (18711938). British psychologist, born in Lancashire. After studying at

Weimar, Manchester, and Cambridge, he became a medical student at St Thomas's Hospital, London. In 1898 he accompanied an important anthropological expedition to the Torres Strait. Having held the Wilde readership in mental philo

Page 445

sophy at Oxford from 1904 to 1920, he emigrated to America, going first to Harvard, and then, in 1927, to Duke University, North Carolina.

McDougall rejected*behaviourism and made*purpose the centre of his philosophy of psychology. He wrote extensively and was very widely read. Of particular interest are *Body and Mind* (1911), *Outlines of Psychology* (1923), *The Energies of Man* (1933), and *An Outline of Abnormal Psychology* (1926), which has an account of hypnosis. McDougall held a theory of mind involving monads, somewhat similar to*Spinoza and*Leibniz (see LEIBNIZ'S PHILOSOPHY OF MIND). He suggested that the mind is a kind of interacting network of monads linked by telepathy, and that brain damage can have little effect provided these links remain. His hydraulic analogies of purpose were taken over by the early ethologists. Late in life, McDougall espoused*Lamarckianism, carrying out with an assistant (who probably falsified the results) experiments in which rats' tails were cut off to demonstrate inheritance of an acquired characteristic. These experiments damaged his reputation; but his books remain worth reading today for their clarity and verve. The significance of some of his concepts for current thinking is well brought out by Margaret Boden in *Purposive Explanation in Psychology* (1972). In particular, his account of*emotions as the experience of thwarted drives remains important; as, more generally, does his attempt to use purpose as an explanatory concept in psychology.

MACH, ERNST (18381916). Austrian physicist and philosopher of science. Born in Moravia, he studied at Vienna, and became professor of mathematics at Graz in 1864; of physics at Prague in 1867; and of physics at Vienna in 1895. His experimental work was largely on the flow of gases. His philosophical writings both laid the foundations for*logical positivism and were a basis for Einstein's theory of relativity. (Mach's Principle suggests that effects of accelerated motion, including rotation, are absolutely related to the mean mass of the universe; in practice, to the 'fixed' stars.) Mach contributed to knowledge of*perception, especially in his *Beiträge zur Analyse der Empfindungen* (1897; trans. C. M. Williams, *The Analysis of Sensations*;

and the Relation of the Physical to the Psychological, 1959). He was among the first to use visually ambiguous figures as research tools, for separating what we now call 'bottomup' and 'topdown' processing. (See ILLUSIONS.)

He tried to base the whole of physics on the observer's sensations. This was important philosophically, as it is an extreme form of operationalism which led to logical positivism and criteria of verification (as set out in A. J. Ayer's *Language, Truth and Logic*, 1936). The attempt has, however, turned out to be unsuccessful—

unless, at least, we allow very large gaps with many unverified steps between observations (and

especially sensations) and accepted facts of the world. Further, the relation between sensation and perception remains far from clear, for—as Mach himself showed—how we perceive objects affects sensations, such as surface colour and brightness. So, though important, sensations can hardly be the building blocks of perception or of physics.

Other works by Mach available in English are: *Space and Geometry: in the light of physiological, psychological and physical inquiry*, trans. T. J. McCormack (1960); *The Principles of Physical Optics: an historical and philosophical treatment*, trans. J. S. Anderson and A. F. A. Young (1926); and *The Science of Mechanics: a critical and historical account of its development*, trans. T. J. McCormack (1960).

' **MAD AS A HATTER**'. This expression probably derives from the fact that mercury, used in the manufacture of felt, which in turn was used to make hats, produces loss of memory and other symptoms of the*Korsakoff syndrome when absorbed by the skin. The idea is immortalized in the Mad Hatter in Lewis*Carroll's *Alice's Adventures in Wonderland*.

MAGENDIE, FRANÇOIS (17831855), French physiologist, was born at Bordeaux and died at Sannois. He studied and practised medicine in Paris, researching in many fields and lecturing on experimental physiology; he was appointed professor of medicine at the Collège de France in 1831.

In 1809 he demonstrated that poison from the plant *Strychnos* was carried in the bloodstream and not by the lymphatics. This led to the isolation of strychnine in 1818, and he introduced it, as well as emetine, morphine, iodides, and bromides into medical usage. He also studied nutrition scientifically, and realized the importance of proteins.

Magendie's discovery in 1822 that the dorsal root of a spinal nerve was sensory and the ventral root motor was also claimed by Sir Charles*Bell: It is generally accepted that Magendie gave the final proof and description to work originated by Bell. His wide interests included research on the cerebellum, on olfaction, and on the circulation.

See also REFLEX ACTION.

D. D. H.

MAINE DE BIRAN (PierreFrançois Gonthier de Biran, 17661824). A French philosopher, son of a doctor from Bergerac, he held public office after the Revolution, under the Consulate and the Empire, and after the Restoration. For most of his mature life, he pursued the project of producing a single major work devoted to the Science of Man. Though he wrote extensively, this central project was never fulfilled, and he published very little during his lifetime. Most of the works subsequently published are (sometimes misleading) editorial reconstitutions and compilations. However, the historical place of his work and the main lines of development of his thought can readily be seen.

Biran marks an important transition in man's attempt to explore and understand his own mind.

We must place him on the one hand in the introspective tradition of those like Montaigne and *Pascal who gave prominence to the analysis and exposure of the intimacies of their own souls, and on the other hand in the empiricist tradition stemming from *Bacon, especially as it emerged through *Locke and the British empiricists in the sensationalism of the eighteenth century propounded by authors like David Hartley, *Condillac, and Charles Bonnet. He represents not only an intersection of these traditions, but also a source of later very divergent approaches to the mind, in experimental psychology, in psychoanalysis, and in *phenomenology.

His works fall into three main periods: an exploratory period in which he read and wrote very widely and in which his ideas were beginning to take shape, a mature period in which 'Biranian' theses found their clearest and most systematic expression, and a late period in which he stepped beyond his central psychological concerns to a consideration of questions of transcendent metaphysics and to an exploration of the nature of religious experience.

A main task which Biran set himself, above all in the mature period, was to explicate the notion of the will, holding that we should not understand anything in psychology if we did not understand the phenomenon of willed action; while if we did understand it, we should already have a framework for the understanding of other psychological notions. Willed action was in this sense the 'primitive fact' of psychology.

This contention already contains his central critique of the traditional empiricist view of the mind. Though the empiricists had, he thought, been right in respecting the empirical methodology of the natural sciences, and right also in giving the role which they often did give to introspective experience, they went disastrously wrong in adopting a passive model of the mind, in which *perception was thought of as simple reception of data, and action became either the mechanical result of accumulated inputs, or an arbitrary intrusion in the causal nexus.

For Biran, the operation of the will was known through immediate introspective experience; this experience was centrally the experience of willed *effort*—especially muscular effort—and the phenomenon of the will like all other mental phenomena was essentially *relational* ('Rien n'est dans la conscience qu'à titre de rapport').

This last claim represented another important break with the classical empiricists and foreshadowed phenomenology. But what is its force? It may seem that a case of willed action such as my raising my arm will be rightly analysed into two components—an act of will, followed by a bodily movement. The act of will would then presumably be an inner event known introspectively to the agent. But Biran denied the existence of such inner objects of attention: 'The inner sense has no object.' By this he meant that what is present to the inner sense is always properly a *fact*, and never an *object*—in this case, the fact of deliberately raising one's arm. This fact is *understood* as a relation between two terms, the active self, and the action performed, a relation occurring in the effort exerted. But these two terms are inseparable.

When I deliberately raise my arm, the action is willed; but it does not contain a component of willing which might occur without the movement, and of which I could be independently aware through my

inner sense. Thus, if in the natural sciences we observe independent events between which we attempt to discover a causal relation, using hypotheses of an underlying causal mechanism, in psychology, on the other hand, it is the causal relation which is given (in the central case of willed activity), and the extrapolation to a separate mental act of willing (whose causal link with the movement would then become problematic) must be resisted.

What then of the underlying physiology? Biran had an extensive knowledge of and respect for contemporary work in physiology and related empirical disciplines.

However, he denied the reductionist thesis that psychological statements could be reduced, for instance, to physiological ones. This thesis encouraged absurdities like Cabanis's claim that the brain 'digests impressions' and 'secretes thought'. What then was the relation between psychological events and physiological processes? Biran denied that a thought was identical with, or caused, or was caused by such a process. He claimed rather that the relation between a physiological and a psychological statement was *symbolic*, meaning by this that the two kinds of account were partially isomorphic: they corresponded systematically, without corresponding in full. Thus we could pass from a statement that I deliberately raised my arm to a statement that certain physiological processes occurred in me, and thereby attain a greater understanding of human action; but we could not *translate* the one into the other without loss.

However, there is a further complexity in willed action: for I cannot act deliberately without knowing what I am doing. More generally, the separation of reason and will, or action and cognition, is a fundamental error. To act is to know, and vice versa. The first act of will is the origin of humanity: it is the birth, not only of the will, but of the intellect, of consciousness, of language and knowledge. Just as acting must in part be an exercise of cognition, so perception, for instance, is an active faculty, and not a mere receptivity.

However, though Biran thought that will, consciousness, thought, and knowledge were inseparable features of the active life, he also claimed that this life came into being by raising to its level materials drawn from a complex passive underlayer of our experience—a vast subconscious, which, though sometimes drawn up into our conscious life, nevertheless lay broadly untapped, mysterious in its fashioning of our conscious being.

Page 447

Biran wrote in his diary of 'an inner New World to be discovered one day by a Columbus of metaphysics'; the task would require one to 'plunge into the subterranean caverns of the soul', and would require a partnership of introspection and physiological knowledge.

This striking prediction of the nature and importance of psychoanalysis, together with his extensive anticipations of crucial areas of research in empirical psychology, whether on the influence of drugs (see PSYCHOPHARMACOLOGY), the nature of conditioning, the application of educational research, the study of the mechanisms of dreaming, or the interplay in clinical psychology of abstract theory and pragmatic cure, and, thirdly, the equally striking anticipation of the programme of

phenomenology—all these things should lead us to correct Biran's own estimate of his work. Near the end of his life, he reviewed his life's work in his diary. It had been, he felt, too schematic and too limited. It had ignored the religious and the social dimensions of human experience. 'I despise what I have been doing,' he said; 'I have spent my life erecting a mere scaffold.' That scaffold has served for the construction not of one theory but of a multiplicity of theories of the nature of the human mind. For that reason alone, it should command our respect and our attention.

MAKARENKO, ANTON SEMYONOVITCH (1888/1939), Russian educationist. Already a trained teacher, he took on the task of working with homeless juvenile delinquents left behind after the upheavals of the 1917 revolution and the civil wars which followed it. The numbers were never firmly established, but Lenin's wife estimated there were as many as seven million who were homeless and forced to survive by crime and violence. Makarenko was unimpressed by the Rousseauist educational theories of the early revolutionaries (see ROUSSEAU AND EDUCATION), who were in favour of leaving the child to educate himself by his own efforts. He thought the theorists were too distant from the masses and in particular from the *besprizornye* (waifs, homeless children) he had to face. He found inspiration in the writings of Gorky, particularly *My Childhood*, *My Universities*, and *The Lower Depths*.

His approach to young people was based on actual observation and an awareness of the material necessities of their situation. When he set up his first colony he had almost singlehandedly to find food and accommodation, and he displayed a concern which gained the respect of the young people who were brought to him. He ignored the elaborate police dossiers which accompanied them, preferring, like the children themselves, to forget past misdemeanours and to make a new start. He realized that their basic necessity was security. As a Bolshevik he saw the collective as a mode of

organization giving security to the individual but also developing a sense of obligation to others. He had no compunction about enforcing conformity: 'The individual has to be incorporated into the collective in such a way that he believes himself to belong to it freely and without compulsion.' He believed in selfdiscipline as the goal of moral education but thought that the teacher had a responsibility to develop it. Children learned through being given responsibility: a persistent thief would be sent to collect money for the colony, and the children had to grow their own food.

The colonies were organized into 'detachments', each with a student leader, and all jointly responsible for running the whole community. Workshops were set up to produce goods which could be sold outside. There were large numbers of cultural activities, among them drama, modelmaking, pantomime, and brass bands, as well as conventional schoolwork. However, the school was not simply a place where knowledge and skills were acquired, but a way of life where members learned initiative and selfrespect through the discipline of working for each other and through selfgovernment. Each member of the youth collective belonged to the group not as a faceless cipher but as one who takes responsibility, not only for his own actions but also for those of his fellows. Because the collective provided support for the individual, it could also make demands which enlarged his capacity as a human being. Respect for the individual led Makarenko to challenge his pupils with difficulties to overcome. In his relationship with pupils, he argued that a balance had to be kept between kindness and severity; sentimental indulgence was to be avoided. His intention was not simply to rehabilitate but to prepare for life in a Communist state. It is arguable that his influence on Soviet education inspired the almost incredible selfsacrifice demanded and obtained by Russia during the war against Germany.

Makarenko was an idealist, one of the few who survived the Stalinist purges of the 1930s. Although influential, his work has not prevented social stratification in the USSR, and it would seem, too, that youthful hooliganism and delinquency are still a problem. Despite the totalitarian implications of his work, Makarenko's Page 448

practicality and humanity are still relevant, even

outside the USSR.

MALTHUS, THOMAS ROBERT (1766-1834), English economist and mathematician, born at Dorking, Surrey, and educated at Jesus College, Cambridge. His *Essay on the Principle of Population* (published anonymously in 1798; enlarged, 1803) inspired, or triggered, both Charles*Darwin and Alfred Russel*Wallace to develop the theory of evolution of species by natural selection.

MANIA. A form of mental disorder manifested by uncontrolled excitement, overactivity, and obsessive behaviour.

MANIC DEPRESSIVE. A personality oscillating between overactivity and inability to summon up energy or make decisions. In extreme form, it is *manicdepressive psychosis*. In a controlled form it can be useful for creativity. The writer Samuel Johnson was supposed to be manic depressive, using the manic phase for writing and the depressed phase for selfcriticism. See DEPRESSION.

MANNERS. Rules of manners can be found in every culture. They are meant to regulate the behaviour of the individual in everyday life and social intercourse. There are rules for walking, sitting, laughing, eating, speaking, greeting, etc. Manners are not identical (though closely related) to either rites or morals. Although some of them are very refined and change with fashion, manners probably reflect a more primitive level of behaviour than rites such as sacrifice (see BLOOD MYTHS), or moral commandments such as the Ten Commandments. In general, rules of manners focus either on neatness (which may have hygienic origins) or respect: two examples of the latter are elaborate systems of salutation, and a rule not to stare into another person's eyes. Francis*Bacon has given one of the best definitions: 'The whole of decorum and elegance of manners, seem to rest in weighing and maintaining, with an even balance, the dignity betwixt ourselves and others' (*The Advancement of Learning*, 1605).

Many of these aspects of behaviour can also be found in higher animals. Dogs and cats have elaborate rules of greeting which also determine the order of rank. Many animals—for example, rhesus monkeys—interpret fixating the eyes as aggressive behaviour. A subordinate animal would instantly turn away with some submissive gesture, while an animal with a higher rank might start an attack. Monkeys display such behaviour not only towards other monkeys but also towards man. The existence of certain basic modes of behaviour which can be instantly understood by man and by some higher animals suggests genetic determination. However, one should not conclude that manners are genetically fixed; rather, the potential that manners develop seems to be genetically fixed in man. The individual rules are determined by tradition and can differ widely. Also, rules of manners for men usually focus on ideals, which may be very different from actual behaviour.

History. European antiquity does not have special books on manners. There are, however, several hints in the Bible as well as in writings on morals by Plutarch, Epictetus, and Cicero. Two concepts characterize the ancient ideal of the goodmannered man: the concept of propriety and the concept of urbanity.

Acting 'properly'—that is, with propriety— means doing the right thing at the right time in the right place. The Greek idea of propriety belongs to the ideal of universal harmony; the rule itself seems to

arise from the more primitive rules of obeisance and submission to society. That the definition of 'proper' could be a matter of public opinion and therefore be changed is a discovery of later times.

Urbanity may be defined as the courteous and elegant and therefore charming behaviour of (educated) citizens. The frequent social intercourse of those who live closely together might have made it a necessity that people should not only respect but also please each other. The aim to please is reflected in the ancient art of rhetoric, which acquired so much importance during the urban democracies of ancient Greece and Rome. It was a work by Cicero; *De oratore* (On the Orator), which inspired the Renaissance author Baldassare Castiglione to write one of the first widespread books on manners: *Il Libro del Cortegiano* (The Courtier, 1528), stressing the courtier's duty not only to submit to the rules of propriety but to do so gracefully. Indeed, in most of the conduct books following *Il Libro del Cortegiano* the art of good behaviour has been reduced more or less to an 'art of pleasing'. At court the meaning of propriety sometimes changed to simple conformity; and since the decisions of the monarchs were often influenced by sudden humours or moods, the art of pleasing degenerated to open flattery.

Consequently the art of compliments—which forms an important part of the older books on manners—was later heavily criticized, and even banned, during the ages of bourgeois democracy.

Life at court also for the first time set forth rules to respect and even worship women, an idea unknown to ancient moralists. From the Middle Ages women had an increasing influence on the refinement of manners, though there can also be observed a strong tradition of misogyny, especially in England.

The first important books on manners for the bourgeoisie were written by Erasmus, *De civilitate* Page 449

morum puerilium (On the Civility of Boys' Manners, 1528), and Giovanni della Casa, *Il Galateo* (1558). Both books were translated into the main European languages and often imitated. Rather detailed rules were given, such as: comb your hair, clean your ears and nose, wash your hands, lift your hat. In the English tradition of conduct books of the sixteenth and seventeenth centuries, a puritanical attitude towards 'pleasing' manners predominated; the books mostly taught moralistic and religious maxims or principles, and the first American books on manners were based on this tradition. In the age of Louis XIV (1638-1715), France became the leading nation on questions of conduct. Several treatises were translated into most of the European languages, for example the *Art de plaire dans la conversation* (The Art of Pleasing in Conversation, 1688) by Pierre d'Ortigue. The moral pressure of court life 'to please' was even apparent in the famous *Letters* by Lord Chesterfield (1694-1773), who wrote to his son: 'By *manière* I do not mean bare civility; everybody must have that, who would not be kicked out of company: but I mean engaging, insinuating, shining manners: a distinguished politeness, an almost irresistible address ...' (19 April 1747). Since the nineteenth century, books on etiquette, which were simply guides in how to conform to the rules of society, have enjoyed a wide distribution. Good manners were no longer considered to be an

'art'.

Manners at table, and in conversation. To select two of the many possible aspects of manners, *table* and *conversational manners* will be described: two forms of civilized behaviour which were closely connected in the ancient institution of the symposium. From the fifteenth century the upper class developed highly restrictive rules, not only for the more natural needs but also for the use of napkins, handkerchiefs, and cutlery. Many tablebooks were published, in which detailed instructions for the use of spoons and especially of knives were given. By the end of the eighteenth century the use of individual plates and cutlery (knife, spoon, and for the first time also fork) was general. Until then it had been quite usual to eat communally from the same plate. Similarly the manner of how meat was served changed considerably. In the Middle Ages the entire animal (often decorated with its own fur or feathers to suggest the illusion that it had been hunted down on the spot) was presented and carved in front of the family or the guests, either by the host or somebody especially trained. Whole books on the art of carving were written—strangely enough sometimes combined with the 'Art of Compliments', as if hungry people could have been calmed down only by compliments while waiting. Then, later, the carving of the meat was largely banned from the table and delegated to the cook in the kitchen or even to the butcher himself.

Conversational manners also has a welldocumented history. Characteristic human behaviour has been described by types: the chatterer, the flatterer, the silent man, all of whom are familiar in all societies. One of the most influential works in antiquity was Cicero's book *De officiis* (On Duties). Cicero reprimands those who speak too long, too loud, or too aggressively, and those who praise themselves or criticize others. He also stresses an important point of good conversational manners: respecting the right of everybody to take part. Interest in the *theory* of conversation awoke only in the Renaissance, i.e. around 1500. Castiglione in *Il Libro del Cortegiano* differentiates between conversation with monarchs and with equals. Conversation with monarchs should consist mainly of information, flattery, or respectful silence—witticisms are allowed only in conversation with equals. The bourgeois conduct books give Ciceronian rules and prescriptions: Do not interrupt other people, Do not speak in riddles, Do not hurt anybody with jokes (the lastmentioned rule became a typical bourgeois taboo). At the time of Louis XIV, conversation meant the opposite of 'talking on serious matters'; in the drawingrooms of French gentlewomen, it degenerated to more or less brilliant chat. Since the rules of conversation have always aimed at the protection of mutual respect, conversation theory consequently tends to demand not only social but also intellectual equality in those who converse with each other. In fact in the eighteenth century the ideal of Henry Fielding gained increasing influence: 'Certain it is, that the highest Pleasure which we are capable of enjoying in Conversation is to be met with only in the Society of Persons whose Understanding is pretty near on an Equality with our own ...' (*Essay on Conversation*, 1742). Real development of conversational ideals in the nineteenth century seems to have taken place only in so-called intellectual circles. At least in America and Germany a certain distrust of conversation began to prevail: 'Good as is discourse, silence is better, and shames it', wrote Ralph Waldo Emerson (*Circles*, 1841). On the other hand there was a tendency to confine conversation not only to equals but to the privacy and intimacy of dialogue: 'The best conversation probably takes place between two persons' (Emerson, *Clubs*, 1847).

Conversation in all its possible forms has never ceased. Books on conversational manners are written nowadays as never before. The concentration of theoretical interest towards the end of the nineteenth

and the beginning of the twentieth centuries on the most private dialogue (and even the soliloquy) may have been due to the development of a democratic society, in which conversation between equals, i.e. public discussion, is now taken for granted. C. SC.

' **MAPS' IN THE BRAIN.** See LOCALIZATION OF BRAIN FUNCTION AND CORTICAL MAPS.

MARR, DAVID COURTENAY (194580), British psychologist, born at Woodford in Essex.

Page 450

In his short life, David Marr made a contribution to the psychology of vision that could be regarded as more important than that of anyone since Hermann*Helmholtz.

He was educated at Rugby School and Trinity College, Cambridge. He put his mathematics to use in the construction of a model of the function of the cerebellum.

Despite its ingenuity, it was at best oversimplified and he himself became dissatisfied with it. After a junior research fellowship at Trinity College, he moved to a senior research fellowship at King's College, which he held from 1972 to 1976. He became increasingly aware of the promise of computer simulation for modelling brain function, and while still a Fellow at King's made a protracted visit to the artificial intelligence laboratory at the Massachusetts Institute of technology (MIT) in order to learn the techniques of computer modelling. In 1975 he again visited MIT and decided to remain there permanently. The last five years of his life were marked by an outburst of creative energy that culminated in a book entitled *Vision*, which was posthumously published in 1982.

Marr's main work was on three topics: first, the method by which the visual system recovers lines and edges, which, although they look so clean to the viewer, are extremely hard to reconstruct from the messy retinal image; second, stereopsis, particularly the correspondence problem, that is the method by which the brain matches a point in the image on one eye with the equivalent point in the other eye's image; and third, the problem of how objects are represented in the brain in such a way as to facilitate recognition. Although he made highly original and important contributions to all three problems, he will probably be remembered less for the details of his research than for the style of his approach. Before Marr, most computer programs in vision dealt only with very restricted 'toy' worlds, for example planesided blocks. Marr set out to model vision as it operates in the real world in all its complexity. Moreover, he was the first person to construct computer models that took account of neurophysiological and psychological findings. He did not want to produce just any model—he wanted to uncover the way the human visual system actually works. Finally, he saw more clearly than almost any of his contemporaries that in order to build an adequate model of how the brain executes a certain task, it is first necessary to obtain a clear understanding of that task: his mathematical ability helped him to achieve this kind of understanding. In addition to carrying out his own research, Marr through his intelligence, charm, and liveliness attracted around him a group of outstanding research workers drawn from all over the world. Inspired by him, they made important contributions of their own, many of which are recorded in his book.

David Marr's move to MIT seemed to lead to a remarkable flowering of his imagination and personality. Part of his vitality over the last few years of his life may have come from the fact that he knew he had not long to live. Three years before he died he contracted leukaemia, a disease that necessitated repeated and painful stays in hospital. He faced his illness with quiet courage and no matter how weak he felt, he went on working: his fascination with his work was so great that however ill he was he never had to force himself to do it. His attempt to grapple with the deepest problems of vision was for him a source of spontaneous enjoyment. As he writes at the beginning of his book, 'This book is meant to be enjoyed'. One can be sure he enjoyed writing it.

See also PERCEPTION.

N. S. S.

MASOCHISM. Pleasure (especially sexual) from being subjected to pain or cruelty. It is named after Leopold von Sacher-Masoch (1835-95), an Austrian writer and lawyer who wrote *Der Don Juan von Kolomea* (1866) and other books describing sexual pleasure derived from pain. The converse is *sadism*—sexual pleasure from inflicting pain.

A curious problem arises as to whether one could say that an animal is motivated by masochism—for normally motivations for behaviour are supposed to be pleasurable. Pleasure might, of course, be deferred, but how far these subtle and important distinctions can be made on purely behavioural grounds, as in animal experiments and observations of animal behaviour, is an open and difficult question.

MATERIALISM. See MIND-BODY PROBLEM: PHILOSOPHICAL THEORIES.

MATTER. The distinction between mind and matter is as old as philosophy and as controversial. Both are ultimately mysterious. On the view known as *dualism* (developed by *Descartes*), matter has spatial extension and nonmental properties such as divisibility, while mind is not extended in space and does not obey the laws of physics. According to the *idealism* of *Berkeley*, the notion of matter existing independently of mind is incoherent. As physics has advanced, its accounts of matter have grown even further from the 'common sense' knowledge given by perception. This has given rise to 'two worlds' of physical reality and perceived experience.

With this development matter seems to be more and more different from mind, whereas in mythology and early science mind and matter are hardly separated, and matter is seen as alive and intelligent. See also MIND AND BODY.

MEANING. The concept of meaning is every bit as problematic as the concept of mind, and for related reasons. For it seems to be the case that it is *only for a mind* that some things (gestures, sounds, marks, or natural phenomena) can *mean* other things. The difficulties which we have understanding the place of mind in nature spill over, and create problems for, our understanding of the phenomena of mean

ing. Anyone who conceives of science as objective, and of objectivity as requiring the study of phenomena (objects and relations between objects), which exist and have their character independently of human thought, will face a problem with the scientific study of meaning.

One might attempt to overcome this problem by finding a natural relation holding between things which have meanings (i.e. signs) and the things they mean (or signify).

The idea that meaning is, or needs to be, founded upon a natural relation is responsible for the lure of causal, picture, and onomatopoeic theories. Cause and effect and similarity of shape are thought to be relations which hold independently of being recognized by a mind.

*Plato (*Cratylus*, 4325) argued against the idea that the meaning relation could be founded purely on a natural relation of similarity. No signs, he observed, can be exactly similar to the thing signified without duplicating that thing in all respects. What counts as sufficiently similar is governed by convention (*nomos*) and there must, therefore, be an element of convention in every use of a thing as sign.

But while it appears unavoidable that meaning should have some component of convention, it does not seem unreasonable to seek a theoretical account of the general conditions under which such conventions, established for a relatively small number of linguistic elements (a basic vocabulary), would fix the meanings of complex terms and sentences constructed out of these elements. It would be the work of that branch of the science of logic known as compositional (or recursive) semantics to determine these general conditions, and the result would constitute an objective account of how parts of a language can mean something. If one added assumptions about how it is proper to fix the meanings of the basic elements—say they had to be tied in some way to sense experience—one could test any piece of discourse for meaningfulness by applying the principles of logic to analyse the discourse until it became clear whether its elements had been properly constituted or legitimated by experience, and hence whether it was a meaningful piece of discourse.

Early efforts in this direction were made by the classical British empiricists (*Hobbes and *Hume), but the important advances in logical technique at the turn of the nineteenth century gave those attracted to this approach a new selfconsciousness and selfconfidence, and they emerged as 'logical empiricists' (or 'logical positivists').

These were the philosophers (A. J. Ayer, Rudolf Carnap, and Moritz Schlick) who challenged the 'cognitive meaningfulness' of metaphysics, theology, and ethics, and whose slogan was 'the meaning of a sentence is its method of verification'; for the analysis of a sentence would, if carried out, also show how one could go about verifying the sentence. (See FALSIFICATION.)

The logical empiricists, however, differed over the way basic elements should be tied to sense experience. One group (including Ayer, Schlick, *Mach, and Bertrand *Russell) saw basic elements as grounded in subjective experience; another (including Otto Neurath and Carl Hempel) did not regard it as proper to anchor scientific discourse in subjective experience, and urged instead publicly

accessible outcomes of publicly accessible (e.g. laboratory) procedures as the proper foundation for cognitive meaningfulness. The approach of this second group underwent a development as a result of the realization that what constitutes a test of something in science is not independent of the constellation of theories which scientists accept. The result was the abandoning of the idea that some elements of a language can be treated as basic with regard to the verification of all other sentences of that language. Hempel proposed instead a 'translatability criterion' according to which a whole body of discourse would be regarded as cognitively (i.e. scientifically) meaningful if it could be translated into a logically regimented language whose primitive vocabulary consisted of either 'logical locutions' or 'observation predicates'. None of the sentences, however, were to be regarded as basic for the purposes of verifying the sentences of the body of discourse thus translated. Instead of individual sentences confronting experience, the body of discourse as a whole stood or fell in the face of experience.

W. V. Quine and Donald Davidson developed further the line of this second group of positivists, by shifting attention from the attempt to say what it is to be cognitively meaningful to what is involved in one person understanding another person's (or culture's) language. In each case, they maintained, the interpreter has to work as a scientist works. The interpreter has to collect data, which consists in observations of the conditions under which the people whose discourse is to be interpreted will assent to, and dissent from, certain sentences. The interpreter also has to select basic elements (by proposing 'analytic hypotheses') and has to construct a theory which assigns truth conditions to basic elements and, through this, truth conditions to all the sentences of the language in such a way as to conform to the data. (Since the development of the logical apparatus, the compositional semantics, thought to be needed for this theory building, is due to Alfred Tarski; his name is often mentioned in this context.) As in Hempel's account, which is supposed to reflect the actual practice of natural scientists, the theory constructed stands or falls by its ability to accommodate the data taken as a *whole*.

As Quine and Davidson acknowledged, indeed urged, this approach to interpretation in an important sense undermines the idea that sentences or fragments of sentences have a meaning, or that names have a reference. The body of data is never adequate to determine uniquely one system of interpreting a language. There is no sense to the

Page 452

question what a noun *really* refers to, or what a speaker *really* means. In effect we should, in order to treat language as a natural phenomenon, abandon the notions of meaning and reference, and make use only of the concept of truth.

It was in the context of this challenge to the conceptions of meaning and reference that the 'causal theory of reference' was advanced by Saul Kripke and Hilary Putnam. According to this theory, A refers, for example, to a liquid chemical composed of two parts hydrogen and one part oxygen as 'water', because A heard *B*, *C*, *D*, etc., refer to it by that name, and they did so because they heard others do so; and so on back to an 'initial baptism' of that stuff with the name 'water'.

Although the phrase 'initial baptism' suggests a conscious attempt to establish a conventional pattern of linguistic response (as in a genuine christening), the initial baptism need not be regarded in this way. It could be treated as an unspecified natural occurrence, which under the circumstances holding at that time established a pattern of response to all essentially similar features of the environment. The similarity of feature, which is the basis of the pattern of response, need not be understood by those conforming to the pattern, although understanding could be achieved later by scientific investigation. This account thus underwrites the possibility of saying that what Aristotle *meant* by ' *to hudor*' was H O, even though it is obvious that Aristotle did not possess our understanding of the composition of water. It is clear 2

from this illustration how the notion of meaning can be conceived as a relation which obtains independently of what humans think.

To its critics, the causal theory failed to provide a historically plausible account of the mechanisms by which reference is secured and maintained. But to those sympathetic to it, it offered an alternative to abandoning the use of these notions and accepting the conclusion drawn by Quine and Davidson that meaning and reference are too indeterminate for scientific study. (A corollary of this conclusion, to the effect that mind is insufficiently determinate for proper scientific study, was subsequently drawn by Bernard Williams.)

One might also try to escape Quine's conclusions by calling into question the positivist conception of science which underpins them. Those prone to read the theoretical pronouncements of scientists literally, i.e. 'realists', brush aside the possibility, which is frequently stressed by Quine, that any body of scientific evidence, e.g. electrical phenomena, can be accounted for in a variety of incompatible ways, not just by postulating the existence of electrons. They insist that we are often justified in selecting one of the competing accounts as *the best explanation*, and this outlook can be applied to the phenomena of language to endorse, as perfectly respectable scientific reasoning, the idea that the best explanation of linguistic phenomena will postulate mental states as the causes of those phenomena.

Although the word 'idea' no longer figures prominently, this approach in effect returns to the position of John*Locke, who held that ' *words, in their primary or immediate signification, stand for nothing but the ideas in the mind of him that uses them,*' (*Essay*, III,ii,2). Instead of ideas, the internal states most commonly appealed to are beliefs and desires, but the approach would still fall under the strictures of those philosophers and logicians who, since Frege, have indicted such theories on a charge of 'psychologism'; for such theories do indeed shift the attention of those studying meaning away from the relationship between signs and the things they signify to the relationship between the (minds of) signusers and the things they signify.

Recent developments along these lines begin with an analysis of speaker's meaning advanced by H. P. Grice. We do quite often use the word 'meaning' to label what a speaker intended or was trying to do with his words. Thus Spooner's audience recognized that he *meant* to refer affectionately to the monarch when he used the words 'our queer dean'. This complex intention was analysed by Grice in terms of an intention to modify the beliefs or behaviour of the audience via the audience's recognition

of that intention; and the presence of such intentions, Grice held, was what distinguished the ('nonnatural') meaning of linguistic phenomena from the ('natural') meaning of natural phenomena (such as in 'those spots mean measles').

Criticisms of Grice's analysis focused on the difficulty of bridging the gap between this notion of (speaker's) meaning and the notion of word (or linguistic) meaning, for which we still need an account. Spooner's *words* after all *meant* something quite at variance with his intention; his words referred slurringly to a college official.

Jonathan Bennett attempted to bridge the gap by integrating Grice's analysis with a sophisticated account of convention, which was devised by David Lewis. Under Lewis's analysis, a convention need not be established by conscious agreement (something which would presuppose, and hence could not explain, the existence of language) but is nevertheless more than a mere regularity because, however it was established, it is maintained by the recognition on the part of those who conform to it that conformity to it solves a 'coordination problem', i.e. eliminates certain disadvantages which would occur unless activities were coordinated. Bennett's account in effect rested linguistic meanings on the hardening into convention of speakers' meanings.

Bennett's approach has been criticized for not providing a convincing account of how what are essentially unstructured and unrelated primitive signalling acts (acts which express communication intention without presupposing a language) come to have the structure evident in all languages; viz. that 'by which each speech act is composed of elements which make a similar contribution to a variety of different speech acts. A second criticism Page 453

called into question the sense of crediting nonlanguage users with intentions sufficiently complex to count as (Gricean) communication intentions. The first of these criticisms rests on an important feature of meaning, its systematic nature. Different theoretical traditions give different accounts of this essential structure, but agree at least on the principle of systematic relatedness. (In the controversy over whether chimpanzees in acquiring the use of Ameslan signs had achieved *linguistic* mastery, a crucial point was whether they had the ability to form signs of sufficient complexity.) (See PRIMATE LANGUAGE.) Compositional semantics offers an account of this structure based on the principle that the meanings of complex expression are functions of the meanings of elementary components. In fashioning the central concepts of this approach Frege had insisted that a sentential (or propositional) unit is primary to language, that singular terms and predicate expressions made radically dissimilar contributions to sentences, and that one must not ask for the meaning (*Bedeutung*) of a word outside the context of a sentence. Bennett's account seems in particular to lack resources to explain how a set of internally unstructured and logically homogeneous signalling nets could yield expressions with the different logical functions of subject and predicate. Frege's ideas were transmogrified in the hands of Quine, and, as the importance Frege attached to reference decayed, Quine replaced Frege's maxim about looking for the meaning outside the context of a sentence by a stricture against seeking the meaning of an expression outside the context of a whole language.

A radically different account derives from the work of the linguist Ferdinand de Saussure, who saw as relevant to meaning not only the relation between sign and thing signified, but also the 'value' of the

sign (word). The value of a word is a function of the words that can in some contexts be exchanged for the word ('strike' and 'hit'

are interchangeable only in some contexts) and the words that stand in contrast to it. 'Sheep' and 'mutton' are used for the animal and its meat in English, where the French use '*mouton*' for both. Thus the latter could have the value of neither of the former words.

Saussure's work provided an important inspiration for the movement known as structuralism. In the hands of the structuralists the relation between signified and signifier was virtually discarded, leaving the meaning of a sign resting on the structure of values constituted by the language as a whole. Coming from a different direction, the structuralists arrived at a linguistic holism which bore a number of striking similarities to that advanced by Quine and Davidson. In neither case could one look to some definite aspect of the world outside of discourse for what an expression meant or signified. If it made any sense to ask for the meaning of an expression, one had to look for it in its connections to other expressions.

Were this a viable account of linguistic meaning, it would support the idea that linguistic mastery (the ability thought by many to be essential to the possession of a mind) can be modelled in computer programs. A program, if it has the power to generate the right syntactic structure and vocabulary, could represent the way expressions interact with each other to constrain the formation of expressions and the assent to or dissent from sentences. Computer modelling along these lines has tended to draw more on the tradition which Frege founded than on that which Saussure founded. Such computer modelling leads to a second application of the 'realist'

strategy mentioned above. Instead of postulating beliefs and intentions (in the head) to account for linguistic acts, what is postulated is an internal configuration formally isomorphic to a computer program (one we have yet to write) which accounts for what is conceived of as human linguistic 'printout'. Many cognitive scientists see their task as the writing of such a program, or possibly working in conjunction with physiologists to determine which of several possible programs the human mind actually runs. (See also ARTIFICIAL INTELLIGENCE.)

There are, however, several doubts about the aspirations of such cognitive scientists. If these aspirations * are based on a thoroughgoing holism, it is difficult to see how language mastery can be acquired (as humans evidently acquired it) in stages. For the whole of language would have to be mastered in order to have mastered any part of it. It is difficult also to see how two adult human beings could communicate with one another, so long as their vocabularies did not precisely coincide. For it would be impossible to determine whether a difference of opinion was based on one person being misinformed or the two speakers at cross purposes because they in effect spoke different languages.

Computer modelling need not rest on a holistic approach, but if there is thought to be some component of the meaning of an expression which is independent of its relationships to other expressions in the language, this component would seem to have to be sought in the relation that the expression bears to things outside the language. Computer models can be extended by connecting the machinery and

software to 'external sensors', so that the printout bears an appropriate relation to the world. But this expedient leaves open the possibility that different sensors responding to different external features (or even direct interference from the programmer) could produce the same internal states and the same printout; and in so far as this is possible, the computer fails to model the meaning of the words on the printout.

Those, such as Jerry A. Fodor, who are convinced of the adequacy of computer models have tried to make a virtue of this difficulty and have advanced

'methodological solipsism ... as a research strategy in cognitive psychology'. Others, such as John Searle, have turned these difficulties into an a priori argument against the possibility of computer

Page 454

modelling of human languages and against the claim that the human mind is in all essential respects a computer.

So far we have considered approaches to meaning which look either to the relation between language and the world or to the relation between language and mind.

(The latter may seek to preserve the meaning relation as a fit subject for scientific study by treating mental structures or intentions as natural, possibly purely physical, phenomena.) A third approach would argue that the difficulties of the first two arise from not recognizing that meaning must be studied in the context of a (three-term) relation between mind and the world and language, where the last of these is conceived of as a social phenomenon. This was an important feature of Saussure's theory, for he insisted that 'language never exists apart from social fact', but it is also an important principle of the outlook of such diverse thinkers as *Hegel, Marx, *Dewey, Mead, *Vygotsky, and *Wittgenstein.

It is from this perspective that Bennett's programme would be criticized for assuming that nonlanguage users could have, and recognize in others, intentions as complex as required for Grice's analysis of (even) a simple act of signalling. Thought, from this perspective, cannot exist without (or prior to) language.

According to the social behaviourists, George Herbert Mead for example, it would be acceptable to regard social animals as affecting the behaviour of one another in the following complex way: the beginning of a pattern of behaviour (a gesture) on the part of one animal elicits from another a pattern of behaviour which modifies the development of that pattern as it unfolds in the behaviour of the first animal. But to behave as a human does in such a social interaction, the second animal would have to respond not only to the gesture, but to the relationship between the gesture and the object, which had acted as stimulus to the gesture, *and to do so from the standpoint of the first animal*. This is what is required for the second animal to respond to something as meaningful, the concept of meaning implied here being 'an individual reaction which an object may call out'. For the meaning of an object to be 'ours' we must have adapted ourselves to a comprehensive set of reactions toward it, which we can

not only adopt ourselves but do so also in the role of others who can respond in that way. Meaning is not, on this account, primarily a property of objects, John Dewey observed, it must be primarily a property of behavioural responses and derivatively of the objects that enter into those patterns.

Another development of an essentially social approach to meaning will be found in the later work of Wittgenstein. Wittgenstein interpreted Frege's suggestion that a word has a meaning only as part of a sentence, as a way of saying that things cannot have names except in a 'language game' (*Investigations*, I, 49), a label which Wittgenstein applied to social contexts in which words are used in structured ways of interacting with the world. All three, language, language users, and the world are bound up in this concept, and its implications were spelled out in the advice, 'Don't ask for the meaning, ask for the use.' Wittgenstein, moreover, mounted controversial and much debated arguments against the possibility of a person assigning a meaning to a word on the basis of an intention to use that word to apply to something experienced privately. The use of language to describe subjective experience is dependent on and derivative from linguistic practices in which several people coordinate their interactions with each other. (See also WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE.) Whether one treats this third approach as conforming to or repudiating the demand for a scientific approach to language depends on whether one conceives the study of human social interaction as (at least potentially) continuous with the scientific study of nature. A tradition going back to Giambattista Vico in the early eighteenth century regards the study of human institutions and artefacts as the province of a study which, if scientific, involves methods quite discontinuous with the natural sciences. More recent developments in this tradition insist upon the need for the imaginative recreation of the experience of other human beings, of the need for empathy or sympathy in grasping the meaning of a text, and generally refer to their methodology under the rubric 'hermeneutics'. Not all those, however, who insist on the importance of the social in the study of meaning adopt this methodological dualism. Whether or not one does adopt a dualist approach is related in an important way to the conception one has of scientific knowledge. This in turn rests on the way one conceives the relationship between human beings (in particular their minds) and the rest of nature.

MEMORY. When we learn something there must be a change in the brain, but no one knows what the change is. Until quite recently the concept of memory was used only in mentalistic contexts. Few dictionaries contain any reference to memory as a feature of a physical system, though we now have the language of computer scientists to help us in thinking about our own memories, as physical records in the brain. In computer language the memory is an instrument in which is placed a store of whatever information is to be used for calculation. This information is thus a representation of some set of events, embodied in a code. How does the nervous system come to contain useful representations of its environment?

The code of the nervous system is provided basically by the fact that each nerve fibre carries only one sort of information. In such a system learning must consist in a change in the connection pattern of the pathways from input (say the eyes) to output (say movement). The initial basis of the nervous memory is thus provided by heredity (the genetic memory), which establishes the nervous pathways of the newborn. Natural selection has ensured that at birth each individual is provided with potentialities suitable for its future type of environment. A young kitten already has the connections which ensure that each cell of its visual cortex responds mainly when a particular contour moves in front of its eyes, though the responses are less vigorous than they are in an adult. If the kitten is only allowed to see vertical lines then it will later be found to have lost the power to respond to horizontal (or other) lines. Meanwhile the response to vertical contours has become much stronger. (See VISUAL SYSTEM: ENVIRONMENTAL INFLUENCES). Memory thus depends upon selection from the original multiplicity of possible actions of those that represent useful responses to the environment. Other work with kittens shows that normal capacities only develop if there is appropriate input at certain short*critical periods. (See SPATIAL COORDINATION OF THE SENSES.)

A human child similarly is born with a range of capacities, and given the right stimulus he then learns to take those actions that are appropriate (see INFANCY, MIND

IN). Thus from twelve months onwards he learns to speak whatever language he hears, making certain vocal movements and rejecting others. All skills involve such selection. As development proceeds we thus build a model in the brain that ensures appropriate behaviour. The problem of memory is to find the mechanism that increases the probability of use of some pathways and decreases that of

others.

The decision as to whether a nerve cell is to send a signal depends upon the synapses that it receives from other nerve fibres. It was early suggested by the histologist*Ramón y Cajal that memory depends upon forming synapses. By contrast, Ivan*Pavlov, who pioneered the physiological study of learning, attributed the

'conditioned reflexes' in his dogs to vague processes of spread of excitation and inhibition in the cortex. These two types of theory persist to the present. The majority of neuroscientists probably believe in a synaptic change, but there is little direct evidence of the details of it.

The nervous system contains many pathways that reexcite themselves, and it was suggested that these might serve for memory in the brain, as in some computers.

This is not likely to be true for longterm memories, which must surely be physically embodied, since they can endure for up to a hundred years, in spite of shocks and anaesthetics and (in rats) even freezing. But it frequently happens that immediately after a shock there is no memory, say of an accident (see AMNESIA). It is therefore postulated that memory is recorded on two or more timescales. The*shortterm memory is transient and easily interrupted. Perhaps it is carried by the chains that reexcite themselves. It must endure for long enough to allow a record to be 'printed' in the longterm memory. This may involve synaptic change, perhaps by some sort of growth process. Parts of the brain concerned with memory contain many very small nerve cells ('amacrine cells' or 'microneurons'). One suggestion is that these serve to produce an inhibitory substance whose action closes the unwanted pathway. This would allow the other one to be used: its synapses would then become more effective and those of the other pathway would wither away. All such changes would involve synthesis of new protein, and there is evidence that, if a substance inhibiting protein synthesis is given shortly after a learning occasion, no memory is established. This does not mean that the new protein carries the memory.

It alters the probability of use of one set of channels rather than another. Information in the brain is coded by channels not molecules. Not appreciating this, biochemists have sought for a memory molecule, on the mistaken analogy of DNA. They have even claimed that memory can be transferred by injecting extracts from a trained brain, or even by the cannibalism of worms. Many injected substances will indeed change brains, but the claims of transfer of specific memories have not been substantiated. The attraction of the idea of cannibalism tells more about human psychology than about the biology of memory.

The capacity to change nervous pathways, that is to learn, is quite widespread. A *cockroach* without its head will learn not to dip its leg into water from which it gets a shock. From such simple learning systems it has been discovered that various changes in the electrical and chemical properties of the nerve cells are involved. But memories like our own usually store more complicated information, and this involves special nervous equipment. In each species the brain has a memory system suitable to its special way of life. Memories are not parts of a generalized computer system but specific analogue devices. In octopuses we have been able to find two anatomically distinct memory mechanisms. In

in the other records of objects touched or tasted. The decisions that an octopus makes are rather simple—whether to attack a particular object or to draw in an object touched with its arms. It can learn to attack a horizontal rectangle and avoid a vertical one or to discriminate between rough and smooth spheres. (See INVERTEBRATE LEARNING AND INTELLIGENCE.) Such choices are typical of the selections between alternatives that are the essential features of recording in memory. The animal or man must be provided with feature detectors that can allow the performance of two or more actions. Learning which action to perform must depend upon a system that allows for information about past results to alter the probabilities of the use of the pathways in the future. We believe that this is done by initially reducing the effectiveness of the wrong pathway and then increasing the right one—perhaps by new synaptic growth. Many special features are required to make such a system effective, and it is not surprising that neuroscientists have not yet fully unravelled the secret of the memory mechanism. And, of course, in mammals memory does not depend upon switching single neurones, say in the visual cortex, but somewhere the pathways are changed when we learn.

There must be nervous tracts that bring information such as that of *taste or *pain together with signals from the outside world. In mammals there is evidence that these come through the reinforcement pathways, which can be activated by self-stimulation for reward. These lead through the hypothalamus to the hippocampus, which is a part of the brain particularly concerned with memory.

Another special need is for mechanisms of generalization in the memory, and here the octopus has proved most helpful. It does not have to learn everything eight times over. Martin Wells was able to show that what is learned by one arm can be performed by the others—but not if a particular piece of the brain is removed. This piece, the median inferior frontal, has a weblike structure that allows signals from the different arms to interact. This is one small example of how study of parts of the brain can tell us about the memory mechanism. Again, in an octopus the visual memory can be removed without damaging the touch memory, and vice versa. So the memory record in the octopus brain is localized. In mammals it has proved difficult to find where the record is, so that the psychologist Karl *Lashley, after his lifelong

'search for the *engram', could not decide whether it was nowhere in the brain or everywhere.

The model of the mnemon, or unit of memory, can be considered either as an anatomical reality, as I believe it to be in the octopus, or as a logical schema representing the much more complex situation in man. The essence of it is that establishing a permanent memory record involves selection from an initial set of possible pathways.

Selection is made on a basis of the rewards that follow from different actions. The particular type of memory of each species depends upon modification of the connections of an inborn feature-detector system. In man these detectors are particularly tuned to respond to features of human behaviour. The

child is specially sensitive to human speech sounds even at two months, long before he can talk or understand speech (see BRAIN DEVELOPMENT). By learning to react in appropriate ways to particular features he then builds a model in his brain that allows him to live in his human environment.

MEMORY: BIOLOGICAL BASIS. For materialist theories of the mind, it is axiomatic that in some way there must be brain representations of memory. This may not be intuitively obvious when we consider our own individual memories, for we can clearly rehearse in our minds the histories of past experience (the memories of a childhood birthday party, the image of an absent friend's face, the opening notes of a Beethoven symphony, or the taste of a roast dinner) without these rehearsals affecting our external behaviour in any obvious way. However, for an experimenter studying memory in others, whether human or nonhuman animal subjects, what is observed is a change in behaviour—a human showing a new skill, or an animal traversing a maze correctly and thereby finding food or avoiding electric shock—and it is from this change that memory is inferred. Indeed memory is a portmanteau expression which includes within itself two processes and, by hypothesis, a thing. The processes are the*learning of some new skill, behaviour pattern, or piece of information (sometimes called the *acquisition* of the memory) and, at some later time, the recall and reexpression of the skill or information (sometimes called *retrieval*). The thing that connects the two processes of learning and recall is a change in the properties of the brain system so as to store the new information which the learning represents, in such a form that it can subsequently, in response to appropriate cues, be searched for and retrieved. This change is known as the memory trace, or*engram. The relationship between the language used to discuss these phenomena in the brain and that used in the description of the properties of computers and their memory stores is not accidental, for much of our presentday thinking about biological memory is directed—and constrained—by a framework of analogies from computer technology and*information theory.

For experimental science, the question is how far memory and its brain representation are amenable to experimental analysis rather than to logical and philosophical enquiry. Over recent decades, this has been one of the central problem areas for psychology and neurobiology. However, the nature of experimental method in these disciplines is such that most attention has been focused on a

Page 457

study of the processes of learning and recall; the engram which links them has been inferred rather than demonstrated. Research has concentrated on asking questions concerning the strategies and temporal processes involved in learning and recall—what and how much can be learned, how fast, and over what period—and concerning the brain systems, at the biochemical, cellular, and

physiological levels, that subserve these processes. This research may be conducted either by a direct comparison of the brains of experimental animals which have learned, with those of controls which have not, or by examining, in humans or other animals, the effects of procedures which enhance or retard learning or recall.

The major obstacles to advance in this area are on the one hand conceptual—the need to develop clear and testable alternative models—and, on the other, experimental—the development of appropriate control procedures. As will become apparent shortly, it is relatively easy to perform experiments which show that in experimental animals particular drugs and treatments prevent learning or recall from occurring, or that when learning occurs, particular changes in braincell properties accompany it. The problem is to be sure that observed biochemical, anatomical, and physiological changes which accompany learning form the necessary, sufficient, and exclusive representations of that learning at the biological level, rather than being merely the correlates of other phenomena which occur at the same time as the learning. For example, in order to motivate experimental animals to learn it may be necessary to subject them to mild stress (hunger, electric shock); in order to learn, the animals may need to be rather active in the exploration of a particular environment. The challenge is to design experiments which eliminate the possibility that any observed change to be studied is a correlate or consequence of stress, activity, sensory stimulation, or whatever, rather than of the learning itself. Rigorous control of all alternative possibilities is virtually impossible to achieve in a single experiment; rather, the goal must be a balance of probabilities on the basis of a number of separate approaches.

There is ample evidence that the learning process is not a simple onestep process. The most popular hypothesis is that there are at least two separate stages, involving different physiological mechanisms and in all probability different brain regions. The first process is shortlived, the second slower but of longer duration, and they are conventionally referred to as shortterm (STM) and longterm (LTM) memory respectively, though some would claim that shortterm memory itself embraces more than one process. The distinction between STM and LTM is illustrated by an experiment in which a list of seven numbers is read out to a subject, who is asked to repeat them back. Most people can repeat the numbers with accuracy if asked to do so within a few minutes of hearing them, but will fail if asked an hour or so later.

However, if the numbers are of importance to the subject (for example, if they form a telephone number) they can generally be recalled days or even years later. Many items are placed in shortterm store—numbers, names, this morning's breakfast menu—but only a few find their way into the permanent memory system. This is obviously functionally desirable from the biological viewpoint, as the utility of recalling most shortterm stored items for more than a brief while is very limited, and there must be a finite capacity to any store and to the retrieval mechanism.

STM, then, is labile, and in the normal course of events, decays over a period of minutes to hours. If the item to be recalled is not, over this period, transferred from STM to LTM, it is irretrievably lost as STM decays. A variety of drugs and other treatments can affect the memory while it is in STM. Substances which interfere with the brain's electrical activity, or treatments like electroconvulsive shock or the infliction of injury, such as a blow to the head resulting in concussion, will effectively

obliterate all items in STM at the time, so that the individual on recovery still have no recall for the events leading up to the injury (see AMNESIA). Certain drugs also appear to enhance STM or facilitate transfer from STM to LTM. These include strychnine and amphetamine (the former having even more considerable and undesirable effects than the latter). We are led to the hypothesis that the form in which STM is held within the brain involves transient changes in the electrical properties of the brain as a system, very likely a result of a reversible modulation of the firing properties of particular neurones or their synapses. There is suggestive evidence, based on studies utilizing microinjection of drugs, electrical stimulation or recording, and ablation techniques, as well as the study of human patients with STM deficits, that the hippocampal region of the brain is closely involved in the mechanism of STM and its transfer to LTM. Yet this is a relatively simple model of the relationship between STM and LTM, and the situation is probably a good deal more complex. Not every item which cannot be retrieved from LTM has been lost for ever by STM decay: it may have been overlaid or suppressed, and can be recovered under appropriate circumstances, sometimes by recreating the context in which the memory was first formed. Such observations have led some psychologists to argue that the terms STM and LTM be replaced by new concepts of 'active' and 'labile' memories. However, for the purpose of studying the cellular mechanisms of memory formation, the exact phenomenological features at the behavioural level are of relatively minor importance.

What matters here is that memories, when fixed, are notoriously difficult to erase (indeed they are the most durable features—other, perhaps, than scar tissue—acquired during a person's lifetime). Their durability has led to the widely shared

Page 458

hypothesis that they must be coded for in terms of some equally lasting change in brain structure, with a consequent effect on physiological processes. There is good evidence that LTM is a cortical function in mammals generally, and that in humans the temporal lobes are likely to be involved in memory processes, but what sort of changes in brain structure might one envisage as being able to code for memory? Since at least the 1940s there has been a longrunning controversy among physiological psychologists over the localizability or nonlocalizability of the memory trace. Localized models essentially suggest that particular memories are coded for in terms of particular pathways, or neuronal circuits, and were given theoretical substance by Donald Hebb, who postulated the existence of a class of neurones whose connections were in the form of synapses which could be modified by experience, thus opening or closing unique pathways. Particular circuits or pathways could correspond to particular memory traces; learning resulted in the modification of synapses and recall from the passage of impulses along the particular pathway concerned. Hebb's modifiable synapse theory found support in the clinical studies of the neurosurgeon Wilder Penfield, who observed, in human patients being treated for epilepsy, that electrical stimulation of particular regions of the temporal lobe of the cortex regularly caused the patient to recall specific, if fragmentary, memory sequences.

The rival memory model suggests that, rather than there being localization of memory circuits, the storage of information is a molar property of the mass of cortical cells, a 'field' rather than a 'point' representation being involved. Experiments which lead in this direction derive from the studies of Karl*Lashley, who, also in the 1940s, showed that when rats had been trained to particular mazerunning skills, these skills could not be obliterated by removal of particular cortical areas; rather the results of such ablations were generalized deficits proportional to the amount, but not the region, of cortex removed. The theoretical rationale for this model was not available until more recently, in the form of analogies with the nonlocalized storage of information on a photographic plate provided by the hologram.

It is probably true that holographic memory theories have found more favour with mathematical theorists than with experimental neurobiologists, most of whom favour a modifiable synapse/neuronal circuit model, with the proviso that it is likely that any individual memory will have multiple representations in the brain, involving numerous different circuits. Could a neuronal circuit model account for the information storage capacity of the human brain? The number of neurones of the human cortex is often quoted as 10¹⁰, and direct counts of synapses would suggest upwards of 10⁴ synapses for each neurone. 10¹⁴ synapses would seem to give ample storage potential for the information acquired in a human lifetime.

How about the direct demonstration of synapses or neuronal circuitry being modified by experience and during learning? Physiological, biochemical, and anatomical evidence on this score has accumulated over the last two decades, though it is fair to say that no fully systematic model exists and rigorous proof that observed changes are the necessary, sufficient *and* exclusive correlates of learning is lacking; we have to make do with indicative rather than conclusive demonstrations.

At the anatomical and physiological levels, most of the evidence concerns longterm changes in the structure and properties of particular neurones or their synapses in response to experience. For instance, the visual cortex of experimental animals responds to the input of new visual information by lasting changes in the number and dimensions of synapses, including changes in the contact areas between pre and postsynaptic sides of the synapse and of the storage vesicles which contain transmitter substances. The physiological response properties of visual cortex neurones are modulated in a predictable manner by the environment in which the animal, for example a cat, is reared (see VISUAL SYSTEM: ENVIRONMENTAL INFLUENCES). The neurones are thus 'learning' to recognize and respond to characteristic features of the environment.

Such plastic brain responses to environmental change are regarded as analogies of what happens, on a much more precise scale, during learning. But they are only analogies. To move to greater precision a learning 'model' is required. This is not as easy as it sounds. Psychologists explore memory in rats learning to run mazes, or pigeons pressing levers for reward. Such tasks often require training animals over a long period, and encouraging them to learn by keeping them either hungry or thirsty so that they may be rewarded with food or drink for correct responses, or by punishing them—for instance, by mild electric shocks—when they make mistakes. In such situations, if one trains an animal and finds a subsequent biochemical or cellular change, how can one be sure that the change is not the result of the shocks, or the motor activity involved in the running of the maze, or the sensory

stimulation, or the stress?

Although biochemists could and did know in the 1960s and in the 1970s that training animals under these conditions affected the rate of protein synthesis in particular brain regions, the interpretation of such experiments was open to doubt. Other experiments used drugs which affected the rate of protein synthesis in the brain. In general, drugs which speed protein synthesis enhance the rate of learning of complex tasks, whereas those which inhibit protein synthesis are without effect on STM or the recall of acquired memories, but prevent the development of LTM. None the less it was argued that the effects of these drugs on memory formation and on protein synthesis were independent,

Page 459

both being the consequence of other types of central effect of the drugs concerned. More precise models and methods, at both behavioural and biochemical levels, were required.

In more recent years, three types of experimental system have begun to yield particularly revealing information about the cellular mechanisms involved in learning processes. In the first, the learning 'model' is the young chick. Day-old chicks readily learn a number of tasks—for instance, they become '*imprinted'—learning to distinguish their mother (or, in the experiments, a mother substitute) from all other objects in their environment, and following her subsequently. The chicks also continually explore their environment by pecking, and learn to distinguish food objects from inedible or distasteful items. For Pat Bateson and Gabriel Horn in Cambridge and Steven Rose's group at the Open University, these spontaneous forms of learning proved particularly amenable to cellular study. When a bird pecks at a distasteful object which it learns to avoid, there results a series of biochemical changes in very specific regions of the forebrain. The changes involve first the mobilization of certain key enzyme systems which modulate synaptic transmission, and then, as part of a longer-term process, the synthesis of new glycoproteins, which are transported from the nerve-cell bodies in which they are made to the synapses, where they become incorporated into the synaptic membranes. As a consequence of these biochemical modifications, synapses in at least three separate but connected left hemisphere regions of the brain of the chick change in their structure in ways which can be detected at high magnification in the electron microscope; in particular, the number of synaptic vesicles—the transmitter-containing bodies at the synapse—increases and the region of the synapse that directly apposes the pre and postsynaptic cell changes in length. All this looks uncommonly like what might be expected if synaptic connectivity were being modulated and new pathways being formed. Over the period of hours following learning, the electrical properties of the cells in at least one of these forebrain regions also change dramatically, with large increases in the rate of neuronal firing. Such changes occur only in birds which remember the aversive stimulus. If they are trained but made to forget, the changes in physiology and biochemistry do not occur. Moreover, as Gabriel Horn has shown, using imprinting, these regions of synaptic change are *necessary* for memory formation to occur; if one particular region is excised from the chick brain before training, learning the imprinting task becomes impossible. If the bird is trained and then the region is immediately excised, the chick behaves as if it is naive and has no recall for the task. In other respects it behaves normally, and sham operations do not produce the memory deficits.

The young chick may seem a simpler organism in which to study memory than the psychologists' traditional beasts, but the other two recent types of experimental system have even greater simplicity. For Eric Kandel and his colleagues in New York, the organism of choice was the seemingly unpromising sea slug, *Aplysia californica*. These large molluscs have a limited repertoire of behaviour, and do not even have brains in the vertebrate sense; their nerve cells are distributed through their body in a variety of groups of cells known as ganglia. What makes them attractive to the neurobiologist is that whereas vertebrate brains have many thousands of millions of smaller cells, *Aplysia* have fewer than a million neurones, and many of them are large—up to a millimetre in diameter as opposed to the vertebrate size of 10–100 micrometres. Individual nerve cells are thus amenable to physiological study: the 'same' cell can be located in many different individuals; it can be dissected out, and its connections studied. The entire ganglion plus its inputs and outputs can be isolated from the rest of the organism and maintained in physiologically functional condition for several days. Kandel studied in particular the nerve cells involved in a number of cellular systems active in the processes of habituation and sensitization of reflexes. When they are lightly touched, regions of the surface of the animal around its gill contract vigorously, as part of an escape and withdrawal reflex. This response diminishes if the same region is repeatedly touched (habituation) but may be extended to form a reaction to previously neutral stimuli if they are coupled with potentially noxious ones (sensitization). Kandel has mapped in some detail the neural pathways involved in these processes and has been able to record physiologically, from the pre and postsynaptic cells involved in the responses, the changes that occur as habituation or sensitization takes place. He has been able to show the direct involvement of transmitters such as serotonin in the process, and has followed a number of key biochemical steps in the synapse—specially the role played by a combination of a synaptic membrane protein, capable of being reversibly phosphorylated in response to external stimuli, and the intracellular 'second messenger' substance cyclic AMP. These molecular processes are involved in regulating the entry of calcium ions into the cells; the calcium ions alter the membrane potentials and directly modulate synaptic connectivity. Kandel argues that such changes in the electrical properties of individual synapses as a result of experience both occur and underlie at least relatively short duration memory processes.

The third experimental approach has been to abandon living organisms altogether in searching for a system in which to study the molecular biology of neuronal plasticity. It is well known that if thin slices of brain tissue—no more than a third of a millimetre in thickness—are cut and placed in a warm, oxygenated, glucose-containing medium, they retain their biochemical properties and some physiological properties for a period of several hours. If the slices are cut appropriately they can be

made to retain at least some of their nerve inputs. Recording electrodes can be placed among the cells of the slice, and the effect on the cells of electrically stimulating the inputs can be followed. A particularly interesting brain region to study in this way is the mammalian hippocampus, for long considered to be involved in aspects of the process of transfer of short to long term memory. Gary Lynch and his colleagues at Irvine, California, among others have shown that if hippocampal slices are electrically stimulated from their appropriate nerve inputs, there can be longlasting (up to an hour or more) changes in the electrical outputs from these cells—the so-called hippocampal potentiation. This

phenomenon *in vitro* is known to mimic the *in vivo* properties of the cells of this brain region, which were found to show such potentiation by Bliss and others in the early 1970s. *In vitro* the biochemical mechanisms involved can be studied in detail, and shown to involve, as in *Aplysia*, phosphorylated membrane proteins, cyclic AMP, glutamate receptors, and calcium ion channels in the membrane. Lynch argues that hippocampal potentiation is an *in vitro* analogue of memory processes.

All this may seem a long way from Marcel Proust's evocation of youthful memory, *À la recherche du temps perdu* with its sense imagery. Are young chicks, sea slugs, or slices of brain tissue really going to reveal the molecular mechanisms of such a durable if elusive property of the human brain? It is an act of faith perhaps, to claim that they are. Complex phenomena are not merely the result of the additive properties of simpler ones, because as systems increase in complexity their properties change qualitatively (which is why we may speak of human consciousness, but are much more doubtful about animal consciousness despite the similarities in basic brain structure). Nevertheless, the general principles of organization that underlie these brain systems are similar. Biochemically, nervous and hormonal systems of body regulation involve similar chemical processes subserving different ends. The organization of nervous transmission is almost identical over a range of living organisms from insects and molluscs to humans. There seems no reason to doubt that the mechanisms involved in nervous system plasticity will turn out also to be related, even though the complexity and richness of the plastic response will vary qualitatively as we move from smallbrained and rather 'hardwired' organisms into the immensely plastic and flexible brain of the human.

However, it is important to emphasize what it is that such studies will not reveal. Some years ago there was wide publicity for experiments which purported to show that particular memories were encoded in particular molecular structures—substances which could be extracted from a trained animal and then injected into a naive one, carrying the memories with them. This type of experiment, always theoretically dubious, has since been largely discredited in practice as well, as being based on fallacious and artefactual errors of experimental design. What the biochemical and anatomical studies show is *not* specific 'memory molecules', but general cellular systems which underlie all plastic responses of the brain to experience. Although it is not known whether such mechanisms occur in all types of neurones in all organisms, a general parsimony principle which does not multiply processes needlessly would suggest that this is likely to be the case. If it is so, then the specificity of a memory—as when the brain distinguishes between remembering a telephone number, a friend's face, and a childhood recollection—does not lie in the particularity of the biochemical substances concerned. Rather it depends on which cells are involved in the circuits, where in the brain they are located, and with which other cells they are connected.

In this respect, analysing the biochemistry and anatomy of memory is like studying the chemistry and design of the recording head of a tape recorder and a cassette of magnetic tape. To know how a tape recorder works, these things must be studied. But no amount of information revealed by such study will enable one to predict the message on the tape. For that, one has to play the machine. This is likely to remain true for analysis of the cell biology of memory as well.

MEMORY: EXPERIMENTAL APPROACHES. One of the problems in the study of psychology is that it deals with the familiar. And the familiar, being taken for granted, provokes little curiosity. It is therefore often easier to perceive scientific problems when we are confronted with unexpected malfunction. The study of memory is a case in point. The failure of memory, or*amnesia, not only excites interest but also reveals unsuspected facets of the memory process. The form of amnesia which we will first discuss often occurs after blows to the head have produced unconsciousness. Upon recovery the subject cannot remember certain events that occurred in the past. However, it is not the events in the distant past, the memory of which is normally dim, that are most severely affected. It is precisely those events whose memory would be

Page 461

sharpest at the time of the accident that cannot be recalled—the events which occurred closest in time to the accident. For instance, in car accidents the injured person cannot remember the accident itself. The last thing he may remember is being at a place many miles from where the accident occurred. In severe cases the memory of weeks before the accident is unavailable. However, with the passage of time the blank in the memory shrinks, those episodes farthest away in time from the accident returning first. The extent of recovery is variable but a short period of about one second before the accident seems always to remain inaccessible to memory.

From this quite common type of amnesia (retrograde amnesia) some quite surprising consequences follow. It is obvious that some change occurs at the moment of the registration of a memory. Not so obvious is the observation that such a change is more vulnerable to trauma the more recent the change is. Apart from anything else, this 'agedependence' indicates that the physiological change underlying

memory is not all or none but alters in a continuous manner with time. The remarkable length of time over which such alterations occur can be most clearly seen in the Korsakoff syndrome, a condition which sometimes occurs in association with alcoholism. The patient here also suffers from retrograde amnesia. However, the memory blank may be very extensive, perhaps extending over many years and often spreading further and further back until the patient can only remember events in his early youth or childhood. This indicates that the changes in memory we spoke of above must continue over decades.

Unfortunately the physiological changes that occur to produce amnesia clinically are somewhat obscure. A blow on the head can hardly be considered to be a delicate biochemical or anatomical dissecting tool. Consequently scientists have attempted to produce amnesia in animals using more controlled methods. One such method produces amnesia through the use of electroconvulsive shock. A brief surge of current is passed through the nervous system of a rat so as to produce unconsciousness. Twentyfour hours later the rat appears not to recall habits it learned just before the application of such a shock. However, other habits acquired a little while before the shock survive unscathed. These results encouraged theorists to postulate that memory existed in two stages—a labile shortlived stage, disruptible by electric shock, and a permanent stage invulnerable to such interference. Two main problems with such an interpretation are that slightly different experimental circumstances produce widely varying estimates of the duration of the time during which a memory is vulnerable. The second and more severe difficulty emerged when rats were tested at other times besides the traditional twentyfour hours after learning. It emerged that if rats were tested four hours later they did remember, though matched animals would not remember twentyfour hours later. Further rats, given electroconvulsive shock five minutes after training, would remember well twentyfour hours later, but remember nothing a week later, when untreated rats showed good retention. Such findings are difficult to square with a twostage theory of memory, but suggest instead that electroconvulsive shock causes an acceleration of forgetting. However, such forgetting may not be permanent because there exist wellauthenticated cases of recovery of memory after such amnesia. In any case it turns out that passing a large current across the head is hardly more sophisticated as a research tool than a sharp blow to the skull.

In an effort to increase the specificity of physiological interference, various chemical agents have been administered after a learning task, and some of these, such as potassium chloride, flurothyl, and barbiturates, were found to have effects qualitatively similar to electroconvulsive shock. Nevertheless, no specific process in the central nervous system could be pinpointed, and the conclusion seems to be that almost any agent capable of producing a profound interruption in the working of the brain will also induce retrograde amnesia.

Because of advances in the understanding of the storage of genetic information, attention became focused on the possibility that some analogous processes carried information in memory, and attempts were made to affect memory by administering RNA, DNA, and protein synthesis inhibiting drugs. While there is no doubt that these drugs do have effects similar to electroconvulsive shock, interpretation of the way they achieve those effects is in doubt. Even if we accept the premiss that amnesia is caused as a result of protein, RNA, or DNA synthesis inhibition by the drug and not by one

of its sideeffects, this does not necessarily mean that memory itself is coded by what the drug inhibits. Protein synthesis inhibition might very well interfere with some other changes that underlie memory. Suspicious also are the facts that the amnesic consequences of the above treatments may be countered by the administration of stimulants and that the memories that should lack a physiological substrate have in several experiments been shown to return. In any case the idea that the information stored in memory is encoded in a large molecule seems rather unlikely. While such a molecular hypothesis would solve the problem of storage, it fails when it comes to an equally important characteristic of the memory system—namely fast access. It is difficult to see how the nervous system would find the information once it was stored.

A more likely hypothesis than the molecular, concerning memory storage, that was put forward as early as the end of the nineteenth century, is that the change underlying memory consists of synaptic modification. Synapses are the gaps across which neurones communicate with each other, and it is easy to envisage how changes in the facility of

Page 462

transmission across such gaps could be used to store easily accessible information. Even so, in spite of its plausibility, such a hypothesis has received no experimental support till recently. The test that was made utilized a fact already mentioned above, that of a rather slow change in the substrate of memory. If this change is in the transmission capacity of a synapse, or a group of synapses, then pharmacological tools are available to show the existence of such changes. Poorly conducting synapses react differently to the same dose of drug from normally conducting synapses. A good example of this occurs in myasthenia gravis. In this condition the patient has great difficulty in contracting skeletal muscles. The neural pathways to the muscles are intact and so are the muscles themselves. What is impaired is the junction between the neurone and the muscle. This junction is a type of synapse. For reasons that need not concern us here, the transmitter substance, acetylcholine, which is ejected from the neurone, has a much smaller effect on the muscle than normal. When the patient is given a certain dose of the anticholinesterase group of drugs, the destruction of acetylcholine which normally occurs is slowed, and so more acetylcholine becomes available to cause muscle contraction. As a result, movement is facilitated and normal functioning is made possible. However, the same dose of drug administered to a normal person produces paralysis instead, as a consequence of too much transmitter. In a similar manner, we might expect new or weak memories to be facilitated and older or strong memories to be blocked, if the substrate of memory was a synapse that varied in efficiency. As a test of this, rats were trained to perform a habit. The rats were then divided into a large number of groups and made to wait different lengths of time before being retested. They were injected with anticholinesterase in the same dose at the same time, before being tested on their memory of the habit. Any effect of the drug on performance should therefore have been the same. However, the memory of the task was strongly affected by the age of such memory. Little effect of the drug was seen on memories of up to three days. Almost complete forgetting was manifest when the habit was seven to fourteen days old. However, when the habit was twentyone to twentyeight days old and almost forgotten by rats not treated with the drug just before retest, the treated rats showed very good retention. It was thus possible in a simple experiment to show both block and facilitation of a habit using a synaptically active drug.

These experiments strongly suggest that memory is based on a change in synaptic function. As a result of learning, a synapse begins to transmit, then transmits more strongly, and eventually such transmission attenuates to express itself as *forgetting. Because of the changes in susceptibility to drugs, it became important to look for changes in the strength of memory that these changes in susceptibility suggested. As a result it has now been found that when the memory for a habit is tested at various times after learning, such memory does get progressively stronger before forgetting sets in. For instance, rats are placed in a box consisting of two compartments, one lit and the other dark. These are connected by a hole in a partition. When rats are placed in the lit compartment they invariably, after a certain average time, enter the dark compartment. Upon entering the dark compartment they are given an electric shock. On being placed in the lit compartment again, the time it takes the rats to enter the dark compartment is greatly increased. It is the magnitude of this increase that gives us an index of the strength of memory. It has been shown that the time that rats stay out of the dark compartment increases with the time since they were shocked in it. Interestingly enough, the longer the time that rats stay out of the dark compartment the greater the effect of anticholinesterase in reducing memory strength, again as measured by the time that rats choose to stay out of the dark compartment. So that, as memory improves, so does its susceptibility to anticholinesterase, confirming the notion that the physical change in memory occurs at a cholinergic synapse.

Separate from the question of what the change is that underlies memory is the problem of where in the nervous system the change occurs. Is there a place in the nervous system whose destruction abolishes memory? The answer is complex. During operations for removal of epileptogenic loci it is necessary for the surgeon to stimulate the brain while the patient is conscious. Such a procedure, while it may seem extreme, is actually quite innocuous and quite painless. During stimulation of the temporal lobe, complex memorylike imagery arises. However, while such local stimulation triggers recall, the memory does not reside within this locus, because surgical removal of the locus does not abolish later recall of the same memory. Bilateral lesions in the same general area do produce memory disorders, but again these are not due to the destruction of existing memories. Rather, the disorder closely resembles the Korsakoff syndrome, mentioned above, in which old memories survive while new memories are strangely transitory.

There seems to be no particular area in the nervous system that functions as a memory store, as no lesion so far has abolished all memory. There has been an assumption, now shown to be false, that the cortex somehow mediates memory and learning. However, totally decorticate animals, while diminished in the capacity to discriminate, show good learning and retention. This of course does not mean that each particular memory is diffusely stored all over the brain. It probably implies that the specialized capacity to change is a characteristic of most neural tissue. There is also suggestive evidence that memories are stored in those parts of the brain which mediate the perceptions on which those particular memories are

based. For instance, patients with lesions of the visual cortex are blind, but unlike people whose blindness is due to an injury to more peripheral organs of sight they cannot even remember what it

was like to see. Further, it has been shown by experiments on how items in memory inhibit each other that it is those items that are represented as neighbours in the sensory part of the brain which interfere with each other most. Such a pattern of interference would be expected if memory storage occurred in the parts of the brain devoted to perceptual processing.

MEMORY AND CONTEXT. A popular standby of writers of detective stories over the years has been the witness who is unable to recall some crucial piece of information until the cunning detective hits on the idea of reconstructing the exact situation in which the incident occurred, whereupon all comes flooding back. Such a device did indeed play a central role in the first ever detective novel, *The Moonstone* by Wilkie Collins. But is there any foundation to the belief that context may have such powerful effect? In fact there is.

A number of studies have been carried out in which subjects learn material, typically lists of words, in one environment and attempt to recall it in either the same or a different environmental context. There is usually a tendency for recall to be better when it takes place under conditions identical to those in which the material was learnt. The effect is, however, typically rather small, and certainly not enough to suggest—for example—that examinees should do all their revision in the examination hall. With really dramatic shifts in environment, however, quite large effects can be obtained.

Godden and Baddeley (1975) used divers as subjects and had them learn a list of words either on the shore or on the ocean bed at a depth of about 6 metres. The divers then attempted to recall either in the same environment or in the other one. A drop of about 40 per cent occurred when divers who had learnt under water were required to recall on land, or vice versa, indicating that it was crucial to reinstate the context if good recall was required. A subsequent experiment showed that if instead of asking the subjects to recall the words, they were given a recognition task in which they simply picked out the words they had seen before from a list comprising both presented and nonpresented words, no such decrement occurred. This seems to suggest that context dependency is a retrieval effect, with context helping the subject to locate the relevant information in his memory store. Under recognition conditions, the presentation of the word itself acts as an excellent retrieval cue which dispenses with the need for environmental context to assist in locating the relevant memory trace.

A phenomenon which is closely related to that of context-dependent memory is that of state-dependent memory in which, instead of varying the environmental context, the internal state of the organism is manipulated, for example by means of drugs (Kumar et al., 1970). Goodwin, Powell, Bramer, Hoine, and Stern studied the role of state dependency in alcoholics. They cite (1969) clinical evidence of heavy drinkers who, when sober, are unable to find alcohol and money which they hid while drunk, but who remember the hiding places once they are drunk again. They attempted to test this, using a group of heavy drinkers and studying the learning and recall of a series of tasks, including memory for words, and for pictures, which included both neutral pictures taken from a mail order catalogue and 'emotional' pictures from a nudist magazine. They found clear evidence of context dependency in all the tasks involving recall, but no effect for picture recognition. A similar lack of effect has subsequently been shown for word recognition. As in the case of environmental context, an effect

occurs for recall, but disappears when the retrieval component is diminished by using recognition testing.

One very powerful source of context effects is that of mood. In one series of experiments, subjects were hypnotically induced to feel either happy or sad during the learning of a list of words, and to be either happy or sad during recall. Words that were learnt when sad were recalled best when sad and vice versa (Bower, 1981).

Similarly, quite powerful effects have been observed in the case of depressed patients who have great difficulty accessing memory for pleasant and happy events during periods of depression, while they are well able to recall sad incidents. This tendency of course tends to reinforce their depression, locking them into a vicious circle of increasing sadness and increasing difficulty in remembering anything not associated with sadness. Breaking away from this cycle has obvious therapeutic potential, and forms one component of the cognitive treatment of depression.

We have so far been concerned with the role of *extrinsic* or environmental context in memory. As we have seen, this typically occurs in the case of recall but not of recognition. Much more dramatic contextual effects can be obtained by means of *intrinsic* context, that is contextual cues which change the interpretation of the material to be remembered. To take an extreme example, suppose I ask you to remember the word 'jam'. I can bias the way in which you encode and remember the word by preceding it with the word 'traffic' or with 'strawberry'. If I have initially biased your interpretation of the word in the direction of traffic jam, you are much less likely to recognize the word subsequently if it is accompanied by the word 'raspberry', which biases you towards the other meaning of jam. This effect occurs even though the subject knows full well that he is only supposed to remember the word 'jam' and not the contextual or biasing words. As Tulving and Osier have shown, this effect is not limited to words that have more than one meaning. If one takes a word like 'city',

and presents it alongside a weakly associated word such as 'dirty', then recognition is substantially impaired if the test item is accompanied by another but different weakly associated word such as 'village'. This suggests that the subject is not remembering the word 'city' in and of itself, but is creating some representation which is biased by the context. For example, he may be thinking in terms of the dirt and litter associated with a busy city. When 'city' is subsequently presented with another biasing word such as 'village', he may well be thinking of some secluded district within a city, a district which has many of the neighbourhood characteristics of a village, and which would therefore be very different from the original encoding of a busy, dirty city. Note that this intrinsic context effect differs from that of the environmental context effect in that the intrinsic context determines what is learnt by the subject during the initial presentation, whereas the extrinsic or environmental context merely assists the subject in accessing a particular memory trace. Since the effect of intrinsic context is on learning rather than simply retrieval, it shows up both with recall and recognition.

Most of the instances we have discussed have been concerned with remembering words. However, there are clear and important examples of the role of intrinsic context in other areas, and in particular in the recognition performance of witnesses. The Australian psychologist Donald Thomson has extended the original verbal studies into this particular area, and has shown that the probability of a

witness falsely identifying someone in an identification parade, as the person observed at the scene of a crime, can be dramatically increased by changing irrelevant contextual features, such as having the suspect wear similar clothes or showing him in a similar contextual environment. He has shown that even careful and experienced witnesses such as police or lawyers are very subject to bias of this type. His work adds to the considerable evidence that eyewitness identification is very much less reliable than juries typically realize. We do not perceive or remember in a vacuum. The context within which we experience an event will determine how that event is encoded and hence retained. What we *have* learned, we are not always able to call to mind, particularly if we try to recall it when our internal or external environment is dramatically different from the conditions during learning.

MENTAL CONCEPTS: THE CAUSAL ANALYSIS. In recent years analytical philosophers have become increasingly aware of the importance of causality (see CAUSES) in the logical analysis of mental concepts. Consider, for instance, what it is for somebody to *infer* one proposition from another. A person, *A*, believes that *p* is the case, and, on that basis, infers *q* is true (whether reasonably or unreasonably is of no concern), so acquiring the belief that *q* is true. It seems clear that *A*'s believing that *p* is true brings about, that is, causes, the acquiring of the belief that *q* is true. For consider the case where *A*, believing that *p* is true, later acquires the belief that *q* is true, though the original state of belief is in no way causally responsible for acquiring the belief that *q* is true. In such a case we should not allow the possibility that *A* had inferred *q* from *p*. It is a necessary condition of *A*'s making such an inference that the belief that *p* is true give rise to the belief that *q* is true.

Similar considerations may be adduced in the case of other mental concepts. When we *remember* an event, that event must play a part in bringing about the later recall. When we *perceive* an object, that object must play a part in bringing about the perception of it.

Awareness of the ubiquity of causal conditions in analyses of mental concepts has led some philosophers to make a more ambitious, though more speculative, proposal. They suggest that a logical analysis can be given of all the mental concepts in purely causal terms. This proposal, or research programme, in logical analysis constitutes the Causal theory of the mental concepts.

As models for the proposed undertaking, consider the ordinary language concept of 'brittleness' and the scientific notion of 'gene'. To say that something is brittle is to say that it is in a certain state. If, in addition, the object is struck sharply, then the combined influence of the two factors, the state and the blow, brings it about (generally) that the object shatters. The state of brittleness is defined simply in

terms of what it causes. The concrete nature of the state cannot be elicited simply from its definition, but may be established by further scientific research.

Genes were originally conceived of simply as a set of causal factors at work within the organism. These factors, acting and interacting in a certain way, bring it about that the organism has certain hereditary characteristics (the notion of a hereditary characteristic being itself causally definable). The further nature of genes cannot be elicited simply from the notion as originally introduced. It is a later scientific discovery that genes are in fact DNA molecules. The original concept of the gene is simply the concept of that, whatever it may be, which brings about certain effects.

The causal analysis of the mental concepts asserts that all mental concepts are of the same general sort as the concepts of 'brittleness' and 'gene'. The mental concepts are concepts of states, events, processes, etc., which are definable purely in terms of their *causal role* (the phrase is due to D. K. Lewis). The causal role of brittleness is con

Page 465

stituted by the fact that, in conjunction with striking, it produces shattering. The causal role of the gene is constituted by its production of hereditary characteristics. The causal role assigned to mental processes, etc., by this analysis is primarily the production of certain sorts of physical behaviour by the organism. As a rough characterization of that behaviour, it is the most flexible and sophisticated behaviour exhibited by the organism. An account of*purposes, for instance, is sought for along the following lines. The purpose to do *X* is a state of the organism, whatever that state may be, which initiates and sustains those trains of physical activity which, in favourable circumstances, bring *X* to be.

Minds are the most complex and sophisticated systems known to exist. It is to be expected, therefore, that the concepts which we have evolved for dealing with mental processes should be among the most complex and sophisticated concepts that we possess. Given that the causal theory is correct, it is quite certain that the causal roles involved will be exceedingly complex and correspondingly difficult to spell out. What was just said about purposes, for instance, can be no more than the crudest first sketch for an analysis. It turns out, in particular, that the different causal roles which constitute different mental processes are of an interlocking sort, so that it is not possible to give an account of one sort without giving an account of others, and vice versa. For instance, purposes and beliefs involve a packaged deal so that, although their causal roles in the production of behaviour are different, the one causal role cannot be described without reference to the other. This reflects the familiar point that actual behaviour is always a joint product of purposes and beliefs.

Those who have actually proposed the causal analysis have been materialists. They wished to give a purely physicalist account of mental processes. The causal analysis makes it easy to do this, because the nature of that which plays these complex roles is not determined by the analysis. The causal theorist can then go on to maintain, on grounds of general scientific plausibility, that mental processes are in fact ordinary physical processes in the brain. This yields the doctrine of *central state* (as opposed to*behaviouristic) materialism. However, it may prove possible to uphold a materialist

view of the mind without accepting the causal analysis of the mental concepts. Furthermore, the causal analysis is entirely compatible with an antimaterialist view of the mind. A causal theorist could maintain without contradiction, for instance, that mental processes are, in their own nature, processes in a spiritual substance, processes which produce certain bodily effects.

The causal analysis of the mental concepts is far from having been completed. It remains a research programme. How promising a programme it is, is a matter for controversy among those philosophers who seek a general view of the mind. No fullscale critique of the causal theory has yet been developed, but various difficulties have been raised.

First, a property such as brittleness or an object such as a gene is a *theoretical* entity. It is something which is postulated as an explainer of certain phenomena: shattering after being hit; the recurrent patterns of characteristics in organisms related by descent. To give an account of mental concepts in terms of the causal role of the entities involved seems therefore to assimilate mental entities to theoretical postulations. Yet, unlike the case of brittleness or the gene, when we introspect we are directly, though no doubt not infallibly, aware of some of our own mental processes. We observe them. But could the content of our introspective observation be confined simply to this: the presence of something playing a certain causal role?

Secondly, all or almost all mental processes have the property of pointing beyond themselves to something which, nevertheless, need not exist. We may desire and pursue that which is unattainable, we may think of and believe in that which does not exist. Franz*Brentano spoke of this phenomenon as the*intentionality of mental processes. Can mere causal role, however complex and sophisticated, fully explain the intentionality of mental processes? If this objection can be made good, it may pose a threat to a materialist doctrine of the mind as well as to the causal analysis of the mental concepts.

Thirdly, by introspection we appear to become aware of certain mental *qualities*. Having an itch is introspectively different from having a pain, having a sensation of something green is introspectively different from having a sensation of something red, being angry is introspectively different from being afraid. In all these cases, it is quite plausible to assert, we are introspectively aware of a difference in the qualities of the mental processes involved. But it is difficult to see how a purely causal analysis of the mental concepts could account for such an awareness of qualitative difference. This objection is attractive to many philosophers working within what may be called the 'British empiricist' tradition.

It is an interesting question whether this objection, supposing it well taken, refutes not only the causal analysis but also a materialist account of mental processes. Such introspected qualities are in prima facie conflict with materialism, but perhaps the conflict is prima facie only D. M. A

MENTAL DISORDERS: CLASSIFICATION. An agreed classification of mental disorders and the nomenclature which goes with it are essential to a scientific psychiatry. Among other things, they

Page 466

provide the common language in which professional colleagues can inform each other about individual patients, and enable investigators in different centres and countries to collate their research findings. Without them epidemiological studies would hardly be possible. The system now in use in Britain is the ninth revision, in 1978, of the International Classification of Diseases: ICD9. It divides mental disorders into three classes: psychoses (see MENTAL ILLNESS); neurotic disorders, personality disorders, and other nonpsychotic mental conditions (see MENTAL ILLNESS); and mental retardation (see MENTAL HANDICAP). The psychoses are subdivided into organic psychotic conditions, which include various types of dementia and other brain syndromes; other psychoses, which include schizophrenic psychoses, affective psychoses, and paranoid states; and psychoses with origins specific to childhood. The neurotic disorders, in the second of the classes, include anxiety states, hysteria, phobic state, and obsessivecompulsive disorders. Also in this class are several types of personality disorder, sexual deviations, alcohol and drug dependence, nonpsychotic disorders specific to childhood and adolescence, and a variety of other syndromes. Mental retardation, in the third of the classes, is subdivided according to its degree.

A more advanced system, elaborated by the American Psychiatric Association, was published in 1980 in The *Diagnostic and Statistical Manual of Mental Disorders*: DSMIII. It starts from a definition of mental disorder in which the key phrases are 'a clinically significant behavioural or psychological syndrome or pattern', 'in an individual', and 'not only in the relationship between the individual and society', which is 'associated with either a painful symptom (distress) or impairment in one or more important areas of functioning (disability)'. Mental disorders exist as separate entities, not as gradations from normal to abnormal. **DSMIII** evaluates each case on five axes, the first three of which—(I) clinical syndromes, (II) personality disorders and specific developmental disorders, and (III) physical disorders and conditions—constitute the diagnostic assessment. This may be supplemented by ratings on axes IV and V, on a sevenpoint scale, of 'severity of psychosocial stressors' and 'highest level of adaptive functioning during past year'. The classification on III is broadly similar to that of ICD9 although with numerous modifications in nomenclature and in criteria, which, widely tested before DSMIII was published, are more stringent.

The classification of mental disorders has evolved gradually over many years, going back at least to Philippe Pinel, who in 1798 divided them into four groups, mania, melancholia, dementia, and idiocy—while remarking that medical science was not sufficiently advanced to warrant a more detailed scheme. (A rougher classification of persons *non compos mentis* was proposed by Sir Edward Coke in 1604. His four categories were the idiot or fool natural; he who was of good and sound memory and by the visitation of God has lost it; the lunatic who enjoys lucid intervals; and he who was rendered *non compos mentis* by his own act as a drunkard. Obviously the first three categories correspond to our presentday ideas of subnormality, the dementias of old age, and the remitting and

relapsing psychoses. Although drunkenness could be classed as an acute toxic psychosis, it would be unusual for this condition to be listed among that group of mental disorders today unless there was some additional evidence of abnormality.) In the second half of the nineteenth century distinctions were made between acute, primary, and curable dementia, on the one hand, and chronic, secondary, and incurable dementia, on the other. Secondary dementia, although sometimes attributed to syphilis, was regarded as hereditary and progressive. Emil Kraepelin, after studying thousands of casehistories, proposed a comprehensive system of classification, much of which has been carried over into contemporary classifications. In particular, he distinguished between the endogenous disorders, caused by inherent constitutional factors, and the exogenous, caused by external conditions. The pattern of a disorder, he noted, depends also on the age at which it starts. In 1896 he made the crucial distinction between *dementia praecox*, which begins in adolescence or early adult life, is endogenous, and tends to show a progressive deterioration, and manicdepressive psychosis, the course of which tends to be cyclic, with intervals of normality between attacks. *Dementia praecox* was renamed schizophrenia in 1911 as a result of Bleuler's revision of the clinical description; its course is not now regarded as inevitably progressive. The various forms of manicdepressive psychosis are now called affective psychoses.

Support for the distinction between the two disorders has been found in the raised incidence of schizophrenia, but not of manicdepressive psychosis, in the families of patients suffering from schizophrenia, and the raised incidence of manicdepressive psychosis, but not of schizophrenia, in the families of patients suffering from manicdepressive psychosis. These findings also support the hypothesis that the genes, and therefore the underlying metabolic defects, are different. (See SCHIZOPHRENIA for further details.) Attempts to confirm that there are two forms of affective psychosis corresponding to the endogenous and exogenous (or reactive) have not been conclusive. Statistical analysis of the correlations of symptoms has not produced consistent evidence that the symptoms fall into two patterns.

The distinction made between organic and nonorganic psychoses, however, is strongly supported on clinical grounds.

Supposing the disorders to arise from metabolic or other defects, Kraepelin described their manifestations as if they were neurological signs—'soft' signs, they have been called—and certainly not as reflecting continuing and changing processes of adaptation. This bias still influences the criteria

Page 467

on which contemporary classifications are based. Their strength, and their weakness, lies in that they are 'generally atheoretical with regard to aetiology', as has been claimed for DSMIII. This avoids the difficulty that the correlations between the forms taken by disorders and the external causes to which they might be attributed are small. In DSMIII the ratings on axis IV of the 'severity of psychosocial stressors' and on axis V of the 'level of adaptive functioning' are significant innovations which do something to compensate for the bias. However, the main concern in the international collaboration of the last two decades has been so to define the criteria that they provide a consistent and reliable basis for the collation of research findings. In this some success has been achieved. Evaluations of ICD9 and DSMIII continue, and new revisions are to be expected in due course.

MENTAL HANDICAP. It is estimated that about one in every thousand children in the United Kingdom and the United States of America is mentally handicapped.

It is not easy to judge the total number because of the various definitions of mental handicap. The American Association on Mental Deficiency (AAMD) describes retardation as 'subaverage general intellectual functioning which originates during the developmental period and is associated with impaired adaptive behaviour'. 'Subaverage' means more than one standard deviation below the normal average level of intelligence commonly accepted (in the UK, 100; in the USA, 90-100);

'developmental period' means from birth to about 16 years of age; and 'impaired adaptive behaviour' means failure to mature, to learn, or to adjust socially.

This definition has been challenged because it does not take account of environmental and social factors, both of which may have an important influence on retardation.

The lack of a clear definition has significance, for failure to diagnose may lead to failure to treat.

The problem of mental retardation emerged in the nineteenth century. Before that time, the retarded were assimilated into the general background of rural societies or they did not survive at all. The percentage of children who were mildly mentally retarded increased with the growth of towns, because of poor housing, lack of care before, during, and after birth, malnutrition, poverty, and poor working conditions for mothers. These causes remain, but, with the improvement of general standards of living and literacy, children retarded in this way are now among the 'ablest' of the mentally handicapped. As societies become more complex and technologically oriented, the number of people unable to cope with life increases, and the burden on the working population is correspondingly increased.

In the nineteenth century many schemes to train and educate the mentally retarded were begun and found to be successful. Possibly the first attempts at education were made by Jean-Marc Gaspard Itard, who described his work with a wild boy found in the woods of Aveyron. Truffaut's film *L'Enfant sauvage* is an account of Itard's attempts to socialize and educate the boy Victor, who was, however, probably already retarded when he was found.

Since the success of treatment depends very much on the cause of the illness, improved skills in

diagnosing mental retardation have also meant improved chances of rehabilitation. The aetiology of mental retardation is divided into two parts: intrinsic and extrinsic causes.

Intrinsic causes. These are biological, mainly genetic. One of the commonest is*Down's syndrome (mongolism), which results from a chromosome abnormality. One birth in 250 will have a chromosome abnormality, which can be diagnosed by counting the chromosomes taken in smears. Unfortunately the cause of the damage to the chromosome structure that produces Down's syndrome has not yet been identified, although a connection with infective hepatitis has been suggested. Genetic counselling may reduce the incidence of one type of Down's syndrome, for if one or both parents has an abnormal chromosome structure there is a greater likelihood that their child will have an abnormality. The chances of an abnormal birth increase with the age of the mother, and after the age of 35 special attention should be paid to the chromosomal compatibility of the parents.

Other intrinsic causes are metabolic. In phenylketonuria (PKU), which occurs in one in 10,000 births, failure to metabolize the amino acid phenylalanine results in a toxic condition which affects the brain and causes retardation unless a phenylalaninefree diet is given to the child. In the United Kingdom, every newborn baby is now tested for PKU, and so a dangerous condition is prevented by early intervention. Osteogenesis imperfecta ('brittle bones'), TaySachs disease, and Duchenne's muscular dystrophy (both degenerative killing diseases) are other intrinsic causes of mental retardation. The causes of many intrinsic diseases are not yet known. The American Association on Mental Deficiency and the American Psychiatric Association maintain lists of most of the categories of intrinsic causes of retardation, and these lists are updated as knowledge extends.

Extrinsic causes. These are mental handicaps

Page 468

that result from infections, accidents, poisoning, or other brain damage. Difficult or premature births may cause brain damage because of anoxia (shortage of oxygen supply to the brain). Babies may be born blind and/or mentally retarded if the mother is infected with rubella (German measles) before the fourth month of pregnancy.

Congenital syphilis can also damage the child. (It used to be thought that this disease was the cause of Down's syndrome. The misery and anxiety such a mistaken belief must have caused parents whose children suffered from Down's syndrome can hardly be imagined.) Smoking, excessive use of alcoholic drinks, poor prenatal care, malnutrition, infection, or poisoning from environmental pollution (such as mercury or lead) may lead to immature or damaged babies.

During the neonatal period, factors such as high fever, jaundice, failure to breathe properly, or inadequate or unsuitable nutrition may cause retardation. The child's brain may be damaged by poisoning from sucking toys painted with paint containing lead monoxide or cadmium, or by baby battering (see CHILD ABUSE), or by falls. One category in the AAMD list should be looked at with particular attention: diseases and conditions due to unknown or uncertain factors with structural reaction alone manifest—a category into which the 'wild boy' of Aveyron might well fit. It is known that a child deprived of tender loving care will grow up with deficient sensory and social ability. If the impoverishment and lack of stimulus in a child's upbringing are not remedied early, he will grow up with reduced social and intellectual capacity and may be diagnosed as a case of 'mild' (category I)

retardation.*Autism is a condition which may fit into any of the categories of retardation, from I to V, and which causes great distress—particularly, perhaps, as at first sight the child may seem to be quite normal. There continues to be much debate about the nature and causes of autism.

Treatment and provisions. The amount of retardation in individual cases varies as much as intelligence does among 'normal' people, and this range makes management and discussion complex and difficult. Diseases caused by poisoning (intoxication) may be halted or even cured by removing the source of the poison, and eliminating the poison already in the child, before there is irreversible brain damage. Diseases caused by social factors—such as malnutrition, lack of care before, during, or after birth, poor stimulus, or infection of the mother—could be eliminated or at least reduced by social welfare programmes (for example, inoculation against measles and rubella) and by the education of parents to help counter retardation of this kind.

Treatment of intrinsic causes is more difficult because the damage is irreversible. However, prevention is beginning to be possible. Amniocentesis can be used to detect chromosome abnormalities while the child is still in the womb. The technique cannot be used until the fourth month of pregnancy, and, as the fluid has to be taken out of the uterus, there is the possibility of damage to a normal foetus and the risk of natural abortion; also it must be practicable to offer induced abortion as an alternative.

Once a child is born with irreversible brain damage, drugs can help to prevent fits and special programmes can help to develop existing intelligence and mobility. The DomanDelacato course of treatment may improve the abilities of some children, although it demands tremendous dedication and energy on the part of the parents, while the cost to the family as a whole should not be disregarded. More usually, braindamaged children go to nursery schools and then to special schools where attention is paid to individual differences and needs. If this sort of help is given from birth onwards it may be possible to educate the child and support the family who look after it. In the United Kingdom such programmes have been devised by Mr R. Brinkworth, the founder of the Down's Babies Association.

In some parts of the world there are excellent provisions, while in others they are sadly lacking or even nonexistent. At best the mentally handicapped may be helped to lead relatively normal lives, to do some sort of work, and to live in sheltered housing with some support. Whether the work is in workshops or on the land, it will give the moderately handicapped a sense of individual dignity and purpose. The severely handicapped will have to spend their lives in hospitals and will need dedicated nursing as well as support from all the other social services. It is important to distinguish here between the mentally handicapped and the mentally ill (see MENTAL

ILLNESS). In the popular mind these two conditions are often confused, leading to much illinformed fear and prejudice. None the less, there is good evidence that the mentally handicapped do have a higher incidence of neurotic and psychotic disorders.

Wherever adequate provision is made for the mentally handicapped, it will be found that the cost is great. Against this cost must be set the cost *of not* providing. The incidence of broken marriages is ten

times higher where there is a mentally handicapped child. There are risks to physical and mental health—mothers typically suffer more than fathers, while the normal children in the family are also under pressure. Widows and deserted wives figure prominently in surveys.

In the past the mentally handicapped often died at birth or in early childhood. They survive into mature adulthood with the help of care before and after birth and the widespread use of antibiotics. Should doctors perhaps not strive 'officially to keep alive' if spina bifida has been diagnosed and the child, and later the adult, is condemned to a crippled and handicapped life after operations which may relieve the symptoms but cannot cure the condition? How can we balance, for instance, the cost of keeping a mentally handicapped child against the cost of a kidney machine for a working man who supports a family? In a sensitive and civilized society, euthanasia is an emotive and difficult subject. Doctors need guidelines and support to avoid accusations of murder when they must make decisions which affect not only the individual family but society as a whole.

MENTAL HEALTH. Answers given nowadays to the question 'What are the characteristics of a mentally healthy person?' are likely to refer to such signs as the capacity to cooperate with others and sustain a close, loving relationship, and the ability to make a sensitive, *critical* appraisal of oneself and the world about one and to cope with the everyday problems of living. At other times or places, different qualities would have been mentioned, according to the values prevailing in the culture.

For the English middle class at the turn of the nineteenth century, *mens sana in corpore sano*—a sound mind in a sound body—would have included a disciplined intelligence, a wellstocked memory, qualities of leadership appropriate to the person's station, a respect for morality, and a sense of what life means. There was at that time an absolute refusal, as Clouston (1906) put it, 'to admit the possibility of a healthy mind in an unsound body, or at all events in an unsound brain'. Nowadays we regard mental health as attainable by even the severely crippled. Brain injury may put limits on the degree to which social capacities can be developed, but it does not prevent their development altogether; the influence of the milieu may be as strong as that of the severity of the injury. For a vigorous critique of the concept of mental health one can hardly do better than turn to Barbara Wootton's review (1960) in which, after commenting on a number of proposed definitions, she concluded that 'whichever way, therefore, the problem may be approached, no solid foundation appears to be discoverable on which to establish the propositions (as) formulated'.

The shift in emphasis from intellectual ability to harmonious relationships as the criterion of mental health can be partly attributed to the recognition that, whatever part physical inheritance plays in determining intelligence, intellectual development depends largely on learning in the setting of a relationship. The publication in 1951 by the World Health Organization of John Bowlby's monograph *Maternal Care and Mental Health* was a landmark because it made it widely known that an essential condition for the mental health and development of the child is 'a warm, intimate, and continuous relationship with his mother in which both find satisfaction and enjoyment'. 'Sound cognitive development', it has been said, 'occurs in a context of communication.' The abilities which enable the child to play the roles appropriate to a boy or girl are acquired through the learning engendered by the expectations of the family. Interruption, or disturbance, during early childhood in the relationship with the mother has been shown to retard or distort the development of language and the skills related to it, and to lead in some circumstances to an impairment in social relationships which lasts into adult life. The effects depend on the character of the 'support' or 'security' system, of which the mother is usually the chief member. The father, the grandparents, older siblings, and family friends contribute to the system. The young child is vulnerable if the system is weak or fragile.

The young child tends to attach himself to one person especially, usually the one who mothers him, and this relationship, established in the second half of the first year of life, prepares him for a monogamous relationship when sexual maturity is reached, and influences then his choice of partner. (See ATTACHMENT.) Social training of other kinds, in the family and outside it, prepares him for the several roles he is to play in adult life. A boy tends to take his father as a model, and a girl, her mother.

Of importance too is membership of a peer group in the early teenage years. From his experience in relationships with his mother and father, peers of the same sex, and then a peer of opposite sex, the young person discovers what sort of person he is—i.e. he forms a conception of himself, or establishes his 'identity', especially his sexual identity. His education and early experience in a job establish his occupational identity. This conception of himself is tested out by further experience which confirms or modifies it. The first *affaire* confirms or, if it goes badly, confuses his sexual identity. He becomes emancipated in greater or lesser degree from his parents, and free to form relationships outside the family. The rapid intellectual development at the time of puberty helps the

young person to understand, and in some degree gain control over, the world around him.

The social training he has had during childhood is put to the test at turningpoints in circumstances, or 'crises', which require old habits to be abandoned, new habits to be developed. Crises are conveniently divided, following Erikson (1968), into 'developmental' and 'accidental'. By developmental crises are meant those decisive changes in

Page 470

circumstances ordinarily expected to occur in the life cycle—for example, being born, going to school, leaving school, getting married, becoming a parent, or retiring from work. Examples of accidental crises are the untimely loss of a member of the family, a spouse or other loved person, the loss of a job, or illness. If he is prepared for the new circumstances, as is usual when the crisis is developmental, a person acquires new habits quickly through the processes of learning. If not prepared, because the crisis is untimely, or social training has been lacking or inappropriate, a person may go through a period of instability and distress while he works out new ways of coping.

In studies of bereavement—for example, by C. M. Parkes—are to be found illustrations of the differences between mental health and illness. After the loss of a loved one, one person mourns for a time. While doing so, he is able to express to others his grief and distress openly and authentically, and thus to review his relationship with the person lost. He soon reengages in relationships with others, which change and develop. Another person becomes preoccupied by his fantasies about the person lost. These may be out of keeping with the realities, which are denied. He withdraws from other relationships, and shows a general contraction of activities and interests. He feels diminished and depreciated. Withdrawing from relationships, and unable to communicate his distress, his conception of himself remains uncorrected, and he does not work out a new pattern of relationships. This kind of severe reaction to bereavement occurs especially when the loss has been sudden or unexpected, or there have been distressing circumstances: for instance, if the death was due to suicide, or to the negligence or misconduct of others. Such a reaction may also reflect the personality of the bereaved person and his relationship with the person lost. He may have been unaccustomed to taking decisions for himself, or have had limited personal resources, or have been unduly dependent, or the relationship may have been discordant and fraught with unresolved difficulties.

The features of the reaction of the latter person are the antithesis of mental health, and amount to mental illness if he also claims exemption from normal social responsibilities. Yet they reflect psychological processes which are part of the organism's normal reactive equipment, and which are adaptive in that they serve to reduce anxiety. They can be described as due to 'the renunciation of functions which give rise to anxiety' (which Sigmund Freud said was the essence of neurosis). The psychological processes are maladaptive in the particular circumstances in that they do nothing to remove the sources of the anxiety. There is thus a deadlock. By avoiding a situation or staying out of relationships in which he has experienced pain or anxiety, a person does not explore and reevaluate the situation, or learn to cope with it in more effective ways. Other characteristics of behaviour in mental illness are persistence or repetitiveness and resistance to modification by experience, whereas

behaviour in mental health tends to be flexible and modifiable.

To break the deadlock, and to restore mental health, a therapist creates conditions in which the testing of reality and learning can be resumed. New habits can then be acquired which are more appropriate to the circumstances. The person's conception of himself can be corrected by further experience. He is encouraged to reenter into relationships. In other words, the therapist intervenes or mediates in order to bring about reconciliation, and to enable communication with others to be reopened.

MENTAL ILLNESS. Most people think of mental illnesses as strange and frightening conditions which can affect other people but not themselves or their families.

But in the average family doctor's surgery psychological symptoms are surpassed in frequency only by common colds, bronchitis, and rheumatism. In the course of a year, about one in every eight people in Britain consult their general practitioners for problems which are predominantly or completely psychological in nature. General practitioners refer about 10 per cent of such patients to a psychiatrist; most of these will be treated as outpatients but some will need admission to hospital, which in Britain is nearly always on a voluntary basis. Thus, out of all those who seek medical help with psychological problems, only a small minority become psychiatric inpatients. It is then a striking indicator of the extent of such problems that psychiatric patients occupy nearly half of all the hospital beds in Britain and in most other industrialized nations.

Arguments continually rage over the exact limits of mental illness. Some authorities regard the concept of mental illness as a myth while others, by contrast, consider that the majority of seemingly normal people suffer, often unknowingly, from psychiatric abnormalities amenable to treatment. Furthermore, some believe that psychiatric disorders are simply mental equivalents of physical diseases, while others argue that there are as many sorts of psychological problems as there are individuals who suffer from them.

In practice it is possible to discern certain recurring patterns of complaints and disabilities which can be regarded as reasonably discrete entities. These disorders can be divided into two broad groups: organic disorders, in which some demonstrable physical illness including brain disease

Page 471

underlies the psychological symptoms, and functional disorders, where no definite physical abnormality has yet been replicably demonstrated. Since most forms of mental illness fall into the latter category, the classification of psychiatric disorders is generally based on the clinical distinction between different clusters of symptoms each with a characteristic outcome. (See MENTAL DISORDERS: CLASSIFICATION.) In general medicine, advances in classification occurred when technological progress allowed the elucidation of the underlying causes of illnesses. Unlike their colleagues practising general medicine or surgery, however, psychiatrists are unable to rely on laboratory or other tests to refute or confirm their clinical diagnoses. Recent attempts to develop specific diagnostic investigations, such as the dexamethasone suppression test for depressive illness, have yet to produce a procedure of proven value. Unfortunately other mental illnesses show the same response that was found with a proportion of depressed patients, but the search for laboratory tests to aid with the diagnosis of affective disorders and other conditions continues.

In the meantime it is useful to distinguish between the neuroses and the psychoses. Neurotic symptoms correspond to what is commonly called 'nerves' and comprise feelings and thoughts which most normal people have experienced at some time or other, albeit in a relatively minor form. However, if they become persistent and severe, such symptoms can become markedly disabling, and result in a frank neurotic illness or 'nervous breakdown'. Psychotic symptoms, on the other hand, are not part of normal experience and are almost invariably severe. The picture of psychotic illness is quite distinct from normality and corresponds to what in popular usage is called 'madness' or 'insanity'. Women outnumber men among neurotics by about two to one, but psychosis is equally frequent in the two sexes.

Neurotic problems account for about twothirds of those consulting family doctors because of psychological symptoms, the remainder being made up by a variety of conditions including*psychosomatic complaints, abnormalities of personality, alcoholism, and the psychoses. Most neurotics are treated by their general practitioners, but individuals with psychotic illnesses are almost always referred on to psychiatrists. Thus, while those with psychoses form only about 4 per cent of patients consulting GPs because of psychological problems, 25 per cent of psychiatric outpatients and more than half of all psychiatric inpatients suffer from psychotic illnesses.

Table 1 lists the expectancies of being affected at some time during life by the different psychiatric conditions for (i) a member of the general population and (ii) someone who has a firstdegree relative (i.e. parent, sibling, or child) with one of the disorders.

Neuroses. *Anxiety states* are among the most common of all psychiatric disorders and are characterized by persistent apprehension and fear, at times amounting to panic. They are often accompanied by sensations caused by overactivity of the*autonomic nervous system: these include excessive sweating, tremor, faintness, choking or breathlessness, and 'butterflies' in the stomach. (See ANXIETY for further discussion.) *Phobic neuroses* have much in common with anxiety states in that the predominant symptoms are again of fear or panic together with autonomic overactivity. But in phobic neuroses the symptoms are provoked by certain specific stimuli, such as dogs, spiders, the sight of blood, or having to talk to strangers. The most common variety is agoraphobia, which literally means fear of open spaces The agoraphobic is afraid of leaving home and subject to panic

attacks in crowded public places such as supermarkets. He or she often dreads travelling on public transport, especially underground trains, and has great difficulty in tolerating lifts or rooms from which there is no ready exit. Since these symptoms considerably limit normal life, agoraphobic patients may become totally housebound. (See PHOBIAS for further discussion.)

Obsessivecompulsive neurosis is much rarer, but nevertheless the symptoms which form its core are phenomena with which, in milder form, most people will be familiar. There can be few people who have not at some time been unable to stop a

Page 472

song going round in their head, or had an irrational urge to avoid stepping on cracks in the pavement, or rechecked windows and doors which they know they have already secured. In obsessivecompulsive neurosis, such thoughts or practices become pathologically exaggerated. Fears of having been contaminated by dirt, or of having harmed someone, may preoccupy the sufferer for most of the day even though he recognizes that they are silly. Similarly, he may wash his hands or check taps a hundred times a day, while all the time trying to convince himself that his behaviour is ridiculous. Such repetitive thoughts and compulsive acts become so intrusive that productive activity becomes impossible. (See OBSESSIONS AND COMPULSIONS for further discussion.) The predominant features of depressive neurosis are gloom and despondency. Bouts of weeping are common, as are edginess, irritability, and a tendency to tire easily.

There is a general loss of ability to concentrate and in particular a lack of interest in things which were previously enjoyed. The symptoms tend to vary in intensity, but often cause difficulty in getting off to sleep. (See DEPRESSION for further discussion.)

A variety of neurosis which was formerly common but is now much less so is hysteria, which in its classical forms beguiled nineteenth-century physicians such as J.

M.*Charcot and Sigmund*Freud. Indeed, it was while studying a hysterical patient, the celebrated 'Anna O.', that Freud and*Breuer developed many of the concepts upon which psychoanalysis came to be based. The essence of hysteria is that, in the face of intolerable stress, symptoms develop which provide a defence against the stressful circumstances. Characteristic symptoms include a paralysed limb, loss of speech, convulsions, or blindness, and are often called conversion hysteria because the psychological trauma has figuratively been 'converted' into a bodily form. Some forms of hysteria involve a different mechanism called dissociation, in which an individual may forget even his own identity. He may wander off in a 'fugue state' which carries him many miles from home, or he may take on some new identity or switch from one identity to another—the 'split personality' of popular films, such as *The Three Faces of Eve*. (This phenomenon is discussed under DISSOCIATION

OF THE PERSONALITY.) Although hysterical mechanisms are usually unconscious, many psychiatrists doubt the genuineness of some of the more theatrical forms.

Indeed one of the problems confronting psychiatrists in legal work is where to draw the dividing line between hysteria and conscious simulation or malingering.

Fortunately, hysterical symptoms are becoming less common due to improved education and awareness of psychological matters; this allows the expression of emotional difficulties for what they are, and renders the communication of suffering via hysterical symbolism redundant. None the less, it is important to remember that conversion hysteria can develop against a background of serious organic brain disease, either preexisting or unsuspected, in a considerable percentage of cases. (See HYSTERIA for further discussion.)

In contrast to hysteria, anorexia nervosa appears to be on the increase, particularly among adolescent girls and young women. The central feature is self-imposed starvation, which frequently starts with a slimming diet and occasionally ends with complete inanition and death. Weight loss, physical overactivity, cessation of menstrual periods, and the growth of downy hair on the face and back are the cardinal symptoms. Surprisingly, most patients shun treatment and instead show considerable ingenuity in avoiding weight gain. Thus they hide food or secretly throw it away, and abuse laxatives. Like the obsessive-compulsive, the anorexic often recognizes the pointless irrationality of her behaviour but nevertheless feels bound to continue. Psychoanalysts have suggested that anorexia is a desperate unconscious attempt to stave off imminent sexual maturity, but a simpler explanation is that the anorexic has a distorted perception of her body which causes her consistently to overestimate her own size. The rise in anorexia has been attributed to increasing pressure on women to diet, as over the past thirty years or so the ideal female shape has become thinner and less buxom. All anorexics can be shown to have abnormalities of function of the hypothalamus, a part of the brain which controls appetite and many hormonal responses, but it is unknown whether this is cause or effect of the illness. (See ANOREXIA NERVOSA AND BULIMIA NERVOSA for further discussion.)

Causes and treatment of neurosis. Everyone is probably capable of experiencing neurotic symptoms

in some form or degree, but individuals differ in their susceptibility to stress. Some neurotic patients develop their symptoms without obvious precipitating factors, whereas others only become ill after major tragedies, such as the loss of a husband or child. Vulnerability to anxiety states and to phobic and obsessional neuroses appears to be partly influenced by hereditary traits such as introversion, general nervousness, and the reactivity of the autonomic nervous system. But it is generally agreed that life experiences play a major role. What is not generally agreed is which life events are crucial, and how they produce their effects. According to psychoanalytical theory, neurosis is an outward manifestation of deep-seated intrapsychic conflicts which were set up in early life. Treatment, which is necessarily prolonged and intensive, aims to make this unconscious material accessible to consciousness, and the resultant insight is expected to produce resolution and relief.

The behaviourists, however, think that the symptom is the neurosis and that it is the result of faulty learning processes. Theoretical assumptions concerning unconscious mechanisms and insight are regarded as irrelevant. Instead the aberrant behaviour is examined closely

Page 473

and broken down into its component parts, and the goal is then to persuade or educate the patient into adopting more appropriate and adaptive patterns of behaviour.

This approach is particularly useful with phobias and obsessive-compulsive neurosis. (See BEHAVIOUR THERAPY.) Psychoanalytically-based psychotherapy, behaviour therapy, or an eclectic mixture of the two are the approaches favoured by psychiatrists. However, in practice most patients with milder neuroses never see a psychiatrist, but are instead treated by their general practitioner with a combination of simple support and minor tranquillizers of the benzodiazepine group (such as Valium® and Librium®). These drugs are very useful in allaying anxiety over a few weeks, but their effectiveness tends to diminish over longer periods. Unfortunately, they are often prescribed for inappropriate reasons, with the result that their consumption is increasing at a rate alarming to all—bar the manufacturers. Antidepressant drugs like Tryptizol® and Tofranil®, which are effective against discrete episodes of depression, are less likely to be misused, although they can be very dangerous when taken in overdose by someone with suicidal intent.

Organic psychoses. *Acute.* A variety of physical illnesses may produce an acute reversible mental disorder called delirium; the causes include fever or disturbance in body chemistry as well as infections of the brain. Delirium may also follow intoxication with drugs or withdrawal from barbiturates or alcohol ('DTs'). The most striking feature is the rapid onset of confusion. The patient has no idea where he is or what day it is, and only the most tenuous grasp of what is going on around him. He may see or hear things which are not really there (*hallucinations), or experience distorted perception of things which are there (*illusions). He is often very fearful and may believe he is being attacked or persecuted. Evelyn Waugh's *The Ordeal of Gilbert Pinfold* is an excellent, presumably firsthand, account of an acute organic psychosis which could possibly have been an example of alcoholic hallucinosis complicated by the taking of other drugs. Most delirious patients recover completely when the cause of the insult to the brain is corrected.

Chronic. By contrast, dementia refers to chronic insidious organic psychoses which are usually

progressive. Loss of memory for recent events is often the first symptom. Thus, an elderly woman may be able to describe vividly the days of her childhood, but be unable to recall what she has just eaten for breakfast. She then begins to forget the faces of friends and relatives, and may be unaware of where she is or what year it is. Deterioration in intellect and personality may show itself as a lack of propriety, lack of attention to personal appearance, and loss of normal social niceties and inhibitions. In about 10 per cent of cases dementia in later life is caused by remediable conditions such as benign brain tumours and hypothyroidism, but the great majority of cases are due to degenerative disease of the brain or its blood vessels. The ageing of Britain's population has rendered these disorders, senile and so-called multiinfarct dementia, so common that the increase has been called 'the quiet epidemic'. Sadly, there are at present no effective cures. (For further discussion see DEMENTIA.) Functional psychoses. *Schizophrenia*. In 1898 Emil Kraepelin made the now classical distinction between the two major types of functional psychosis. He contrasted manicdepressive psychosis with its recurrent gross swings in mood with a more severe and progressive illness starting in young adulthood which he termed *dementia praecox*. This distinction still holds, although *dementia praecox* is now termed schizophrenia because this better describes the characteristic disintegration of mental life. Most schizophrenics suffer at some point from hallucinations which usually take the form of voices talking to or about them. Occasionally these voices are friendly but in the main they are disparaging and abusive. The schizophrenic is beset with strange beliefs (*delusions). He may think, for example, that he is the victim of a plot, that everyone can read his thoughts, or that alien forces are inserting or removing thoughts from his head or controlling his body.

Schizophrenia is only correctly diagnosed when these beliefs are unshakeable and totally out of keeping with the ideas and philosophies of the sufferer's own class and culture. Thus, a West Indian who believes he is a victim of a voodoo spell, or a spiritualist receiving instructions from the dead, is unlikely to be schizophrenic. But an Englishwoman who is absolutely convinced that her every action is personally controlled by a famous pop singer through a radio receiver he has installed in her mind may well be.

About 80 per cent of schizophrenic patients make a good recovery from their first attack. Unfortunately, many patients later relapse and require further admission to hospital, and in the long term only about 50 per cent remain quite free of any disability. More severely affected people become so preoccupied with their delusions and hallucinations that they tend to withdraw from social contact, and lose touch with reality. As a result their social and occupational functioning deteriorates, and about 10 per cent of all those initially affected become longterm hospital inpatients. In spite of the disorganized and irrelevant speech and disintegration of personality of such severe schizophrenics, their basic intelligence is usually unaffected and improvement can still occur after many years of hospitalization.

If, as some claim, schizophrenia is a myth, then it is a myth with a strong hereditary component! The risk of the identical twin of a schizophrenic also developing the disorder is about 50 per cent,

whereas the risk for a nonidentical twin is less than 15 per cent; this difference presumably reflects

the greater genetic similarity of identical twins. Similarly, children of schizophrenic parents who were adopted and raised by normal families still have an increased risk of schizophrenia, whereas children born to normal parents and by mischance raised by a schizophrenic do not. The precise way in which liability to schizophrenia is transmitted is not known, but biochemical factors may be important.

Some drugs, such as amphetamines, can in excess produce a mental state mimicking schizophrenia; this has led to the suggestion that schizophrenics could be endogenously producing some aberrant chemical.

The once fashionable theories that abnormal childhood experiences could by themselves induce schizophrenia can now be discounted, but environment is undoubtedly important. Traumatic life experiences or intense intrafamilial pressures can precipitate breakdown in the susceptible individual. For example, in many recovered schizophrenics, prolonged contact with excessively critical and overinvolved relatives can cause relapse into florid psychosis.

In treating schizophrenia, the two essential elements are antipsychotic drugs and social rehabilitation. Intrusive therapies such as psychoanalysis are harmful, but a longterm supportive relationship with a concerned psychiatrist or social worker can be invaluable. Phenothiazine drugs are effective against florid symptoms such as delusions and hallucinations, and are needed to induce an initial remission and in some cases to retain it. (See SCHIZOPHRENIA: EVIDENCE FOR AN

ORGANIC CAUSE.) Thereafter, a variety of social measures are used to provide a social and work environment to suit each patient's individual need. Rehabilitation may involve occupational therapy, attendance at a day hospital, or residence in a halfway hostel. The aim of such measures is, of course, to help the patient to find a satisfying role in the community and to stop him becoming institutionalized in hospital. Voluntary organizations such as the Schizophrenia Fellowship often play a major role in this. (See also SCHIZOPHRENIA.)

Manicdepressive psychosis. In its fullblown form, this is a cyclical disorder in which opposite extremes of mood are successively shown. Mania is characterized by an extraordinary sense of wellbeing, overactivity, and elation and is usually accompanied by a conviction of great selfimportance which causes the individual affected to make grandiose pronouncements—for example, that he is the most talented and intelligent person in the world. He may consequently enter into wild and ruinous business ventures, or indulge in other unaccustomed excesses of spending, eating, drinking, or sex. His talk is profuse and prolix, flitting from topic to topic with an unstoppable stream of ideas interspersed with puns and feeble witticisms. His jollity may initially be infectious, but before long he becomes overbearing and tiresome. Not surprisingly most manics eventually dissipate their energy and return to normal, but an unfortunate minority descend straight into depression with no intermediate period of normality.

Mania is much less common than depressive psychosis, the predominant symptoms of which are profound gloom and despair. Life appears futile and hopeless and suicidal ideas are usually entertained, and, not infrequently, successfully acted upon. Depression produces a marked depletion

in selfconfidence and selfregard and the depressive may see himself as the most evil and wicked individual who ever lived. Racked with guilt, the previously blameless character becomes convinced that he has committed some grave infamy or that he is to blame for all the sin and misery which exists in the world. Less commonly he may believe that he has been stripped of all his possessions, or that his body has become hideously diseased and is rotting and decayed. Real bodily disturbance of a less bizarre nature does usually occur.

Appetite is poor, weight loss ensues, and there is often constipation and loss of sex drive. Some depressives physically slow down, and their talk may decrease or altogether cease, a condition known as psychomotor retardation: occasionally such a patient develops a state of mute, immobile stupor. In others restlessness and edginess may culminate in severe agitation.

Manicdepressive illness, like schizophrenia, is partly determined by genetic factors. Again there is evidence that biochemical factors are important: for example, drugs which deplete the brain of chemical messenger substances called monoamines can induce depression, while drugs which raise the level of monoamines relieve depression and can precipitate mania. Despite the importance of these biological components, the part played by psychological factors can in no way be discounted.

Adverse life circumstances or*bereavement or other forms of loss are known to result frequently in depression, and psychoanalytical theory considers that it is the turning in on the self of the consequent feelings of hostility and annoyance which produces the illness. Some behaviourists on the other hand have stressed the importance of learning experiences, such as exposure to inescapable mental trauma which produces a feeling of helplessness. This, they believe, forms the basis of the depressed state.

Manicdepressive illness is a serious condition, not just because of the misery and the disruption it causes, but because about 15 per cent of sufferers eventually die by suicide. Fortunately, treatment is effective. Antidepressant drugs are of proven efficacy in the majority of typical cases, and although the manner in which it works remains obscure, electroconvulsive therapy can often relieve depression which has proved resistant to other treatments. Hospital admission, which is the general rule for cases of mania, provides a temporary sanctuary for many depressives, and is essential

Page 475

when the risk of suicide seems great. Psychotherapeutic help is invaluable and, in people who have recurrent episodes of illness, the *chemical* element lithium may be used on a longterm basis to prevent further relapses.

MENTAL IMAGERY was first investigated and described in useful detail by Francis*Galton (1883). Galton asked his academic and less academic friends and acquaintances to describe, for example, the colours and patterns of the cloth on their breakfast table, from memory. He reported that the more intellectually gifted, the less vivid was the imagery. Several Fellows of the Royal Society were surprised to learn of imagery in other, lesser mortals—as they denied it for themselves.

Galton describes how for some people numbers are mentally imaged and 'seen' in space, in some fixed and often queer order. They may also be 'seen' in colours.

Many examples are quoted by Galton, and perhaps no later study has much to add.

There are experiments attempting to show whether mental images are useful. Consider, for example, the following: a 6centimetre cube of wood is painted all over with red paint. Now the cube is cut into 1centimetre cubes. How many of these have (i) three red sides; (ii) two red sides; (iii) one red side; (iv) no red sides? Most people solve this by *imagining* a red cube; this they 'cut' into 1centimetre cubes which they then 'examine' mentally. It is, however, an open question whether the images we experience (rather than the brain processes presumably producing them) are causally important for solving this problem, or for anything else. This is indeed the problem of awareness, or*consciousness; for what it does, if anything, is totally unknown.

MENTALISM. See MINDBODY PROBLEM: PHILOSOPHICAL THEORIES.

MENTALLY ILL, SERVICE FOR THE. The provision of proper care for the mentally ill has been a problem for centuries (as is described in the article ASYLUMS: A HISTORICAL SURVEY). There is no right solution, for the size and nature of the problem changes according to society's definition of mental illness and its tolerance of unusual behaviour among its members. Therefore, before embarking on detailed planning of services for the mentally ill, it is necessary to establish the need for such services.

It is traditional in Britain to adopt the medical model of*mental illness. This means that the disability is seen in terms of symptoms and signs arising from a pathological process (which may be undefined) for which medical diagnosis and treatment are appropriate. This model has been challenged by those

who consider that much mental illness is related to adverse social or environmental factors. Doctors have not rejected this view, but have tended to extend their areas of interest to incorporate such fields as marital disharmony for which a purely medical model is inappropriate. This extension of medical activity into fields which would previously have been the province of other groups such as priests, with its implied extension of the range of 'mental illness', has to be taken into account when planning medical services.

The development of psychoactive drugs has had a major effect on the need for services for the mentally ill. The ability to control pharmacologically some of the symptoms of severe illnesses such as *schizophrenia and manicdepressive* psychosis has reduced the need for longterm residential care. On the other hand, there has been a massive increase in consultations with general practitioners on account of some form of mental illness. This is partly associated with the ready availability and comparative safety of drugs which affect mood. People have learned that they can be relieved of the discomfort of *anxiety or* depression by means of tablets, and acknowledgement of these conditions is no longer associated with social stigma. The evidence that some drugs which were initially considered 'safe' can in fact be addictive has not reduced the demands for treatment, but has increased the need for nondrug approaches, such as counselling and *psychotherapy. These changes at both ends of the mental illness spectrum, which appear likely to continue, have to be taken into account when planning, so as to develop the appropriate balance of facilities for care.

The demand for medical services for the mentally ill is not determined entirely by the activities of doctors and the opportunities for medical treatment. Society itself contributes to the equation by setting the somewhat arbitrary line which distinguishes between abnormal, though tolerable, behaviour and mental illness. The position of this line varies, both with time and between nations. In Britain at present, people are still relatively intolerant of even mild psychotic symptoms, whereas there is increased acceptance of sexual deviance, especially homosexuality. In some countries, disagreement with the governing regime is considered so deviant as to merit the label 'mental illness'. These differences predominantly affect the requirement for residential care, since the demand is usually for the deviant to be removed from the community at large, and there is indeed an overlap between those labelled mentally ill who are sent to hospital and those who

contravene the law and receive prison sentences. Another influence on the way mental illness is viewed stems from changes in mental health legislation. Undoubtedly the UK Mental Health Act of 1959 led to a far greater acceptance by members of the community of the need for treatment of both major and minor psychiatric disorders. It remains to be seen what effect the Mental Health Act of 1983 will have on this trend.

The needs of the elderly have to be considered separately because of the different nature of their illnesses. It is, of course, not unusual for people over 65 years of age to suffer from the common psychiatric disorders for which the generally available treatment is appropriate; but with advancing years, the incidence of *dementia increases, and it is often accompanied by physical illness or handicap. Special account of the needs of such patients must be taken in planning services, both for assessment in order to ensure that remediable complicating factors are dealt with, and for their longterm care. Greater longevity has increased the need for psychogeriatric facilities, and

governments in most Western developed nations have become concerned over the need to provide care for increasing numbers of aged patients, many of whom are suffering from irreversible dementia. How to relieve the strain on existing facilities is one of the problems to be faced over the next decade.

The planning of medical services demands quantification of future needs and knowledge of the resources which will be available to meet them. However, whereas the size of the population to be served can be calculated with reasonable accuracy on an actuarial basis, the proportion who will be suffering from mental illness is much more difficult to estimate. It depends on guesses about future patterns of designation of mental disorder and future therapeutic developments. Moreover, assessment of the treatment requirements of the mentally ill, upon which provision must be based, is dependent on further guesses about future social attitudes and about opportunities for care in the family when increasing numbers of women work outside the home.

Having reached an estimate of the quantity of service which will be needed, the way in which it will be provided has to be determined. The balance of care between medical and nonmedical agencies, between psychiatrists and general practitioners, between large psychiatric hospitals and units in general hospitals, and between residential and nonresidential facilities has all to be decided. Decisions cannot be reached entirely rationally: in many cases, there is little evidence to support one view or another. The enthusiasms of local practitioners, current government policy, and the necessity of modifying rather than replacing existing facilities may all take precedence over projections of future needs and opportunities, which in any case will be somewhat theoretical. It is important, however, that the factors which are taken into account are recognized and recorded, so that planning decisions taken now can be properly evaluated in the future and the quality of decisionmaking thus improved. In addition, it is essential that the full implications of each option are explored before a decision is reached. For example, expansion of care for the mentally ill in the community inevitably means that the most ill patients with the least likelihood of improvement in their condition will remain in the large hospitals. Realistic proposals for the maintenance of standards and for the recruitment of staff at these hospitals, by such means as rotation of posts with other units, inservice training programmes, and research projects, must be put forward before plans are implemented, in order to prevent serious problems of morale and an unacceptable fall in the standards of patient care.

The change in the balance of care poses problems in the community as well as in the institution. It is difficult to provide mentally ill people living in small groups with the range of supporting staff and activities which can be offered in institutions. When it is practical to offer such facilities in the community, the dispersal of the patients means that the cost of the services is much higher than the cost of an equivalent level of care in a hospital. The policy of transfer from hospital to community care is based on clinical and humanitarian arguments, but much support for it derives from the assumed financial savings. It is now clear that mentally ill people based in the community, receiving services funded at a lower level than hospital services, are at grave risk of 'community neglect' rather than 'community care'.

The prevention of mental illness is a complicated issue to which little attention has been paid in the past. It is unlikely that simple methods like vaccination will ever be appropriate in this field. Like

other common noncommunicable diseases such as coronary heart disease, any advances in the prevention of mental illness are likely to require changes in patterns of behaviour, which are extremely difficult to achieve and may raise ethical problems. Epidemiological evidence on topics such as suicide (see SUICIDAL BEHAVIOUR) and bereavement and on the effect of important life events on the development of mental illness do, however, give clues about possible future activity in this field.

The rehabilitation of the mentally ill is of major importance and has also been somewhat neglected in the past. If, in general, the objective of treatment is to maximize the patient's independence, it is clear that exclusively medical services are inadequate, and must be complemented by help with social and employment problems. It is highly desirable that all the agencies which patients may need should be involved in the preparation of service plans.

The detailed planning of services must take place at a local level if they are to meet the needs of the local community. In Britain, however, the money for health care is not raised locally but comes from

Page 477

central government. The local planning therefore has to be undertaken within the framework of national policy. This determines what proportion of the Gross National Product will be allocated to health and, within that, the apportionment between services. At present, mental illness is a priority service and can expect an increased proportion of the health budget to be allocated to it. It is not, however, always possible to achieve such transfers of resources, especially in a time of economic stringency, because of the difficulties of making cuts in other services.

Planning has also to take account of government policy with regard to medical manpower. In Britain the aim at present is to remove the inequalities in staffing levels across the country and between specialties. Current initiatives to expand the consultant grade and to control entry of junior doctors into training posts in the popular acute specialties may attract more doctors into psychiatry, which has not historically been a popular career of first choice among medical graduates.

Planning of services for the mentally ill is an activity dependent on estimates of future medical, pharmacological, and social changes, but the range of such estimates is inevitably wide, and the interaction between the different factors imprecisely defined. It is not possible to predict with any accuracy the level of the financial or manpower resources that will be available in the next decade. Even so, it is important that planning should continue on as rational a basis as possible and that facts, assumptions, and arguments should be recorded. It is only in this way that planning can move from meeting vocal demands to meeting true needs. Meanwhile, all service plans should maintain the maximum flexibility, so as to minimize constraints on future developments.

J. M. C.

MESMERISM. It is often said that hypnosis was discovered by the controversial Viennese physician

Franz Anton Mesmer (1734-1815), whose name gave the word 'mesmerism' to the English language. While it seems certain that some of Mesmer's patients indeed became hypnotized, it must be borne in mind that no formal concept of hypnotism existed at the time, and Mesmer attributed his therapeutic successes to a hitherto unknown physical agency to which he gave the name 'animal magnetism'. Greatly influenced by Newtonian physics—which he evidently misunderstood completely—Mesmer envisaged animal magnetism as a physical force or

'fluid', somewhat akin to gravitation, which permeates the universe and to which the human nervous system is somehow attuned (Mesmer, 1779). Nervous illness, he believed, results from an imbalance between the animal magnetism in the patient's body and that in the external world at large, which can be redressed by human agency. This Mesmer sought to achieve by channelling animal magnetism through his own body to that of the patient, either directly by applying his hands to the affected part ('passes') or indirectly by requiring the patient to grasp an iron bar or other object which he had previously 'magnetized' by direct contact. Although magnets or magnetized iron filings were sometimes used as intermediaries, Mesmer insisted that animal magnetism is quite different from physical magnetism and in itself possesses no curative properties. None the less, the term 'magnetizer' long persisted as the popular designation of those who made use of Mesmer's methods for therapeutic ends.

Although Mesmer's theory of animal magnetism was rejected by scientists even in his own lifetime, there can be no doubt that he won many disciples and not a few grateful patients. Indeed his colourful personality and robust selfconfidence created a distinct stir, first in court circles in imperial Vienna and later in the fashionable salons of preRevolutionary Paris. Inevitably, perhaps, he incurred the odium of the medical establishment, and the French government was eventually led to appoint a royal commission to conduct an inquiry into animal magnetism under the chairmanship of Benjamin Franklin. Among its members were Lavoisier, the famous chemist, and Guillotin, who gave his name to the instrument of decapitation that a few years later claimed the head of Lavoisier himself. This commission examined exhaustively not only the alleged medical benefits of mesmerism but also the evidence for the existence of animal magnetism itself, to which it quite properly adopted an experimental attitude. Although Mesmer did not give personal evidence to the commission (the brunt of cross-examination falling on one of his followers, Dr Deslon), there can be no doubt that it was in effect Mesmer himself who was on trial.

The commission published its report in 1784 and came out strongly against the existence of animal magnetism as a physical force. It did not, however, deny that in some cases mesmeric treatment brought therapeutic benefit. This the commissioners had no hesitation in attributing solely to the powers of imagination, which is hardly surprising when it is borne in mind that Mesmer, in his Paris days, made his patients sit in groups round a large barrellike object known as a *baquet*, each grasping an iron rod protruding from the interior (which contained water and iron filings, sometimes magnetized), while he himself, splendidly attired, treated them by magnetism to the accompaniment of soft music. Also it is interesting that, in a section of the report apparently suppressed at the time but published over a century later by Binet and Féré (1887), the Commissioners directed special attention to the moral dangers attendant on mesmeric treatment, evidently reminding the reader that a high proportion of those seeking it were of the female sex. This provides a striking anticipation of

Sigmund*Freud's contention that sexual factors are of great importance for our understanding of the hypnotic state (see FREUD ON HYPNOSIS).

In consequence of the royal commission's

Page 478

findings, mesmerism was officially discredited for many years and Mesmer himself disappeared into obscurity. None the less, a small number of 'magnetizers' continued to ply their trade. One of these was the Marquis de Puységur, who is credited with the first account of a case of*somnambulism evoked by mesmerism, with the subject showing a complete loss of memory for the events of the trance after being awakened. This would nowadays be called posthypnotic*amnesia. Among other magnetizers, several of whom visited England and America, was Dupotet, who first introduced John Elliotson (1791-1868), professor of the practice of medicine at University College, London, to the phenomenon of mesmerism (see Bramwell, 1913). Elliotson soon became convinced of its value in medical practice, particularly in the treatment of what were then (as now) called functional nervous disorders, i.e. disturbances of bodily or mental functions for which no physical pathology can be established. Like Mesmer before him, Elliotson was to suffer greatly from the hostility of the medical establishment, but he had the courage to resign from his professorship rather than comply with the ruling of the College council forbidding the practice of mesmerism in the hospital. His temerity was also shown by the fact that, when invited by the Royal College of Physicians to deliver the Herveian Oration, he chose mesmerism as his subject. Whereupon the *Lancet* dubbed him a professional pariah and asserted that his lecture would strike a vital blow at legitimate medicine. None the less, Elliotson duly delivered his lecture, which was received in stony silence, and did much thereafter—if in slightly eccentric ways—to advance the cause of what is nowadays known as psychological medicine.

Thereafter, the history of mesmerism merges into that of hypnotism and, more broadly, into that of psychological medicine. Indirectly, however, it is linked with a number of broader issues in social history, not least that of faithhealing and Christian Science. Mary Baker Eddy, the founder of Christian Science, is thought to have first conceived its tenets through being cured of a hysterical paralysis when a girl, by a faithhealer who had been inspired by a visiting French magnetizer. (For the metamorphosis of mesmerism into hypnotism, see HYPNOTISM, HISTORY OF.)

MESOMORPHY. See BODY BUILD AND PERSONALITY.

MESOPIC VISION. Twilight vision. Vision is poor in the 'half-light' between the scotopic blackwhite vision given by the retinal rods, and the*colour vision given by the cones (photopic vision). It is important to know for driving that mesopic conditions are essentially dangerous and require extra care.

METAPHOR. The topic of metaphor has a history dating back at least to*Aristotle, but not until the twentieth century did it come to be regarded seriously as a problem relevant to the general study of language and thought.

Aristotle took the use of metaphors to be evidence of a superior intellect. At the same time, he seemed to believe that their use was primarily the prerogative of poets and politicians. For philosophers and scientists, they were potentially too misleading. In limiting the use of metaphors to the ornamental, rather than concentrating on their communicative value, Aristotle essentially elevated metaphor from the prosaic to the esoteric. The unfortunate result was that attention to the topic came to be largely restricted to rhetoricians. Indeed, during the nineteenth century, the principal activity of rhetoricians became the interpretation of particular metaphors (and other tropes) in literary texts—an obsession that was largely responsible for the demise of rhetoric as a serious discipline.

In spite of limiting what he presumably considered to be the legitimate uses of metaphor, Aristotle's analysis of the underlying logic of metaphor has always dominated thinking on the topic. He believed metaphors to be implicit comparisons based on the principles of analogy. It can be argued that this view has had the undesirable effect of blurring the distinction between metaphor, analogy, and similarity—ore will be said of this later.

Around the turn of the century there appeared an English translation of Michel Bréal's *Essay de sémantique*. In this influential work, Bréal claimed that metaphor was a linguistic device, widespread in its use, and of great importance in linguistic change. Then, in 1936, metaphor was revitalized in the study of the language of literature by I. A. Richards. Richards introduced useful terminology for talking about metaphors (topic/tenor, vehicle, ground, and tension)—terminology which has come to be fairly standard.

In 1962 Max Black's book *Models and Metaphors* appeared. In it, Black rejected the Aristotelian 'comparison' view wherein metaphors are merely elliptical comparisons, and he questioned the generality of the 'substitution' view wherein metaphors are merely ornamental substitutes for literal language. Instead, elaborating on the views of Richards, he proposed an 'interaction' view. On this view, the *tenor* (or topic, or subject) of a metaphor is seen as interacting with the metaphorical *vehicle* to produce a kind of emergent meaning for the entire sentence—one that could not have resulted from the combination of the tenor with some other predicate, literal or metaphorical. Thus, in the metaphor 'man is a

wolf', 'man' is viewed, as it were, through a 'wolf filter'. Our interpretation of both terms is altered.

By the mid 1970s, an active interest in the topic had spread to all sorts of disciplines, most relevant of which, in the present context, was cognitive psychology.

Psychologists became interested in questions such as: Does the comprehension of metaphors involve special processes not normally involved in the comprehension of literal language? Do metaphors play a role in the development of language? Why do people use metaphors? What is the relationship between metaphor, analogy, and similarity? Many of these questions have their counterparts in philosophy, but the empirical techniques that psychology brings to bear may throw more light on them.

The principal dispute over comprehension mechanisms is about whether or not metaphors are understood by first unsuccessfully attempting to impose a literal interpretation. According to one view, when people encounter metaphors they recognize that a literal interpretation is incompatible with the context and then proceed to reinterpret the metaphor figuratively. According to the other view, ordinarily people interpret the metaphorical meaning directly, without even entertaining a literal interpretation. Flatly stated in this way, each view has its problems. One problem with the reinterpretation account is that it does not specify the basis upon which a reinterpretation is made. Many linguistic forms require 'reinterpretation': sarcasm ('That was a clever thing to do', said of an obviously foolish act), hyperbole ('There were millions of people at the party', said to indicate that there were many—but obviously not millions), and indirect speech acts, such as indirect requests ('Do you know what time it is?', meant as a request to be told the hour of the day), are just some of the many examples. Reinterpretation theories need to be able to characterize the differences between these (and other) kinds of nonliteral uses of language. They need both to specify the different rules that underlie the comprehension of different types, and to offer an account of how people are supposed to know in advance which rules to employ on a particular occasion: it hardly seems likely, for example, that the rules for reinterpreting sarcasm are applied, or even considered, in the ordinary interpretation of a metaphor.

The direct comprehension view finesses this last question. However, as stated, it suffers from underspecification. It amounts to little more than a statement to the effect that when people encounter metaphors, they understand them; on its own, it has no answer to the question, How? A more general theory of language comprehension is needed to answer this question. The theory (or theoretical framework) that is most often appealed to is one based on the notion of *schemas* (or scripts, or frames).

The idea is that comprehension in general proceeds by finding a schema that 'fits' the input. Then, the argument goes, the difference between understanding literal and metaphorical language turns out to be simply one of quality of fit.

Data from experiments suggest that elements of both views are correct. Experiments measuring (for example) the time taken by people to indicate that they have understood a sentence (either metaphorical or literal) show that, with sufficient preceding context, subjects do not require the additional time to process metaphors that the reinterpretation theory predicts. On the other hand, when a metaphor is encountered with very little prior context, the predicted increase in reaction time is found.

In such cases, it seems, people have to 'work out' what the sentence means, whereas in other cases what they do seems more like confirming contextually generated expectations. Of course, 'working out the meaning' is something that is often required for literal uses of language too. Furthermore, there are many 'frozen' metaphors in the language, often idioms, that, once known, never require special processing. Thus, the evidence suggests that extra processing is required by language that is not well integrated into the context, be it literal or metaphorical, and that under appropriate circumstances metaphorical language is processed as quickly and easily as literal language.

Observant parents, as well as developmental psychologists, have often noticed that quite young children (2 to 3 years of age) appear to be very creative in their use of language. When the young child tries to express something for which he has not learned the conventional word, he often uses some other word that succeeds in realizing his communicative intentions, even though the choice may not be literally appropriate. This activity is described by developmental psychologists as 'semantic overextension' (see LANGUAGE: LEARNING WORD MEANINGS), but some have claimed that this behaviour in fact reflects the use of metaphor by young children, and that the use of metaphor is a fundamental ingredient in language development.

Attractive though this view might be, it seems to suffer from some rather serious drawbacks. First among these is the evidence that such young children are unable to understand metaphors. Estimates of the age at which children begin to understand metaphors properly vary considerably. Some investigators claim that it is not until early adolescence, while others claim that by the age of 7 or 8 many children can deal with metaphors. The variations in these estimates are the result of several factors, the principal ones being fluctuating and often rather atheoretical criteria for what is to count as a metaphor, and for what is to count as evidence of its comprehension. However, most investigators agree that 3-year-old children cannot understand metaphors. Since it is well established that children's language comprehension is far ahead of their language production, if 2 and 3-year-old children were producing metaphors it would be the only known example of behaviour contrary to the comprehension-before-production rule. A second problem is that the claim that such

young children produce metaphors fails to recognize that an utterance could be metaphorical from an adult's perspective, but not from that of the child who produces it. In other words, the claim may be excessively 'adultocentric'.

Doubtless part of the attractiveness of claiming that very young children produce metaphors is that an important function of metaphors is to permit the expression of ideas that might otherwise be (literally) inexpressible for a particular speaker in a particular language. In some cases the lack of words in the language has resulted in entire domains being mapped into other domains so that the language itself incorporates now unnoticed metaphorical means of description—this is one of the ways in which, as Bréal pointed out, metaphors are important in linguistic change. A familiar example of such a mapping is the use of temperature terms to describe personality characteristics—we talk of people in terms of their being warm, or cool, cold, or icy. When such metaphors are embedded in the language to fill systematic gaps in the lexicon, they often go unnoticed. But the same principle operates at the level of the individual speaker, except that if the language does not supply conventional resources (be they literal or metaphorical), the speaker may have to create his own. In such cases he uses a novel

metaphor.

The expression of the otherwise inexpressible is not the only communicative function that metaphors serve. They also achieve a certain communicative compactness, since all the applicable predicates belonging to the metaphorical vehicle are implied succinctly through the vehicle itself. Thus, even if what a metaphor expresses may have been more or less expressible without the metaphor, its use may be more economical and hence more effective than the long list of predicates that it entails.

The relationship between metaphors and similarity is a complex one. Without having to commit oneself to one of the various theories about how metaphors work, it is apparent that at some level, and in some way, metaphors capitalize on a similarity between the term used metaphorically (the vehicle) and the thing that the metaphor is a metaphor for. Thus, even though it may be incorrect to claim, as some have, that a metaphor is *merely* a statement of similarity, it is probably not incorrect to say that a metaphor is *largely* a statement of similarity. Clearly, if one says of jogging that it is a religion, the metaphor would not work if jogging and religion were not in some way similar. On the other hand, it is obvious that in many ways jogging is not in the least bit like a religion. It could be argued, in fact, that jogging is not really like a religion at all; if we want something that is really like a religion, a cult is. The interesting thing is that if one now considers the two similarity statements 'Jogging is like a religion' and 'A cult is like a religion', the latter, while appearing to be really true, has no metaphorical potential. This suggests that if metaphors are based on similarity statements, only some similarity statements can fulfil the required role. The similarity statements that seem to fit the bill are those that themselves seem to be metaphorical. According to this view, that is why one can say 'Metaphorically speaking, jogging is like a religion', but not 'Metaphorically speaking, a cult is like a religion'. Now, if the only similarity statements that can form the basis of metaphors are metaphorical similarity statements, two important consequences follow. The first is that it is futile to attempt to *explain* metaphors by reducing them to similarity statements because the statements to which they get reduced still have the characteristic of being metaphorical. The second is that, as a research strategy, the examination of similarity statements may be the best way to uncover the difference between the literal and the metaphorical.

Psychological discussions about the nature of metaphor often seem to use the terms 'similarity', and 'analogy' as though they were interchangeable. It is possible, however, to be more precise about the relationship between the two by arguing that an analogy is a similarity between relations rather than between singleplace predicates. On this view, an analogy is a particular kind of similarity statement, and, from a psychological perspective, whether a particular comparison is or is not an analogy may depend on the way in which the entities being compared are conceptualized or represented at the time. A simple example will illustrate the point. Suppose we are told that cigarettes are like time bombs. If we entertain this proposition in terms of a simple similarity statement, we might say that both cigarettes and time bombs share the property of (potentially) causing death after a delay. In other words, considered in this way we would have something to the effect: 'Being a cigarette is like being a time bomb.' On the other hand, suppose one conceptualizes the statement in the following way: 'People smoking cigarettes are like people exposed to time bombs.' Now what we have is something roughly equivalent in meaning, except that it is stated as a similarity between two relations—it is an analogy. Again, from a psychological perspective, how the terms in a similarity statement will be

represented is likely to depend on the context, it is not fixed by the linguistic structure of the statement itself. Thus, again, the point is not whether metaphors are built on similarity or on analogy, since both are forms of comparison. The point is that metaphors are built on comparisons which are themselves metaphorical, be they analogical or not.

METAPHYSICS is generally taken to mean philosophical speculation beyond the current or even seemingly possible limits of science, and the development of more or less abstract systems intended to explain origins and purpose, phenomena of mind and matter, and the place of man in the universe. The word 'metaphysics' has its origin simply from those books of Aristotle which were placed in sequence after his *Physics*. The pejorative sense of 'obscure' and 'overspeculative' is recent, especially following attempts by A. J. Ayer and others to show that metaphysics is strictly nonsense.

It is a moot point how far science is, or can be, free of metaphysics. There may always be untested and even forever untestable theoretical assumptions which are necessary for interpreting experiments. These assumptions are (by definition) metaphysical, for they are not testable by observation or experiment and so are essentially speculative.

Metaphysics is associated especially with idealist and rationalist philosophers, chief among whom is Immanuel Kant. Kant argued, for example, most clearly in his *Prolegomena to Any Future Metaphysics* (1783), that time and space are categories of mind, and that it is impossible to conceive the physical world without such a priori categories. Empiricism, on the other hand, is often thought to be free of metaphysical assumptions—at any rate for operationalist philosophers, who hold that all knowledge is derived from observation, and especially from observed matches and mismatches

against formally defined test procedures and measurements. This is essentially Karl Popper's aim and claim for objective knowledge.

A very different current view, which is developed especially by the American philosophers Norwood Russell Hanson and Thomas Kuhn, is that there is no such thing as a neutral theory-free observation language which simply records 'the facts'; even the simplest observations and experiments must be made within the context of complex theoretical assumptions (see PARADIGMS). Given that these assumptions cannot be objectively verified or tested operationally, they may be said to be metaphysical; and this leads to a more or less extreme relativism which rejects the notion of 'brute facts' and 'objective' observational data.

METEMPIRIC(AL). Knowledge of, or supposed knowledge of, things outside or beyond experience or experiment. (See also METAPHYSICS.) **METEMPSYCHOSIS**. When a living thing dies, its 'soul' or *psyche takes up a new residence in some other body, which it thereby vivifies: for the psyche, bodily death means emigration, bodily birth immigration. That is the ancient doctrine of 'metempsychosis' or the transmigration of the soul.

Among the Greeks, the followers of *Pythagoras were particularly associated with the doctrine indeed, it is one of the few beliefs that can confidently be ascribed to Pythagoras himself. (In *Twelfth Night*, 'Sir Topas' asks the imprisoned Malvolio: 'What is the opinion of Pythagoras concerning wild fowl?' And Malvolio rightly answers: 'That the soul of our grandam might haply inhabit a bird.' Empedocles, too, subscribed to the doctrine; one of his poems contained the following couplet: For already have I once been a boy, and a girl, and a bush, and a fish that jumps from the sea as it swims.

(Bushes are living things, and therefore have a psyche. The jumping fish is the dolphin.)

Note that the psyche is a principle of individuality for living things: since Empedocles's psyche once inhabited a fish, Empedocles himself once was a fish—

metempsychosis is about the personal survival of bodily death. We are told that Pythagoras 'passed a dog that was being whipped; he took pity on it and said: "Stop!

don't beat it—it is the psyche of a friend of mine; I recognize him by his voice." '

Different thinkers composed variations on the metempsychotic theme: for some, the process of transmigration went on for ever; some imagined a cycle of incarnations;

some spoke of a hierarchy of lives; in some versions of the theory, incarnations are separated by periods of noncorporeal existence, during which divine Judgement may take place. The doctrine was sometimes associated with a theology or with a quasireligious way of life; and Empedocles based a moral theory upon it: if one and the same psyche may animate now a man, now a lion, now an eagle, then living creatures are all akin; and we should have moral scruples about maltreating our psychic kinsmen. Empedocles denounced all bloodshed and advocated a form of vegetarianism; for if you kill and eat a sheep, you may be killing and eating your own father.

('Sir Topas' counsels Malvolio to 'fear to kill a woodcock, lest thou dispossess the soul of thy grandam'.) Strictly speaking, if you eat a parsnip, you may be eating your father; but Empedocles did not have the strength of character to insist upon a wholly inanimate diet.

Metempsychosis may seem at best an irrational form of mysticism, at worst a risible piece of nonsense. To some Greeks, at least, it appeared to be an empirical theory; and its empirical basis lay in

Page 482

memory. Thus, according to Heraclides Ponticus, a pupil of*Plato's, Pythagoras

says about himself that he was once Aithalides, and was deemed a son of Hermes; and Hermes told him to choose whatever he wanted except immortality: so he asked that, both alive and dead, he should remember what happened. Thus in his life he remembered everything, and when he died he retained the same memory. Some time later, he passed into Euphorbus, and was wounded by Menelaus. ... And when Euphorbus died, his psyche passed into Hermotimus. ... And when Hermotimus died, he became Pyrrhus the Delian diver; and again, he remembered everything—how he had first been Aithalides, then Euphorbus, then Hermotimus, then Pyrrhus. And when Pyrrhus died, he became Pythagoras, and he remembered all the events I have mentioned.

Pythagoras claimed to have memories of his earlier lives; and those memories supported the theory of metempsychosis—or at least, they constituted evidence that Pythagoras himself was a migratory psyche. Sceptical Greeks dared to doubt Pythagoras' claim to remember being wounded under the walls of Troy; but Pythagoras was prepared to back up his claim:

They say that, while staying at Argos, he saw a shield from the spoils of Troy nailed up, and burst into tears. When the Argives asked him the reason for his emotion, he said that he himself had carried that shield in Troy when he was Euphorbus. They didn't believe him, and thought he was mad; but he said he could provide a true sign that this was the case: on the inside of the shield they would find written in archaic letters: EUPHORBUS'S. Because of the extraordinary nature of his claim, they all urged him to take down the offering. And the inscription was found on it.

Thus transmigratory claims are supported by an appeal to memory; and memory claims are supported

in their turn by practical demonstration. The stories about Pythagoras's abilities are doubtless apocryphal, but the moral they point is not: even in their most extravagant moments, the ancient Greek psychologists did not lose all touch with reason and empirical reality.

J. BA.

MICHOTTE, ALBERT (1881-1965), Belgian experimental psychologist of high reputation. He is best known for his investigations of perceptual causality. By combining with remarkable ingenuity various types of real object movements (such as coloured rectangles moving on a screen and visible through a slit), he was able to demonstrate that, in certain spatial and temporal conditions, the subjects reported a causal action of one moving object on another, such as 'launching', 'entraining', and the like. These perceptual effects were described by Michotte with a wealth of detail and framed within an overall theory of dynamic relationships between objects. If we were to confine ourselves to the historical developments of Michotte's ideas, we should only refer to this aspect of his work at the end of our analysis; however, his extensive investigations of perceptual causality are too typical of his conception of experimental psychology to be mentioned solely as the last productive moment of his exceptionally creative career.

From 1905 to 1908, Michotte was active in experimental psychology under Wundt and Külpe and tackled various experimental problems ranging from the study of tactile sensitivity to that of so-called superior functions, viz. thought and will processes. There is no doubt that Külpe's *Denkpsychologie* (thought psychology) exerted a considerable influence on him, namely by introducing him to the descriptive techniques of subjective impressions, a major feature of the early German laboratories of experimental psychology. In addition to this, Michotte was exceptionally gifted mechanically. His great skill in designing and even building laboratory devices specially conceived in view of particular effects greatly helped him in realizing numerous original experiments.

In 1906 Michotte became a lecturer at the University of Louvain and was entrusted with the task of developing the laboratory of experimental psychology which had been founded in 1892 by Cardinal Mercier and whose first director was A. Thiéry, himself a direct collaborator of Wundt at Leipzig (1894). Through the work of Külpe on thought processes, Michotte became acquainted with act psychology (the school of Graz), especially with the work of Carl Stumpf and Ernst Mach. Stumpf was the founder of a new kind of psychology, partly descriptive and partly experimental, which he called *experimental phenomenology*. According to his theory, experiments in psychology should be elaborated on the basis of a description of subjective phenomena as related to objects, phenomenology proper being supplemented by a theory of contents (eidology) and a theory of relations between contents (logology).

In view of these influences, it may be said that Michotte's theoretical and experimental position was the joint result of the teachings of Wundt and of Stumpf. To this should be added the fact that, from 1912 on, Michotte became influenced by Gestalt theory, which itself was greatly indebted to the theories of the school of Graz.

However, to the end of his life he resented being called a Gestaltist, because he rejected generalized

isomorphic theory, preferring to call himself an experimental phenomenologist. Summarizing the main trends of his research work, he wrote in 1962:

When *The Perception of Causality* was published, I used the language which was then used by numerous psychologists and by Gestalt psychologists in particular. It seems however that in spite of precautions which may have seemed sufficient at the time, certain expressions and certain wordings are liable to cause some misunderstandings concerning our theoretical standpoint in the study of perception. I therefore consider it necessary to state exactly here the point of view of psychological (or experimental) phenomenology as I conceive it (Michotte, 1962, p. 10).

This kind of experimental phenomenology rests on two methodological hypotheses. (i) The verbal reports of experimental subjects may be considered as the dependent variable of the stimulus

κραινόν

Page 483

tion systems. If the latter change in their spatiotemporal organization, changes will be observed in the categories of responses (as, for instance, causal against noncausal ones). (ii) The changes observed in the responses are not only quantitative (as expressed by frequencies), but also qualitative (as referring to contents). As a consequence, a theory of subjective impressions may be established on the basis of the descriptive properties of verbal responses. It is this second hypothesis alone that qualifies this type of analysis as belonging to experimental phenomenology; and that explains, among other things, why Michotte reflected unceasingly on the role of language in the analysis of perceptual phenomena. He may be best characterized by saying that he was an experimentalist who succeeded in studying with great accuracy the dynamic organization of the perceiver's phenomenal world. In this sense, he is more akin to Gestalt teachings than to phenomenological issues as expounded by*Husserl, i.e. within the framework of transcendental philosophy. The Graz school, which emerged from*Brentano's intentional theory of*consciousness, split at the beginning of the twentieth century into Gestaltism and transcendental phenomenology.

As a laboratory researcher deeply concerned with the analysis of subjective phenomena, Michotte is one of the few psychologists of the time who were able to bring Stumpf's experimental phenomenology to a high level of scientific accomplishment. Because of his early training in scholastic philosophy, Michotte did not develop the epistemological implications of his researches on perception, a task which would have required a comparative analysis of Stumpf's and Husserl's respective phenomenologies. In Michotte's conception, the phenomenological is always equated with the phenomenal. However, it was his achievement to demonstrate that an accurate experimental analysis of the perceptual world is a kind of phenomenological research which leads in some cases to more fruitful theoretical constructs than mere phenomenological descriptions in the classical sense. His outstanding contribution appears therefore as a strong argument in favour of the fairly recent idea that phenomenological psychology may include controlled scientific work.

MIGRAINE (from a French word derived from the Greek

meaning skull) is a transient disorder of brain function which is commonly associated with

headache. The diagnosis is usually made when discrete headaches are accompanied by two or more of the following features: unilateral pain, nausea or vomiting, focal cerebral symptoms (e.g. visual phenomena), and a family history of the condition. Attacks usually start to occur before the age of 30 and decrease in frequency with advancing age. Sixty per cent of sufferers are women.

The headache is often preceded by a variety of warnings. Days or hours before its onset there may be a change of mood (usually elation), or an alteration in behaviour, in wakefulness, appetite, bowel activity, or fluid balance. In 'common migraine' these are the only warnings but in 10 to 15 per cent of patients (those who suffer

'classic migraine') the headache is immediately preceded by disturbances of sensation. These disturbances are usually visual in character, taking the form of flashing coloured lights, zigzag lines, or distortions of visual perception, with or without areas of blindness that begin near the centre of gaze or at the periphery, and then move, usually expanding in size. Less commonly sensations of tingling or numbness occur, usually on one side of the body, particularly in the arm, and even less frequently there can be disturbances of speech and language. In rare forms of migraine other focal neurological deficits may precede the headache: for example, when vertigo, slurred speech, and unsteadiness of gait suggest brainstem dysfunction ('vertebrobasilar migraine'), when there is dysfunction of the nerves that control eye movements ('ophthalmoplegic migraine'), or when there is a unilateral weakness of the limbs (familial 'hemiplegic migraine').

The disturbances, sensory or otherwise, usually last for 20-30 minutes and are followed by a headache which, although often unilateral, may involve both sides of the head, and which is often severe and pulsating in character. When both the sensory disturbances and the pain are unilateral they can involve the same or opposite sides of the body. The pain is often accompanied by nausea (occasionally leading to vomiting) and by an aversion to light and noise. Recovery is almost invariably complete within hours, but can take days. Very rarely an acute attack may result in a permanent neurological disturbance, for example a defect of vision.

Attacks can be precipitated in a number of ways. Perhaps the most common cause is stress of a nonspecific kind, as in the case of loss of sleep or overwork, and in some people attacks tend to occur in the period of relaxation that immediately follows the stress. There are many visual triggers,

such as glare, flashing lights, and striped patterns. Attacks may also occur in relation to the menstrual cycle and sexual activity. In about 20 per cent of sufferers certain foods, especially chocolate, cheese, and fruit, can precipitate attacks. The agents responsible may include biogenic amines and, when attacks are precipitated by red wine, complex phenols.

The origin and nature of the brain disorder are

Page 484

not known with any certainty. Changes in cerebral bloodflow, alterations in*neurotransmitter levels, and electrophysiological disturbances found before, during, and after attacks have led to a variety of hypotheses. The fact that attacks are often precipitated by a strong sensory input suggests that a neurological disturbance leads to the development of the attack (and the role of nonspecific stress would be consistent with such a viewpoint). The onset and progression of visual disturbances in classical migraine suggest the propagation of a wave through the visual cortex of the brain, at a velocity of 3mm/min with abnormal excitation at the front of the wave, followed by a depression of activity. It is not clear whether this neurological dysfunction is due to a progressive loss of cortical blood supply or to a disturbance of the neurochemical composition of the environment that surrounds nervecells (as in the spreading depression of Leao). (For a description of brain structure and how the nervous system functions, see NERVOUS SYSTEM.) These two alternatives are not mutually exclusive, but any possible relationship between them is unclear.

Specific changes in neurotransmitters have been found during migraine attacks, particularly with regard to serotonin (5hydroxytryptamine), a vasoactive monoamine.

Although these changes relate mainly to reduced levels in circulating plasma, it has been suggested that there is also depletion within the brain, which is of interest in view of the role of serotoninproducing neurones in the perception of pain. Nevertheless it goes without saying that many other neurotransmitters (known and as yet unknown) are undoubtedly involved.

The mechanisms of pain in migraine may involve dilatation of the meningeal and scalp blood vessels, which are known to be painsensitive. This dilatation is associated with a sterile inflammatory response in and around the vessels and with the release of a number of painproducing substances such as the neurokinines. There are persistent abnormalities in the pulse of scalp arteries in between attacks of unilateral pain on the affected side.

Treatment of migraine is twofold: medication for relief of the acute attack and, for those individuals who suffer frequent attacks, daily treatment to prevent their occurrence. The pain of an acute attack can be reduced by common analgesics or paracetamol, and the nausea by metoclopramide. In addition, it has been common in the past to use the ergot alkaloid derivatives (e.g. ergotamine) which cause constriction of blood vessels and may alleviate pain for this reason. Frequent attacks can be prevented with a variety of drugs, some of which antagonize serotonin (among other neurotransmitters). These drugs include methylsergide, pizotifen, amitriptyline, and propranolol. Relaxation therapy and*biofeedback may have a role in treatment and claims have been made that the

herb feverfew may help prevent attacks.

MILITARY INCOMPETENCE. An apparently inescapable feature of human progress is the toll in lives and money that occurs through our imperfect management of the institutions and technologies which we develop. The histories of railways, flying, bridgebuilding, communications, and political institutions, to name but a few of man's inventions, are replete with examples of costly disasters and harrowing chapters of human misery—art of the price for growing complexity. If an increasing ability to wage war—to kill more people at a greater distance more quickly—can be considered as a manifestation of human progress, then we have here what is probably the best and certainly the most expensive illustration of this principle. Judging from the recent spate of books that have been devoted to martial mishaps, the military case is also probably the most interesting, for three reasons.

First, despite the fact that the professionalizing of human intraspecific aggression has a longer history than most other human enterprises, the record of incompetence in this sphere is far the worst. As T. E. Lawrence said in criticism of British military endeavour, 'With 2,000 years of examples behind us we have no excuse when fighting for not fighting well.' Secondly, an explanation of the psychological causes of faulty generalship is usually in terms of a single factor—stupidity. (In the writer's opinion this so-called 'bloody fool' theory of military incompetence reflects no more than a natural preference for simple explanations of what are in fact very complex phenomena. If the phenomena are unpleasant and the simple explanation abusive then so much the better.) Thirdly, a feature of military incompetence which, incidentally, belies the 'bloody fool' theory is the recurrent and relatively unchanging pattern of military ineptitude.

If incompetent generalship resulted from stupidity (i.e. low intelligence) then we might expect to find the history of war revealing a random miscellany of errors. This is not the case. Indeed, it is just because military incompetence constitutes a syndrome that it is necessary to seek an alternative theory of underlying causation.

As a first attempt towards providing a viable theory, a study was made of military disasters occurring between the 'imbecilic' Walcheren expedition of 1809 and the Vietnam war. They included the retreat from Kabul in the first Afghan war; episodes in the Crimean war; the FrancoPrussian war, the Indian mutiny and Boer wars;

the siege of Kut, Verdun, and the third battle of Ypres in the First World War; the events leading up to Dunkirk, the attack on Pearl Harbor, the losses of Tobruk and Singapore, and the abortive attempt to

capture the road bridge at Arnhem in the Second World War; the siege of Dien Bien Phu and the Tet offensive in the IndoChina and Vietnam wars; and the Bay of Pigs fiasco. While all these episodes share the distinction of being classed as costly military disasters, the question arises as to whether they reveal a common pattern of errors. The following summary of frequently recurring factors suggests that they do:

1. A serious wastage of human resources and failure to observe one of the first principles of war—economy of force. This failure derives in part from an inability to make war swiftly. It also derives from certain attitudes of mind which we shall consider presently.
2. A fundamental conservatism and clinging to outworn tradition, with an inability to profit from past experience (owing in part to a refusal to admit past mistakes). This also involves a failure to use, or a tendency to misuse, available technology.
3. A tendency to reject or ignore information which is unpalatable or which conflicts with preconceptions.
4. A tendency to underestimate the enemy and overestimate the capabilities of one's own side.
5. Indecisiveness and a tendency to abdicate from the role of decisionmaker.
6. An obstinate persistence in a given task despite strong contrary evidence.
7. A failure to exploit a situation gained and a tendency to 'pull punches' rather than push home an attack.
8. A failure to make adequate reconnaissance.
9. A predilection for frontal assaults, often against the enemy's strongest point.
10. A belief in brute force rather than the clever ruse.
11. A failure to make use of surprise or deception.
12. An undue readiness to find scapegoats for military setbacks.
13. A suppression or distortion of news from the front, usually rationalized as necessary for morale or security.
14. A belief in mystical forces—fate, bad luck, etc.

Contemplation of these 'symptoms' suggests that, far from being a product of ordinary stupidity, military incompetence stems from complex interactions between three things—the hazards of professionalizing violence, the nature of military organizations, and the personalities of some of those

who are attracted to, and then for a time prosper in, a military career.

The theory which attempts to outline and explain these interactions starts from the premiss that in professionalizing violence man set himself the task of legitimizing and then controlling patterns of behaviour which are normally taboo in a civilized society. To achieve this difficult contortion there gradually evolved that system of rules, conventions, incentives, and punishments which constitutes militarism, a subculture of controls and constraints which may be likened to those precautionary measures adopted by any imaginative explosives expert to ensure that his particular stockintrade goes off only when and where he wants it to. Now, since many of the components of militarism bear more than a superficial resemblance to those personal defences which some people erect against their own anxieties and aggressive impulses, it is hardly surprising that a minority of men are attracted to joining organizations which not only provide legitimate outlets for controlled aggression but also have perfected an elaborate set of rules for maintaining order and discipline within their ranks. On the one hand, as I. L. Janis remarks, 'The military group provides powerful incentives for releasing forbidden impulses, inducing the soldier to try out formerly inhibited acts which he originally regarded as morally repugnant.' On the other hand, in so doing, militarism provides a therapeutic gain for some of its members. Thus, according to Robert Holt, It was a common clinical observation during the war that military service was an unusually good environment for men who lacked inner controls.... The combination of absolute security, a strong institutional parent substitute on which one could lean unobtrusively, and socially approved outlets for aggression provided a form of social control that allowed impulses to be expressed in acceptable ways.

Some confirmation of this relationship between personality and liking of a military career has been forthcoming from those recent researches which have found a relationship between authoritarianism and liking of a military ideology. When it is considered that authoritarianism, as measured by the Californian F (Fascist) scale, correlates positively with rigidity and the possession of obsessive traits, a personality type emerges which is remarkably similar to traditional descriptions of the military mind. (The F scale measures anti-Semitism, ethnocentrism, political and economic conservatism, and implicit antidemocratic trends or potentiality for Fascism.) In its most extreme form such a person would be conventional, conforming, rigid, and possessed of a closed mind. He would also be one who is orderly, obstinate, and unimaginative. Finally he would be the sort of individual who believes in force and toughness, is lacking in compassion, and is prone to stereotype out groups (i.e. the enemy) as less gifted than himself. Obviously there are, among this miscellany of characteristics, traits which are no handicap to those seeking advancement in their military career. Such a person would do well because in many ways he fitted in so well.

Unfortunately, however, those very traits which would facilitate his promotion up the military hierarchy are not conducive to competence at the highest levels. Being inflexible and unimaginative, predisposed to 'bull', excessively obedient and having a mind closed to unpalatable information, conservative and conformist, are not the characteristics for handling, let alone fathoming, the great

uncertainties of war. Needless to say, attempts at applying this theory of incompetence to actual

military disasters and particular military commanders encountered the difficulty that we have no personality measures of the characters concerned. However, a comparison between the best and the worst of military commanders, in terms of their military performance and what is known of their personalities and childhood, strongly suggests that failure of leadership and derisionmaking are due less to stupidity than to the fact that militarism attracts a proportion of people whose personalities are ill suited to warring behaviour.

MILITARY MIND. Consideration of whether human beings as a species have an innate tendency towards aggression among themselves has generated a massive literature and negligible evidence: the question remains completely open. Whatever the answer, it is certain that few people lack the qualities required to make at least an adequate member of an armed force: during the wars of the last hundred years, tens of millions of men, and many millions of women, have been taken into the forces of many nations; and very few—for good reasons or bad—ave proved wholly unsuitable. Thus virtually any mind is more or less 'military' on the lower level;

and consequently, when discussing the 'military mind' *per se*, it is usual to refer to the qualities needed for, or associated with, high command.

Any serious examination of the commanders of history (see, for example, Windrow and Mason, 1975) reveals at once that the range of character and personality, even among the successful, is very wide; and this is the case even if we look only at those traits loosely called 'aggression' in individuals: the humane Wellington, the callous Bonaparte, and the sadistic Chingis (Genghis Khan) immediately spring to mind. Can either history or modern experimental studies cast any light, then, on the main qualities of the military mind?

Every successful commander—very great commander, even more—has had to take decisions of grave consequence upon partial and more or less uncertain information, in circumstances of great psychological pressure and often of great physical danger. Small wonder, then, that Wavell (1941) considered '... the first essential of a general [to be the possession of] the quality of robustness, the ability to withstand the shocks of war ... a high margin over the normal breaking strain'.

High intelligence, professional competence, and imagination are naturally desirable; but those who sneer at the failure of commanders to grasp *at the time* solutions which seem simple and obvious in the quiet of a study (see, for example, Dixon, 1976), should ever remind themselves of the circumstances in which the problems were faced. Very often, what was wanting when they failed was a sufficiently 'high margin over the normal breaking strain'.

In modern times all major armed forces have attempted to set up rational selection and training procedures for potential commanders, but difficulties stem from the fact that much has to depend on theory. Whereas the young doctor or engineer can practise under guidance on real patients or bridges, the young officer cannot train in real battle. The solutions adopted differ in detail from one nation to another.

Validation presents considerable problems (Reeve, 1972), but that used by the British army appears to be at least as successful as any. Psychological tests are used first in the process of elimination: for example, with the prospect of combat there is good theoretical reason for rejecting candidates who appear introverted (Corcoran, 1965). Then there is an ingenious technique invented by Major R. Bion and known as the 'Leaderless Group Test' (Bidwell, 1973, esp. ch. 8). Candidates are randomly

assigned to groups of about ten, and a fairly difficult practical task, whose solution is not obvious and which requires cooperation within the group, is set ostensibly as a test for the group as a whole. No instructions are given, and no leader appointed: the testing officers simply stand and watch. It is set in as reasonably stressful a situation as can readily be set up, and no importance at all is attached to whether or not the group actually succeeds: the real object is to observe how the several members respond to the situation—who can cooperate, who can induce cooperation, who 'puts people's backs up', and who simply follows along. Such tests select those who become junior officers.

At a later stage, after some years of experience with their units, officers are given training for higher command at staff college or equivalent institution. The techniques now generally known as 'management gaming' were invented for this purpose and are intensively used. Trainees are placed in groups of eight to ten, known as

'syndicates'. Sometimes these are 'leaderless groups', as described above, and sometimes roles (such as C.inC., divisional commanders, and so on) are allotted to the members. The syndicates tackle a succession of exercises based on carefully prepared (and often very entertaining) 'scenarios' produced by the directing staff. In British staff training there are no predetermined 'best solutions' to these exercises—as there are, for example, in both the American and Russian equivalents; instead, the general virtues of simplicity and flexibility are sought. Solutions produced by syndicates or by individuals within them are subject to thorough and uninhibited criticism by both teaching staff and peers.

Page 487

As with the selection of junior officers, this training for the higher ranks involves a considerable degree of pressure and stress. Not only are the problems faced difficult in themselves, and to be solved in limited time; but those taking part know that their careers are at stake, and that every word they write or utter is likely to be 'shot down' by rivals or tutors. It is thus a selective as well as an instructive mechanism, and, as far as can be discerned, a highly successful one. The students emerge not only with the vast amount of procedural knowledge that any modern officer needs but also with practical experience of solving difficult command problems under harassing conditions. They gain experience, too, in leading teams of equals without being able to rely upon the formal compulsions of military discipline.

Thus, by the time an officer is appointed to senior command he has passed through, first, a rigorous and wellvalidated selection procedure, and, second, a rigorous and highly competitive 'higher education' in his profession. There is thereby as much certainty that he possesses the necessary abilities and skills and as much evidence that he possesses the 'quality of robustness' under stress as can reasonably be obtained. Since the 'mind' of any profession requires a combination of general ability, special skills, and particular aptitudes, it seems difficult, in the present 'state of the art' to go much further than this.

MILL, JAMES (1773-1836), British writer and political economist, born near Forfar, Scotland, and educated for the ministry at Edinburgh. In 1802 he moved to London to start a literary career, editing and writing for various periodicals. He also worked for the East India Company after writing a *History of British India* (1818). Having written *Elements of Political Economy* (1821) he produced *Analysis of the Phenomena of the Human Mind* in 1829 and *A Fragment on Mackintosh* (1835).

He was closely associated with Jeremy*Bentham and was one of the founders of utilitarianism. His remarkable personality is recorded with rare insight by his son, John Stuart*Mill, in his *Autobiography* (1873).

MILL, JOHN STUART (1806-73). British philosopher and political economist, born in London, the son of James*Mill. He was brought up by his father to be a genius—which indeed he became—being taught Greek at the age of 3, Latin and arithmetic at 8, logic at 12, and political economy at 13. His only recreation was a daily walk with his father; and during this he was given oral examinations. Perhaps not surprisingly he suffered a severe mental crisis, but he recovered to become one of the outstanding intellects of his generation. In his *System of Logic* (1843) he provided, among other things, a systematic account of inductive reasoning (see INDUCTION, and, for Mill's predecessors on this matter, ARISTOTLE and BACON, FRANCIS).

Mill also wrote extensively on political economy, and morals and ethics, developing his father's and Jeremy*Bentham's utilitarianism. His essays on *Representative Government* and *Utilitarianism* both appeared in 1861. He disagrees with the earlier authors by admitting qualitative differences between pleasures, and so raising doubts as to whether pleasure can be equated with right action. In his *On Liberty* (1859) he provides a famous principle (the 'harm' principle) which severely limits the extent to which individuals may be coerced by government. He was an early supporter of liberal campaigns for women's suffrage, and his *The Subjection of Women* (1869) provoked antagonism at the time, but heralded equality.

MIND AND BODY. Until quite recently most philosophers have held a*dualistic view of the relation

between mind and body. This dualism has, however, taken several different forms. There have been those, like*Descartes, who ascribe mental attributes to spiritual substances which are supposed to be logically independent of anything physical but to inhabit particular bodies in a way which it has not proved easy to define. Others, like*Hobbes, have admitted only a duality of properties, ascribing both mental and physical attributes to human bodies. Others again have recognized an ultimate category of persons, differentiating them from physical objects just on the ground that they possess mental as well as physical attributes. Exactly what constitutes a mental attribute is itself not easy to define, but it can perhaps be sufficiently illustrated by examples, which may be chosen so as to cover the different varieties of sensation, perception, imagination, feeling, and thought.

For the most part, those who have subscribed to one or other form of dualism have also held that there is causal interaction between mental and physical events. The main opposition to this view has come from those who conceive of the physical world as a closed system, in the sense that every physical event must be explicable in purely physical terms, if it is explicable at all. If they also accept the existence of irreducibly mental occurrences, they regard them as accompanying and perhaps being causally dependent on physical events, but as not themselves making any causal intrusion into the physical world.

This refusal to admit psychophysical interaction does not seem justified, especially if one takes a*Humean view of causation as consisting basically

in nothing more than regular concomitance. Even if there were a physical explanation for every physical event, this would not preclude there being alternative forms of explanation which relied at least in part on mental factors. It is, however, unlikely that such psychophysical correlations would be nearly so stringent as the laws of physics, and the same would apply to any generalizations that were couched in purely mental terms.

The difference in the type of causal laws to which they are subject is one of the ways in which mental and physical events are distinguished in the theory of neutral monism, which was advanced by William*James and subsequently by Bertrand*Russell. According to this theory, the elements of our experience consisted of actual or possible sensedata out of which the physical world was supposed to be constructible. These elements were also regarded as entering into the constitution of minds so that one and the same sensedatum might as a member of one group be a constituent of some physical object and as a member of another group be a constituent of a mind in whose biography a perception of the object occurred. Apart from the fact that there were also images and feelings, which entered only into the constitution of minds, the difference between mind and matter was represented not as a difference of substance, or content, but as a difference in the arrangement of common elements, involving their participation in different forms of causality. This was in many ways an attractive theory, but it met with serious difficulties. Though there may be a sense in which physical objects can be generated out of the immediate data of perception, an outright reduction of one to the other seems not to be feasible. Neither did the exponents of the theory succeed in giving a satisfactory account of*personal identity or of the special relation in which the elements that make up a person's mind stand to the particular physical object which is that person's body.

Similar difficulties beset the attempt made by Berkeley to eliminate matter in favour of mind, by representing physical objects as collections of sensible qualities, which he termed ideas. In Berkeley's case, the want of a criterion of personal identity is especially flagrant, since he followed Descartes in treating minds as spiritual substances. It is, indeed, one of the principal objections to this view of the mind that it is incapable of furnishing any such criterion.

In recent times, monistic theories have mainly taken the other direction. They have gone beyond the older forms of materialism in that they not only ascribe mental attributes to certain physical objects, but also treat these attributes themselves as physical. The strongest theory of this type is that in which it is maintained that propositions which would ordinarily be construed as referring to mental states or processes are logically equivalent to propositions which refer only to people's overt behaviour. This theory may be allied to a verificational theory of meaning. Since the only way in which we can test the truth of the propositions in which we attribute experiences to others is through observation of the ways in which these other persons behave, it is deduced that this is all that such propositions can legitimately be taken to refer to. Then, since it can be shown that one cannot consistently combine a behaviouristic treatment of propositions about the experiences of others with a mentalistic treatment of propositions about one's own experiences, the conclusion is drawn that all references to one's own experiences are to be construed behaviouristically, even when they are made by oneself.

This argument can, however, be turned on its head. One can start with the premiss that the knowledge which one has of one's own experiences cannot be fully set out in any series of propositions which refer only to one's overt behaviour and then use the fact that the analysis of propositions about a person's experiences must be the same, whoever asserts them, as a ground for rejecting a purely behavioural account of propositions which refer to the experiences of others. And, indeed, unless one is prepared to feign anaesthesia, it would seem undeniable that this premiss is true. The advocates of logical behaviourism were indeed able to show that references to behaviour are often comprised in the use of what are classified as mentalistic terms. They were even justified in claiming that intelligent thought and action do not necessarily require the occurrence of inner processes. Nevertheless we do very often have thoughts that we keep to ourselves, and the existence of such thoughts cannot be logically equated with any disposition to report them. Neither, on the face of it, is there any logical equivalence between a person's having such and such sensations or perceptions and his dispositions to engage in any form of overt action.

In recent years logical behaviourism has given way to the less radical theory in which mental occurrences are held to be not logically but only factually identical with states of the central nervous system. On this view, for a person to have such and such an experience *is* for his brain to be in such and such a state, in the way in which lightning *is* an electrical discharge or temperature *is* the mean kinetic energy of molecules. As in those other cases, the suggested identity is supposed to be established not through the analysis of concepts but on the basis of empirical research. It rests on the assumption that there is a perfect correlation between a person's experiences and events which take place in his brain. In fact, this assumption goes further than the evidence yet warrants. There is, indeed, very strong evidence of a general dependence of mental occurrences on the functioning of the brain, but it has still to be shown that the correspondence is so exact that from observation of a person's brain one could arrive at a knowledge of his experiences in every detail.

Even if we make this assumption, it is not clear that it justifies the postulation of identity. If events which appear from their descriptions to belong to Page 489

different categories are capable of being empirically correlated, the implication is rather that they are distinct. It is only on the basis of some theory that we can proceed to identify them. In this case the theory seems to be linguistic. It is thought that a general acceptance of the hypothesis that mental events are causally dependent upon events in the brain will lead to the denial of their separate existence. It has even been suggested that the use of psychological terms will be given up altogether.

This does not seem probable. Even if we were aware of what was going on in people's central nervous systems, it is unlikely that we should cease to find a use for explaining their behaviour in terms of their conscious thoughts and feelings. Nor is it likely, in a case in which an inference drawn from one's physical condition conflicted with one's awareness of one's own experience, that one should not continue to treat this awareness as the better authority.

If we have to adhere to dualism, the most defensible form of it would seem to be that in which we admit only a duality of properties. Unhappily, the problem of showing how these predicates combine to characterize one and the same subject has not yet been adequately solved.

THEORIES.

A. J. A.

MIND AND BRAIN: LURIA'S PHILOSOPHY. The relation between brain and mind has been for many centuries one of the most difficult problems, both of philosophy and of science. Two approaches to the problem have been proposed—and both have failed.

The first was a mentalistic, the second a naturalistic approach.

.For many centuries philosophers and other scholars supposed that the brain was a *detector* of mind, which itself was seen as an inner, subjective state of*consciousness. It was supposed that mind was a primary quality of the inner life whereas all external experience could be thought of as a secondary kind, consciousness of self being treated as the immediate existence of the soul. According to this spiritual approach, the brain was merely a device connecting a man's existence with his inner subjective experience, or—as some other scholars thought—with the objective spiritual reality. This theory—now out of date, it seems—

persisted in some modern studies: Sir Charles*Sherrington and Sir John Eccles postulated brain units as special kinds of detectors of the spiritual life. It is easy to see, however, that such a theory was not amenable to proof.

The second approach was of a naturalistic kind. Brain was supposed to be the highest product of the

natural history of evolution, during which special forms of apparatus of great complexity emerged, resulting in the appearance of internal sensations, memory, and—last but not least—a series of associations that gave rise to the appearance of the most complicated forms of subjective experience.

So, it was supposed, very specific groups of nerve cells (neurones) existed, each having some special function, each serving a special purpose to evoke sensations, images, ideas, motives, and voluntary actions. The hope of this group of scholars was to *find special* mechanisms serving to create *special* mental states.

Unfortunately this is not the case: the oversimplified naturalistic hypothesis of cerebral units creating complex subjective images could no more be verified than could the oversimplified mentalistic hypotheses—and all attempts to postulate that sensations, or images, or ideas, could be found in single units of the brain were as unrealistic as trying to find an image inside a mirror or behind it. They originated in archaic notions of mental functions as elementary, primary properties or 'capacities'

of the brain. Whereas two or three centuries ago it seemed obvious that sensations and images, thoughts and voluntary impulses, were kinds of 'capacities', or immediate functions of specific brain organs—thinking of the brain as a system of specialized 'microorgans'—such a concept is no longer acceptable. It is better to suppose that mental processes are complex informationprocessing activities, reflecting reality. Instead, mind is now considered to be a product of active processing of the flow of information working through elementary drives, or complex motives, set to single out important information about reality, relating bits of information and synthesizing them, and constructing plans and programmes of behaviour, which are expressed through speech.

In other words it is implausible to think of the brain as a 'generator of mind'. Quite a different approach to the brainmind problem is needed. The human brain can be supposed to be a complex working system which consists of different functional blocks or units, every one of which plays a part in reflecting the external world, in complex informationprocessing, in establishing plans and programmes of behaviour, and in conscious control of actions.

It is now known that the deep structures of the brain (the higher brainstem, the old cortex of the limbic system) have a decisive role in the active state of the cerebral cortex. When this functional system is deranged the activity of the cortex is reduced. A dreamy state is observed, selectivity of the cortical processes is no longer possible, and the first and most important condition for the normal working of the brain—its vigilance—breaks down.

A second functional system, associated with the posterior parts of the cerebral hemispheres, can be considered as the system receiving, preserving, and elaborating information the brain accepts from the external world. This system consists of a series of highly specialized ('modalityspecific') units: the occipital lobes dealing with visual, the temporal lobes with acoustic, and the postcentral lobes with cutaneous informationprocessing. Each of these parts of the cortex has a clearly organized hierarchical structure. The primary parts are believed

to be central receptor devices consisting of highly specialized neurones, which are activated by particular signals (for example, in the primary visual cortex some neurones react to lines of specific orientation, others react to specifically oriented movement in certain directions, and so on). The combination of single excitations, with the creation of complex patterns reflecting complex features of images, only becomes possible by transition to the secondary parts. Transition to the tertiary parts (which are seen only in the human brain) allows the separate, modality-specific areas of the cortex to work together; a cooperative functioning of different modalities is provided, and successive series of excitations are reorganized into simultaneous spatial (or quasispatial) schemes.

A third functional system includes the anterior parts of the human brain—the frontal and prefrontal areas, which are responsible for the retention of stable motives, the establishing of complex plans and programmes of actions, and control of their execution. It is the pinnacle of cerebral organization: when it is deranged, elementary forms of activity can be preserved but there are no stable motives, no goal-directed plans or programmes can be executed, and no higher forms of action control, including language, are possible.

Thus the cooperative working of the different systems of the brain supplies humans with information-processing, provides active and plastic adaptation to the immediate environment, and links human conduct to particular goals. It is a complex of functional systems, organized according to plans and programmes created by man's social history. As an alternative to both mentalistic and naturalistic theories, such a concept provides a significant step towards analysis of the intimate mechanisms of the brain as an organ of mind.

MIND-BODY PROBLEM: PHILOSOPHICAL THEORIES. Classifications of theories are bad masters, but may be useful servants. In the following classification of the main theories of the mind-body relationship upheld by philosophers, it is to be understood that the positions sketched are 'ideal types' to which actually held positions may approximate in different degrees.

If we think of mind and body as two opponents in a tug-of-war, then we can distinguish between

theories which try to drag body, and matter generally, over into the camp of mind; those which try to drag mind over into the camp of body; and those theories where an equal balance is maintained. This yields a division into mentalist, materialist (physicalist), and dualist theories.

It is convenient to begin by considering dualism. The major position here is *Cartesian dualism*, named after Descartes, the central figure in postmedieval philosophical discussion of the mind-body problem. For a Cartesian dualist the mind and body are both substances; but while the body is an extended, and so a material, substance, the mind is an unextended, or spiritual, substance, subject to completely different principles of operation from the body. It was this doctrine that Gilbert Ryle caricatured as the myth of the ghost in the machine. It is in fact a serious and important theory.

Dualist theories are also to be found in a more sceptical form, which may be called *bundle dualism*. The word 'bundle' springs from David Hume's insistence that when he turned his mental gaze upon his own mind, he could discern no unitary substance but simply a 'bundle of perceptions', a succession or stream of individual mental items or happenings. Hume thought of these items as nonphysical. A bundle dualist is one who dissolves the mind in this general way, while leaving the body and other material things intact.

Besides dividing dualism into Cartesian and bundle theories, it may also be divided according to a different principle. *Interactionist* theories hold, what common sense asserts, that the body can act upon the mind and the mind can act upon the body. For *parallelist* theories, however, mind and body are incapable of acting upon each other. Their processes run parallel, like two synchronized clocks, but neither influences the other. There is an intermediate view according to which, although the body (in particular, the brain) acts upon and controls the mind, the mind is completely impotent to affect the body. This intermediate view, especially when combined with a bundle theory of mind, is the doctrine of *epiphenomenalism*. It allows the neurophysiologist, in particular, to recognize the independent reality of the mental, yet acknowledge the controlling role of the brain in our mental life and give a completely physicalist account of the brain and the factors which act upon it.

Mentalist theories arise naturally out of dualist theories, particularly where the dualist position is combined with Descartes's own view that the mind is more immediately and certainly known than anything material. If this view is taken, as it was by many of the greatest philosophers who succeeded Descartes, it is natural to begin by becoming sceptical of the existence of material things. The problem that this raises was then usually solved by readmitting the material world in a dematerialized or mentalized form. Berkeley, for instance, solved the sceptical problem by reducing material things to our sensations of them. Berkeley thus reaches a mentalism where the mind is conceived of as a spiritual substance, but bodies are reduced to sensations of these minds.

It is possible to combine Berkeley's reduction of matter to sensations with a bundle account of the

491

mind. In this way is reached the doctrine of *neutral monism*, according to which mind and matter are

simply different ways of organizing and marking off overlapping bundles of the same constituents. This view is to be found in Ernst*Mach, William*James, and was adopted at one stage by Bertrand*Russell. The 'neutral' constituents of mind and body are, however, only dubiously neutral, and the theory is best classified as a form of mentalism.

Just as Cartesian dualism may move towards mentalism, so it may also move towards materialism. Surprisingly, Descartes's own particular form of the theory lends itself to this development also. Descartes was one of the pioneers in arguing for an antiAristotelian view of the material world generally and the body in particular.

First, this involved the rejection of all teleological principles of explanation in the nonmental sphere. Second, it involved taking the then revolutionary, now scientifically orthodox, view that organic nature involves no principles of operation that are not already to be found operative in nonorganic nature. Human and animal bodies are simply machines (today we might say physicochemical mechanisms) working according to physical principles.

A view of this sort naturally leads on to the suggestion that it may be possible to give an account of the mind also along the same principles. In this way, a completely materialist account of nature is reached, and so a materialist account of the mind.

The word 'materialism' sometimes misleads. The materialist is not committed to a Newtonian 'billiardball' account of matter. Keith Campbell has spoken of the

'relativity of materialism'—its relativity to the physics of the day. Materialism is best interpreted as the doctrine that the fundamental laws and principles of nature are exhausted by the laws and principles of physics, however 'unmaterialistic' the latter laws and principles may be. Instead of speaking of 'materialism' some writers use the term 'physicalism'.

Materialist accounts of the mind may be subdivided into *peripheralist* and *centralist* views. A more familiar name for the peripheralist view is* *behaviourism*: the view that possession of a mind is constituted by nothing more than the engaging in of especially sophisticated types of overt behaviour, or being disposed to engage in such behaviour in suitable circumstances. Behaviourism as a philosophical doctrine must be distinguished from the mere methodological behaviourism of many psychologists who do not wish to base scientific findings upon introspective reports of processes that are not publicly observable.

Very much more fashionable at the present time among philosophers inclined to materialism is the centralist view, which identifies mental processes with purely physical processes in the central nervous system. This view is sometimes called *centralstate materialism* or, even more frequently, the *identity* view. Unlike behaviourism, it allows the existence of 'inner' mental processes which interact causally with the rest of the body.

It remains to call attention to one important variety of theory intermediate between orthodox dualism and orthodox materialism. It is a 'onesubstance' view, denying that minds are things or collections of

things set over against the material substance which is the brain. But it does involve a dualism of properties, because brain processes, besides their physical properties, are conceived of as having further nonphysical properties which are supposed to make the brain processes into *mental* processes. Such views may be called *attribute* or *dualattribute* theories of the mindbody relationship. A theory of this sort could be said to be a variety of identity view, since it also holds that mental processes are identical with certain brain processes.

According to the doctrine of *panpsychism*, not simply brain processes but all physical things have a mental side, aspect, or properties, even if in a primitive and undeveloped form.

Although the dualattribute view is important, it inherits the considerable difficulty and confusion which surrounds the philosophical theory of properties. There are many difficulties in giving a satisfactory account of what it is for a thing to have a property, and these difficulties transmit themselves to this sort of theory of the mindbody relationship.

MIRROR REVERSAL. It is surprising how few people can give an intelligible answer to the question: 'Why are mirror images reversed sideways, but not up and down?' Even physicists, and experts in visual*perception, can be shaken by this apparently simple question, and find no ready answer; though 'mirror writing', and lateral reversal of objects—including oneself—seen in mirrors is an everyday experience.

This is best seen with writing. For example,

Distinguishing left from right has been held, especially by*Kant, to depend upon an observer, and not to be a physical distinction of the world. Kant uses this as evidence for his mental categories of knowledge (*Prolegomena to any future Metaphysics*, 1783).

The mirror reflects top as top, bottom as bottom, right as right, and left as left: the mirror does not reverse right to left or up to down. All this is entirely symmetrical, so where does the asymmetry come from? That there is no asymmetry of the mirror round the line of sight may be demonstrated by rotating the mirror (or rotating it in imagination)

Page 492

in its plane. Clearly it is optically the same for any angle of rotation: there is no asymmetry here. To explain horizontal but not vertical reversal with optical ray diagrams is doomed to failure, for they cannot distinguish horizontal from vertical, as they are symmetrical and equally valid when held in

any orientation.

Is the asymmetry of 'mirror reversal' related to the fact that we have a pair of horizontally separated eyes? This is sometimes suggested; but close one eye, and the

'reversal' is unchanged. Consider also a man born blind in one eye: would he not suffer 'mirror reversal' as we do? Yes, he does. The reversals (both upsidedown and rightleft) of the*retinal image by the optics of the eye cannot be relevant either; for this would affect *all* vision. (The inversion produced by the eye's imageforming optics is of no consequence, for the retinal image is not seen by the brain as a picture by some internal eye. Provided its (doubly inverted) relation of external objects remains unchanged, the inversions have no effect, and do not present any special difficulty for babies during perceptual learning. Experiments with inverting spectacles show that we can *adapt* to changed touchvision relationships even when we are adult, which is remarkable, but this is not relevant here.) It is sometimes said of 'mirror reversal' that it is 'merely verbal—how we *speak* of right and left' (Bennett, 1970). But 'mirror writing' is difficult to read: it *looks* very different from 'normal' writing. If the difference is difficult to express, it is present before we attempt to describe it; so it cannot be due to the way we use words, such as 'left' and 'right'.

If 'mirror reversal' is not in the mirror, not in the eyes, and not due to how we use words—can it be some *cognitive* perceptual effect? This kind of explanation has been put forward by recent writers (Gardner, 1964). It is suggested that since we appear behind the mirror, facing ourselves, we make a cognitive rotation—as a mental perceptual act—selecting rotation around the vertical axis because our bodies are nearly symmetrical leftright but not vertically, so this is the easier mental operation to perform. It is remarkable that this explanation appears to have gone unchallenged. If true, it would be of the greatest interest as a dramatic perceptual phenomenon, somehow specifically associated with mirrors. Mental*image rotation is possible, though it is slow and often inaccurate. It is very different from mirror rotation.

If mirror inversion were a cognitive rotation it would have to depend on knowledge that a mirror is involved. Suppose we hide from the observer the fact that he is looking in a mirror. He is shown a large, very clean, walltowall mirror with no frame, so there is no information or knowledge that he is looking in a mirror—but the usual 'mirror reversal' still occurs. Consider, further, a photograph taken by reflection from a frameless mirror: the lateral 'reversal' still occurs in the photograph, and yet there is certainly no information here that a mirror was involved. We may also consider introducing false information that there is a mirror when in fact there is not—a typical mirror frame but with no reflecting glass. Does the world reverse when we look through what *appears* to be a mirror but is not? There is no reversal.

Since absence of knowledge that there is a mirror does not remove mirror reversal, and introduction of 'false' knowledge that there is a mirror when in fact there is no mirror does not produce it, we may rule out such cognitive explanations. What then is the answer?

It is remarkably easy to forget that the reflected object has to be rotated, to face the mirror, for us to see it in the mirror. Now we generally rotate objects, including ourselves, around a *vertical* axis.

This produces the rightleft reversal. The 'mirror reversal' is not in the mirror; or in the optics; or in ourselves as a cognitive reversal: it is the rotation of the object from our direct view of it, to face the mirror, which produces 'mirror rotation'. What is odd about mirrors is that they allow us to get a front view of objects though we are behind them. But for this, the object must be rotated from facing us to face the mirror. The reversal of the mirror image is rightleft only when the object is rotated around a *vertical* axis. It is entirely possible (though often less convenient) to rotate objects around their *horizontal* axis. When, for example, a book is rotated around its horizontal axis to face a mirror, it appears upsidedown, and not in 'mirror writing'.

If we stand on our head before a mirror, then we are upsidedown and not rightleft reversed. But this is a confusing case because, quite apart from mirrors, the world continues to look its normal way up though we are upsidedown. Here there is indeed a perceptual phenomenon; but this is quite different from mirror reversal, though it may be confused with it. In the case of a room seen laterally inverted in a wall mirror, we see the room from the point of view of the mirror, though we stand opposite to it. The inversion occurs as we walk round the room and so rotate to face the mirror.

It is worth pointing out that if we place a transparent glass sheet with writing on it in front of a mirror, we see the writing on the front of the sheet, and its reflection from its back from the mirror, and they both look the same. This is because we have not had to rotate the transparent sheet for the writing to be reflected from the mirror, as we do have to rotate writing on opaque paper for it to be visible in the mirror. In all cases, it is *object* rotation that produces these mirror reversals in plane mirrors.

Mirrors are not even required: the same considerations apply to lateral reversal of type in printing, as the paper is rotated when removed from the type—so type is made leftright reversed.

There is another kind of reversal of mirror images. We see objects *behind* the mirror though we are *in front* of it. This does have an immediate optical explanation;

though this is not quite the

Page 493

whole story. Optically, the light path is from the object to the mirror and back to the eye, so we see reflected objects (and ourselves) according to the total length of the light path, which is always longer than the distance of the mirror from the eyes. So it is not surprising that we see objects *through* the mirror: except that we continue to see this though we know intellectually that the objects (and we ourselves) are in front of the mirror. So here our knowledge does not affect what we see.

This is an interesting limitation of our cognition, which allows us to *see* ourselves through the mirror, as we are optically, though we *know* we are in front of it.

Knowledge of the situation does not correct perception of where we are or which way round we are.

Although we see ourselves in a different place from where we know ourselves to be, we seldom mistake our image for that of another person. This appears not to be true for animals, other than the

higher primates and human infants in their first year of life (Gallup, 1977). Almost all animals respond to their own images as to another individual of the same species. Gordon Gallup placed marks on one side of animals' faces, and did the same for infants, and found that even after lengthy experience with the mirror there was no tendency for the subjects to refer the mark to their own face. He suggests that this is an objective criterion for testing for awareness of self.

Somewhat similarly, tactile writing on the forehead may be read as from the *outside* or from the *inside*. It has been suggested that women tend to 'see' touch writing on their forehead from the point of view of an observer in front of them, while men generally 'see' the touch writing laterally inverted as though from inside their own head. Possibly this difference, if real, is because women spend rather more time concerned with their own faces and with how others see them while men look out.

MNEMONICS. Consider the mnemonic sometimes given to a righthanded child who has difficulty in remembering which hand is called 'right' and which 'left'.

'When you write, you write with your right hand, and the hand that is left over is left.' The puns appropriately link the confused items of knowledge, and the whole is anchored to the act of writing, which the child can readily carry out or imagine (even if he or she can only draw!). The mnemonic organizes the information in a way the child can grasp, and provides a procedure for working out, when in doubt, which is 'right' and which 'left'.

In general terms, mnemonics are mental techniques aimed at helping us to learn and remember specific items of information. They provide organization in terms of which we can more easily comprehend and remember information that has, as we say, little rhyme or reason for us. Mnemonics contrive meaning, sometimes of a quixotic sort, for information we find relatively meaningless and, because of this, they are sometimes called 'artificial memory'.

To illustrate further, consider the problem of remembering the number of days in each month of the year. A commonly used mnemonic runs, 'Thirty days hath September; April, June and November; all the rest have thirtynine; excepting February alone; which has twentyeight days clear; and thirtynine in each leap year.'

This jingle helps by rearranging the information, categorizing it, compressing it, and introducing rhythm and rhyme. A less widely used mnemonic consists of counting each successive month on our knuckles. Long months fall on the knuckles, short months on the hollows between. Once more, organization makes the information easier to grasp and remember.

The mnemonics just mentioned achieve organizations which are relatively conventional and publicly comprehensible. But many mnemonics devised by individuals for private use achieve an idiosyncratic organization involving the person's unique background of experiences, visual imagery, and other features that are not readily communicable. Sir Donald Tovey, for example, was a highly accomplished musician who happened to assign a number to each location on the musical stave. When he wanted to memorize any telephone number, he translated each successive digit into the correspondingly numbered location on the stave, and remembered the resulting tune. Idiosyncratic mnemonics may work well for the individual concerned, but if he tries to explain them publicly they seem tortuous, arbitrary, and even laughable.

They also imply that he cannot easily comprehend the information. Because of this, mnemonics are discussed less than they are used, and there is lack of systematic data on their uses and abuses in everyday life.

The most familiar mnemonics are *ad hoc*, opportunistic, and contrived by or for an individual who is having difficulty with some specific information. However, throughout history, mnemonic *systems* have been devised to provide standard, generalizable techniques for memorizing such things as random lists of words or historical dates. Each of these systems is paradoxical: it enables anyone who masters it to carry out impressive feats of memory, but of a kind that is rarely useful in everyday life. Such systems have been used mainly for entertainment, and their strengths and weaknesses are best illustrated by the Method of Loci.

The Method of Loci was known in classical Greece, described by Cicero in 55 BC, and discussed critically by Quintilian a century later. Used by stage performers into the present day, it has, in recent years, been studied experimentally by psychologists. It enables us to accomplish the kind of Page 494

memory feat in which a randomly chosen list of nouns is read out one at a time, memorized at a single hearing, and later recalled in exact sequence. Under appropriate conditions, the Method works spectacularly well. But it is useless for most practical purposes.

The Method has two main ingredients, *loci* (places) and *images* (images). The *loci* are mentally pictured places arranged in a strict sequence with which we make ourselves familiar—for example, distinctive landmarks on a journey. The first landmark might be a particular church, the second a baker's shop, etc. These *loci* provide the prearranged topography into which the list of nouns will be pigeonholed, one at a time. When we hear the first noun, we mentally picture the thing it represents and relate this, by interactive imagery, to the first landmark.

Suppose the first noun is 'tiger'. We might visualize a huge tiger scrambling over the facade of the church and ripping off the roof with its powerful claws. The many, perceptually like attributes of the imaged tiger and the imaged church facilitate our bringing the two together into lively interaction. We are free to devise whatever interactive imagery best suits us, but the more animated and distinctive, the better. Having thus associated the first noun and *locus*, we dismiss the scene from mind, and deal likewise with the second noun and the second *locus*. And so on.

Memorizing is thus broken down into a succession of small subtasks. Each subtask involves interactive imagery which associates a presented noun with its *locus*;

and the several subtasks are held in sequence by the prearranged *loci*. When the time comes for recall, we revisit each landmark in turn. When we mentally picture the church, this brings to mind the tiger which is attacking it. When we move to the baker's shop, this prompts recall of the second image, and hence the second noun.

The entire procedure may seem absurd. But its efficacy has been repeatedly demonstrated, not only by stage performers but also by ordinary people who have been instructed in the Method and given a little practice in applying it.

The Method has limited utility because it requires certain task conditions, of which three deserve mention. The presented words must be readily translatable into mentally pictured objects. The words must be presented slowly, not faster than one every three or four seconds. The Method breaks down if we depart from considering, at any one time, only one imaged object and its corresponding *locus*—for example, if we allow ourselves to notice relationships among the presented words. Now, such task conditions rarely arise in real life—for instance, the Method cannot be used in the wordbyword memorization of naturally spoken speech. In brief, the Method is an exhibition piece which, as Francis*Bacon observed in 1605, is 'not dexterous to be applied to the serious use of business and occasions'.

The Method is of psychological interest on two main counts. First, it shows that mental imagery is a powerfully effective means of learning and remembering, at least under certain conditions *which* have not yet been fully explored. Second, it sheds light on how people handle information. It shows that intellectual skills may be redeployed so as to accomplish unfamiliar feats: the Method does not require us to master any new component processes, but merely to select existing processes and sequence them in a new way. Again, if the Method is modified, new accomplishments become possible, such as our being able to recall instantly the noun which occupied any given location in the list. It is also surprising that an individual can, without confusion, use the same set of *loci* to memorize different lists; but, although such has been demonstrated to be the case, the explanation is not yet known.

In general, mnemonics take many forms, all aimed at contriving some comprehensibility for information that is relatively incomprehensible to the individual concerned.

On a theoretical level, the chief importance of mnemonics is that they illumine, almost in caricature, what is involved when someone is said to 'comprehend' something, or find it 'meaningful', or 'understandable'. On a practical level, mnemonics dearly have both uses and limitations. Some of these are highlighted by the abilities and inabilities of S. V. Shereshevskii; he was a skilled professional mnemonist who tended to use the Method of Loci offstage as well as on it (see Luria, 1969).

The best way to learn and remember information is to 'understand' it. Most people appreciate this

fact. But they may sometimes want to have in their head information which is not readily 'understandable'. When this happens, the trick is to recognize that a mnemonic is indeed a substitute form of comprehension; and to deploy and devise our mnemonics intelligently, with due regard for what they enable us, and do not enable us, to achieve. Unfortunately, but not surprisingly, it is generally the case that the people with most need of mnemonics tend also to be the least able to devise them intelligently and evaluate their advantages and disadvantages.

MODELLING. See BEHAVIOUR

MODELS, EXPLANATORY. Essentially analogies, drawn from engineering or other physical systems, to explain e.g. behaviour and brain function. The prevailing technology has throughout history been drawn upon to provide explanatory models of mind. For*Descartes it was hydraulics (fluid in the supposed nerve tubes). For the ancient Greeks, marionettes controlled by strings (*neuron* is the Greek word for 'string') provided the model.

Page 495

Recently the complex switching of telephone exchanges has served as a (too passive) model of brain function. Currently, digital computers are the main inspiration.

The highly important notion that behaviour is controlled by internal models (cognitive, mental models) was first effectively put forward by Kenneth*Craik, in his *Nature of Explanation* (1943).

MONAD. See LEIBNIZ'S PHILOSOPHY OF MIND.

MONGOLISM. See DOWN'S SYNDROME.

MONTESORI, MARIA (1870-1952), Italian educationist, born at Chiaravalle, Ancona. Maria Montessori can take much credit for the things that are best in primary schools and in preschool education. When the creative energies of children are allowed free expression, when classrooms are no longer full of the cast-iron-framed desks in which children were once confined, when the teacher is a helper and an enabler rather than a dictator of notes and purveyor of inert knowledge, credit must be given to the Montessori method and the influence of her work which has pervaded our thinking about children and their*education. Like the man who discovered to his great surprise that he had been talking 'prose' all his life, most workers in the education field have been advancing the ideas of the

Montessori method without being fully aware of the debt due to her. By the same token, much of the criticism levelled against modern teaching methods—that children only work when they want to, that they are *supposed* to enjoy themselves in school nowadays, that there are no punishments, no rewards—is in essence criticism of Montessori principles.

Maria Montessori became the first woman in Italy to receive a medical degree. She was a doctor in medicine at the University of Rome at a time when the education of women was still unusual, and she excelled in a field which had been a

preserve. Had she simply continued to work as a doctor her life would have been remarkable enough. Her early work was with feeble-minded children. Between 1898 and 1901 she ran a special school, trained teachers, and lectured internationally on her methods of achieving results with her charges. She came to the conclusion that the same transformation she had been able to achieve with the feeble-minded was needed, and possible, in ordinary schools. Her work with the 'idiots'

had been thought to be miraculously effective: they had learnt to read and they passed examinations. She wrote, 'While everyone was admiring the progress of my idiots, I was searching for the reasons which could keep the happy, healthy children of the common schools on so low a plane that they could be equalled in tests of intelligence by my unfortunate pupils.'

With her medical and scientific training, Dr Montessori observed children rather as an anthropologist watches the customs of a tribe, and free from the limiting views of childhood held by the traditional educators. Her approach was democratic, and it is interesting to note that in Russia after the Revolution and in Italy and Germany during the totalitarian regimes, Montessori schools were closed down. Her method was to treat children not as adults in miniature or as objects to be moulded in some

'correct way' but as individuals in their own right. She maintained that she had 'discovered' the child. This was not a just claim, because the child had already been seen in his own right by *Rousseau, Blake, and the Romantics—though, as Aries has shown us, *childhood itself is a relatively new concept (P. Aries, *Centuries of Childhood*, 1973).

Discovering the child also means acceptance of his relative helplessness, and in Montessori schools the apparatus and whole environment of the classroom are structured with the child's needs in mind. The role of the teacher is based both on respect and on confidence that learning will take place without formally set tasks; the child is assumed to want to learn because he has a creative spirit and wishes to discover the world for himself. Like the Freudian psychoanalyst, the teacher should not intervene unless the moment is right. Parallels between psychoanalysis and teaching were recognized by Dr Montessori.

There are limits to her methods. They demand particularly well-trained and sensitive teachers; for authoritarian personalities cannot flourish in a Montessori environment. Middleclass children will probably do better than others, as will children of parents more interested in individuality than in the corporate state. A society that values skill and conformity more highly than creativity and sensitivity

is likely to reject or modify the Montessori principles.

MOORE, GEORGE EDWARD (1873-1958), British philosopher, born in London. He was educated at Dulwich College, and read classics at Trinity College, Cambridge, where he became a Fellow in 1898 and was professor of mental philosophy and logic from 1925 to 1939. He was editor of the philosophical journal *Mind* from 1921 to 1947. He was awarded the Order of Merit in 1951.

As a philosopher Moore was extremely important for attacking Hegelianism with common sense. For example, in a famous lecture he raised his arm and said, 'I know this is a hand'—meaning that no conceivable evidence or argument could be brought effectively to challenge the statement. The key essay is 'The nature of judgment' (1899), which served to emancipate Bertrand Russell from his early philosophical idealism. Moore's writing now appears overdetailed and somewhat fussy; but this was an essential palliative to the

Page 496

windy metaphysics of Hegelianism, represented in England—with commendable clarity—by John McTaggart (1866-1925). Indeed McTaggart, who was also at Trinity College, provoked Moore and Russell to counter Hegelianism by developing and demanding criteria for meaning: which in its extreme form became 'logical atomism', in which no statement is allowed that cannot be individually justified by some kind of test. This is the basis of logical positivism.

Moore's *Ethics* (1912) was a key work which pointed out that moral philosophers, and particularly the utilitarians, were logically confused: for the word 'good' cannot be defined in terms of natural qualities, as it always makes sense to ask whether anything possessing natural qualities is good. Moore accepted that goodness is a simple, unanalysable, nonnatural quality. This is, however, to give up a theory of the good. (As an example of a simple quality he took the sensation yellow; but unfortunately this is, physiologically, always a mixture of red-green neural signals!)

MORGAN, CONWY LLOYD (1852-1936), British psychologist, born in London. He first intended to make a career as a mining engineer, and entered the School of Mines and Royal College of Science in London. There he came under the influence of T. H. Huxley, who encouraged his interest in biology and put him to study the instinctive behaviour of animals. After five years in South Africa as a college lecturer, he returned to England and became professor of geology and zoology in the University College of Bristol in 1884, and then principal of the College. He was elected a Fellow of the Royal Society in 1899, the first Fellow to be elected for psychological research. This was in recognition of the distinction of two books—*Animal Life and Intelligence* (1890) and *An Introduction to Comparative Psychology* (1894)—as well as numerous papers in scientific journals. When in 1909

the College became the University of Bristol, he served for a short time as vicechancellor. In 1910 his chair was renamed the chair of psychology and ethics; and he continued to hold it until his retirement in 1919.

Modern animal psychology grew out of the work of Lloyd Morgan in England and the early work of E. L. Thorndike in America. Lloyd Morgan established a tradition of careful observation of behaviour in natural settings, with systematic variation of the conditions. He enumerated some of his findings, for example when he showed that the proportion of limpets accomplishing a return home is in inverse ratio to the distance they have been removed. His caution in theorizing is exemplified in the canon named after him—the law of parsimony—which was a corrective to the anecdotalism and anthropomorphism of G. J. Romanes (1848–94): 'In no case may we interpret an action as the outcome of a higher psychical faculty, if it can be interpreted as the outcome of one which stands lower in the psychological scale.'

In 1894 Lloyd Morgan introduced the term 'trial-and-error learning' to describe what he had observed while his foxterrier, Tony, learnt to carry a stick with a heavy knob at one end, and to open a gate by putting his head under the latch. Trial and error, which constitutes the method of intelligence, he remarked, continues until a happy effect is reached. In order to understand a clever performance, one must have observed how it has developed. With this purpose he observed the development of the behaviour of birds after they were hatched—for example, the effect of practice on instinctive pecking, and of experience on the choice of object.

The term 'trial-and-error learning' came into general use when E. L. Thorndike put forward in 1911 the law of effect, which explains the selection or rejection of responses as due to the retroactive strengthening or weakening of connections by the effects. However, one of the neatest experiments, and the first in a fully controlled laboratory setting, on the strengthening of responses by reward—instrumental conditioning—was made in 1932 by G. C. Grindley, a pupil of Lloyd Morgan's who had moved from Bristol to F. C. Bartlett's laboratory in Cambridge. By this time, research into detour behaviour and maze learning, prepared for by Lloyd Morgan's work, was in full flood.

MÜLLER, JOHANNES PETER (1801–58). German physiologist and anatomist, widely regarded as the founder of modern physiology. Born and educated in Koblenz, he studied medicine at Bonn (1819–22), where he became professor of anatomy and physiology (1830), before moving to take up a similar chair in Berlin (1833). He remained in Berlin for the rest of his life. As rector of the university there in 1838–9 and again in 1847–8, he was inevitably involved in the serious student

disturbances during the 1848 revolution, events which troubled him deeply and caused a serious breakdown of his health.

He taught human and comparative anatomy, embryology, physiology, and pathological anatomy, and made important contributions in all these fields. His work included an explanation of the colour sensations produced by pressure on the eye, confirmation of the*BellMagendie law, and studies of*reflex action; he was also one of the first to use the microscope in pathology. His *Handbuch der Physiologie des Menschen* (2 vols., 1833/40; English trans. 1840/9) became the standard text in physiology. Among a generation of brilliant physiologists taught by Müller are*Helmholtz and*Du BoisReymond, the latter of whom succeeded him in the chair of physiology at Berlin after his premature death in 1858.

Page 497

MÜLLERLYER, FRANZ CARL (1857/1916), discoverer of the most famous of all the visual*illusions—the MüllerLyer illusion: that a line terminated at each end with inwardpointing arrowheads appears longer, and a line with outwardpointing arrowheads appears shorter, than a 'neutral' comparison line (Fig. 1). He reported and described this distortion and many related examples, with detailed experiments, in two papers dated 1889 and 1896. MüllerLyer is not a wellknown psychologist, in spite of the enormous literature and the many attempts to explain the illusion that bears his name.

Fig. 1.

Born in BadenBaden, he studied medicine at Strasburg, and at the age of 24 became assistant director of the Strasburg Psychiatric Clinic, where he remained until 1883. He visited and worked with E.*Du BoisReymond and J. M.*Charcot. He ended his career in private practice in Munich. His major work, in extent though not in fame, was in sociology, in which he wrote a sevenvolume book, arguing a somewhat Marxist thesis of direction and inevitable development of societies (Salomon, 1959).

MüllerLyer offered as the explanation of his distortion illusion that 'the judgement not only takes the lines themselves into consideration, but also, unintentionally, some part of the space on either side'. This is known as the principle of confluxion. So, for him, it is not the angles of the figure, but rather the spaces bounded by the lines (or by dots corresponding to the ends of the lines) that produce the distortion. He counters some rival theories in his second paper (1896).

MüllerLyer's two papers, 'Optical illusions' (1889) and 'Concerning the theory of optical illusions: on contrast and confluxion' (1896), are translated by R. H. Day and H. Knuth, *Perception*, 10.2 (1981), 126/49. For his sociology, see entry by F. Salomon in *Encyclopaedia of the Social Sciences*, ed. R. A.

Johnson, Vol. ii (1959), pp. 834.

MULTIPLE PERSONALITIES. See DISSOCIATION OF THE PERSONALITY.

MUSCULAR ACTION. Muscle power has served man's needs for far longer than more recent, and apparently more abundant, sources of power. And even with those additional sources, doing work with muscles remains essential to most human activity. But it is so commonplace that we easily forget how complex are the processes which make chemical energy from food available to us as mechanical energy. Not only has the energy derived from the oxidation of food to be stored so that it can be released when needed as mechanical energy, the release must be precisely controlled in order to make movements coordinated and purposeful.

The contractile properties of a muscle reside in the cells (muscle fibres) of which it is composed. Each muscle fibre is a long cylindrical cell which may be several centimetres long and is nearly a tenth of a millimetre in diameter. As cells go it is very large, and it is almost wholly specialized as a generator of mechanical force. By far the greater part of the constituents (apart from water) of each muscle fibre are two proteins, actin and myosin, whose interactions provide a means of generating a force. Actin is a moderately sized protein (molecular weight 60,000); myosin is substantially larger (molecular weight about 250,000), but both molecules have the property of aggregating with themselves into rods between 1 and 2 micrometres in length. These rods of actin and myosin are arranged within the muscle fibre in a very highly ordered array: transverse bands of actin rods and myosin rods alternating in the length of the fibre; and overlapping in such a way that each type of rod can slide along rods of the other kind. Small quantities of additional proteins are incorporated into the arrays of actin and myosin rods; their functions are to give order to the arrays of rods and to regulate the interactions of actin and myosin.

When a muscle is relaxed, the protein rods slide without hindrance past each other, allowing easy stretching of the muscle fibre by an applied force. When a muscle is contracting, the actin rods are pulled towards the centre of each myosin rod, and if the force generated by the pulls of all the myosin rods exceeds the external force the fibre will shorten.

How do the myosin rods move the actin rods and, in so doing, do work? From the sides of the myosin rods short flexible arms (about 200 on each myosin rod) can swing out and form crossbridges between the myosin rod and an adjacent actin rod. Provided calcium ions and adenosine triphosphate are present, a cyclical process occurs, triggered by calcium ions and powered by the hydrolysis of adenosine triphosphate to adenine diphosphate and inorganic phosphates, a reaction which is well known as an immediate source of energy in living systems. The adenosine triphosphate is synthesized in the muscle fibre with energy derived from the oxidation of food. The cycle of events appears to involve a myosin crossbridge attachment to a site on an actin rod; a multistage and progressive change in the crossbridge attachment which results in a small but finite movement of the actin site past the myosin rod; and finally crossbridge detachment. The cycle may be repeated and the actin rod moved on by another small distance. Hydrolysis of adenosine triphosphate is involved at Page 498

each turn of the cycle because, however small the movement of the actin rod, if it is achieved against an external load mechanical work is done, and even if no net movement is achieved there will still be some stretching of elastic structures in the muscle. In any actual muscle fibre there are, of course, very many crossbridges (approximately 5×10^{12}), and in any short timeinterval many will become detached from, and many will become attached to, actin: the net result is a smooth movement of the actin rods along the myosin rods and a smooth shortening of the fibre. If movement is prevented by an external force, the repeated attaching and detaching exerts a steady tension which is proportional to the degree of overlap of the actin and myosin rods, that is to the number of the myosin sidearms which find an actin site for attachment.

In each fibre, contraction depends on the presence of a sufficient concentration of calcium ions (about 10^{-6} molar), and it is turned on and off by the release of calcium from, and uptake of, calcium ions into an intracellular compartment, which is separate from the main part of the cell containing the contractile proteins. This special compartment for calcium storage is called the sarcoplasmic reticulum, and it is bounded by a membrane containing a special protein capable of transporting calcium ions from the sarcoplasm—which is the main part of the fibre and contains the actin and myosin rods—to the interior of the sarcoplasmic reticulum, from which the calcium ions cannot normally escape.

This calciumpumping protein does work by scavenging calcium ions from the sarcoplasm and concentrating them within the sarcoplasmic reticulum. It therefore also requires an energy source. As with contraction, the energy is provided by the hydrolysis of adenosine triphosphate. The calciumpumping by the membrane of the sarcoplasmic reticulum can account for the normally relaxed state of a muscle fibre and for relaxation following a contraction. What events lead to a release of calcium ions into the sarcoplasm and thereby to a contraction?

Muscles (with the important exception of the heart and visceral muscles) only contract when there are nerve impulses in the nerve fibres which run from the spinal cord to the muscle. Skeletal muscle contraction is initiated and controlled entirely by the brain and spinal cord by impulses in these motor nerve fibres. All movements, whether skilled and voluntary or postural and apparently automatic, are organized and initiated in the central nervous system, and a nerve going to a muscle is the pathway by which executive instructions for contraction are passed to the muscle fibres and by which sense organs in the muscle (muscle spindles) signal information to the central nervous system about the results of the contraction and the effects of external loads on the muscle. The nerve contains many nerve fibres carrying impulses to the muscle and a separate set of fibres carrying nerve impulses from the muscle spindle to the spinal cord. The nature of these nerve impulses is the same, but the directions and fibres in which they travel as well as their purposes differ.

Impulses in nerve fibres going to a muscle produce from the end of each nerve fibre, where it is in close contact with a muscle fibre (at the neuromuscular junction), the release of a small molecule, acetylcholine. The release of acetylcholine is brought about by a small entry of calcium ions into the nerve terminal, resulting from the propagation of the nerve impulse into the terminal. Acetylcholine has the role of a chemical transmitter because it is released by the nerve terminal and reacts with a special receptor protein in the membrane of the muscle fibre. As a result of this transmitterreceptor

interaction, a propagated electrical change occurs in the entire surface membrane of the muscle fibre, and this action potential in the muscle fibre is very much akin to the nerve impulse in the nerve fibre. The acetylcholine has served to bridge the gap at the neuromuscular junction between the propagating electrochemical changes in the nerve fibre and the very similar propagating electrochemical changes in the surface of muscle fibre. In the case of the muscle fibre, its surface includes a network of very fine tubules which are invaginated from the outer surface of the fibre and ramify in the entire crosssection and length of the fibre interior. By means of this transverse tubular system the electrical changes initiated at the neuromuscular junction spread rapidly to all parts of the volume of the fibre; the transverse tubular system enables contraction to be started more or less synchronously in the entire muscle fibre. Not only do the transverse tubules extend throughout the fibre—they also make special and intimate contact with parts of the sarcoplasmic reticulum. Just as the nerve fibre contacts the muscle fibre at a special neuromuscular junction, so the transverse tubule comes very close to the sarcoplasmic reticulum at a recognizable structure called a triad junction.

We know in some detail about the release and role of acetylcholine at the neuromuscular junction; our knowledge of the physiological events at the triad is as yet sketchy. But we do know that an appropriate electrical change at the wall of the transverse tubule at the triad results in the rapid release of stored calcium ions from the sarcoplasmic reticulum and therefore triggers a contraction of the fibre.

We have traced the sequence of events between the spinal cord and the contraction of a muscle fibre, but this tells us nothing about the organization of a coordinated movement. We can say that any voluntary movement has its origin in the cerebral cortex. Such a statement begs many questions. One can, however, within the central nervous system trace pathways of nerve fibres in which impulses give rise to muscular movements. In a very general way there are two kinds of pathway in the spinal cord which can cause muscles to contract. Descending impulses from the brain

Page 499

may directly excite the nerve cell (motor neurone) in the spinal cord whose main process is the nerve fibre going to a group of muscle fibres in a muscle. Alternatively, descending impulses may excite the motor neurones whose fibres go to special muscle fibres which form part of the muscle spindles. In a normal muscle there are so few of these spindle muscle fibres that they themselves generate no detectable tension in the muscle, but their contraction increases the frequency of nerve impulses going from the spindle to the spinal cord. These impulses in turn may be able to excite the main motor neurones and make the muscle contract. Stretching a muscle also increases the frequency of impulses from a muscle spindle in that muscle and can produce a contraction which resists the stretch. It is possible, too, that the sensitivity of the motor neurones to the incoming signals from the muscle spindles may be under the control of the higher parts of the central nervous system, providing a variable gain to the feedback pathway made up of the muscle spindle and its sensory nerve fibre.

Any actual muscular movement probably results from complicated temporal sequences of descending impulses; these play with varying intensities on the neurones which send fibres to the ordinary muscle fibres and to the spindle muscle fibres. Many parts of the brain interact and cooperate in the

generation of any particular movement or sequence of movements. Interference with the functioning of the cerebral cortex, the basal ganglia, and internal capsule and the cerebellum diminishes motor performance in varying but characteristic ways; however, the precise roles of each part are still matters of speculation (see NERVOUS SYSTEM).

One can describe in some detail the cellular and even molecular events associated with muscular action, but gaps in the account are more obvious when it concerns the role of the mind, or even of the brain, in originating and organizing movement.

A.

MUSIC, PSYCHOLOGY OF. Music has existed in all human cultures, as far as we know, and all scale systems are based on the octave, which suggests a neurological factor. This suggestion is supported by the fact that animals conditioned to respond to a certain pitch will do so almost equally to its octave, whereas the intervening notes will evoke either much less response or none at all. However, only the Western tonal system originated in the Pythagorean division of the octave into intervals according to the frequency ratios of small whole numbers by which the harmonic series of overtones in a complex tone are related. This ratio basis of the

'chord in nature' was given theological significance and determined the early history of concerted music, which developed from octave ensemble (ratio 2:1), to perfect fifth (3:2), perfect fourth (4:3), and major third (5:4). These intervals occur in the first four overtones of the series and were deemed consonant. After the great development of polyphonic music their ratios were adjusted to very complex ones in the eighteenth-century compromise of equal temperament tuning, yet our experience of the tension of dissonance and the repose of consonance survives in these newer complex interval ratios. Moreover, people prefer an octave tuned slightly larger than the exact 2:1 ratio, whether of pure tones (Ward, 1954) or complex tones (Sundberg and Lindquist, 1973), and this applies whether they are trained in the Western tonal system or in the Indian system of twenty-two *srutis* (microtones) to the octave (Burns, 1974). Sensory theories of consonance, which attribute it to the ear's special sensitivity to the harmonic series, must reckon with these anomalies, and also with all the nonharmonic, complex ratio scale systems of other cultures. Thus, psychologists recognize that ultimately they must span the chasm between psychoacoustics and ethnomusicology. They must also endeavour to account for the whole response to music, not only sensory and cognitive, but also emotional and aesthetic. This latter task is beset with difficulties of method, and at present the main concern is with perception and memory in the Western tonal system, and its later development (using the same intervals) towards atonality.

In seeking to understand how the listener makes sense of music, should psychologists treat it as a set of arbitrary conventions (as David Hilbert views mathematics), or as a description of reality (as Plato sees both mathematics and music), or as a property of mind (as Chomsky regards language)? All three approaches are essential, since all three characteristics—pattern-structural, acoustic, and grammatic—play their part; moreover they function interdependently in musical perception. Though a musical grammar may have been culturally evolved, acoustic characteristics and the constraints of performance will have contributed to its formation. That we perceive music

phrase by phrase is not only because of repeated practice in hearing conventional design, but also because phrase length, as in sentence structure, has been historically constrained by what can be managed in one breath. The human auditory system evolved not only to be receptive (as are those of other species) to the sounds of nature, but also apparently to be 'wired for speech'. Vowel perception, like that of musical pitch and timbre, depends on the spectral characteristics of the complex wave form. Even so, perception phoneme by phoneme is not totally an acoustic process, for it also depends on knowledge of phonological constraints. In both speech and music, this 'wiring' for sequential processing of meaningful acoustic events must form the basis for the subsequent, more specialized expansion of perceptual skill through experience.

Music as pattern. Nevertheless, the Hilbertian approach is relevant, since the brain is biased towards detecting regularities, the nonrandom organization of pattern, irrespective of sense modality.

Experiments on auditory temporal

Page 500

pattern (Garner, 1974; Jones, 1978), treat music as arbitrary design, evoking perception of features such as symmetry, repetition, and imitation, which occur also in other nonmusical symbolic or visual design. The span of shortterm memory sets a limit to the perception of auditory pattern; musical palindromes are difficult to perceive for this reason, whereas visual perception of bilateral symmetry is immediate. Listeners tend to impose structure and to discover or unconsciously apply the rule by which a pattern is defined. Formal transformations of melodies used in serial music are perceptible (depending on their length) in an ascending order of difficulty from exact repetition, to inversion, retrograde, and retrograde inversion. Perceiving retrograde tunes is a particular tax upon shortterm memory, and the strong salience of forward temporal order is apparent if one plays backwards the tape of a wellknown piece, even one of equal note values, where rhythm plays no part. In experiments where subjects are asked to identify the startingpoint and the segmentation pattern of a sequence which is continually recurring, like auditory wallpaper, their perception tends to conform to*Gestalt principles of organization. Patterns of eight or ten recurring events, composed of only two pitch elements, seem to evoke a*figureground perception, sometimes reversible, as in an Escher picture. A slow tempo of presentation affords active coding into memory, whereas a fast one yields a more passively received Gestalt. The formal devices of composition are amenable to this approach, often presented by psychologists in terms of*information theory.

But such an approach can only give an inadequate account of musical perception where it disregards the listener's use of an implicit tonal grammar in perceiving even quite simple melodies.

Music and psychoacoustics. The second approach, the acoustic one, is the study of constraints imposed upon the perceptibility of musical phrases by psychoacoustic factors. Throughout musical history these constraints have been intuitively respected or exploited by composers, even when not yet scientifically defined. For instance, tonal proximity in melodic steps is an important perceptual organizing principle. The ear requires some milliseconds of extra processing time to monitor large pitchintervals in melody. This need has been explained as due either to the 'critical band' (the theory that the ear functions neurally as a series of bandpass filters), or to the brain's momentary conflict

between integrating the frequency change as one of pitch or of timbre (this also is a neurological theory). Palestrina and other sixteenth-century composers observed the rule that, after a melodic leap in polyphonic music, that voice must return by stepwise motion within the compass of the leap—an intuitive recognition of the ear's need of extra steadying time. Even a well-known tune, when transposed note by note into disparate octave registers, becomes unrecognizable. Yet this very widely spaced layout is a characteristic device of twentieth-century serial music, and either of the two psychoacoustic theories mentioned would suggest why it is notoriously difficult to perceive. The salience of tonal proximity in perceptual organization is also apparent when two tunes, each consisting of large ascending and descending leaps, are presented one to each ear (Deutsch, 1975). They are heard as consecutive by the tonal proximity of the notes arriving alternately at each ear, and not, as might be expected, as a left ear tune and a right ear tune. A similar perception by tonal proximity which overrides that by separate sources occurs with the layout between violin parts in Tchaikovsky's Sixth Symphony (see Fig. 1).

J. S. Bach, in his solo violin partitas, exploits a related phenomenon now called 'auditory stream segregation' (McAdams and Bregman, 1979), where alternating notes will appear to separate into two coexistent tunes, depending on the tempo and on the pitch separation between the alternate notes. An eighth-note tune, continually recurring, will perceptually separate into more than two streams of ever more restricted frequency ranges: the faster the tempo, the more streams are heard.

Prestissimo gives the experience of eight coexistent streams forming a continuous chord or an inharmonic timbre. (See Fig. 2.) However, streaming does depend on what is being listened for, whether streaming itself or coherence, so it cannot be entirely attributed to neural factors. In some sequences, one of the eight notes may be

'captured' by either of two adjacent streams; the brain makes the best bet on the basis either of tonal proximity or of harmonic pleasingness. This latter criterion, however unconsciously it is used, reflects the listener's internalized musical grammar, derived from past experience, which will affect his performance in all experimental tasks, however musically neutral they may be. In general, the validity of explaining perception as due to acoustic rather than attentional processes rests on the experimenter's selection of subjects, how rigorously he distinguishes between nonmusicians, musicians, those with absolute pitch, and acoustic engineers, for experience endows each group with demonstrably different coding processes.

The drawback of many psychoacoustic experiments hitherto has been their endeavour to regard perception as context free. Furthermore, the functions—amplitude, duration, frequency, and spectral complexity of the waveform—of the four main attributes of music—loudness, rhythm, pitch, and timbre—have often been treated independently of each other. This has perpetuated the philosophical notion of 'raw sense data'. For music the notion originated in the Pythagorean naive realism concerning sensory coding, which assumed that sensory processes exactly matched physical events in the world. It survived in the assumptions of classical music theory (e.g. that of Rameau and Tartini)

Adagio lamentosa

lin II

The musical score for the violin parts of Tchaikovsky's Sixth Symphony, Adagio lamentosa. It shows two staves, lin I and lin II, with musical notation and dynamics (mf, p). The tempo is Adagio lamentosa.

Adagio lamentosa

b

The musical score for the violin parts of Tchaikovsky's Sixth Symphony, Adagio lamentosa, showing how the music is perceived by the listener. It shows two staves, lin I and lin II, with musical notation and dynamics (mf, p). The tempo is Adagio lamentosa.

Page 501

Fig. 1.
A section of the violin parts of Tchaikovsky's Sixth Symphony, showing a the music as it is actually played, and b how it is perceived by the listener.

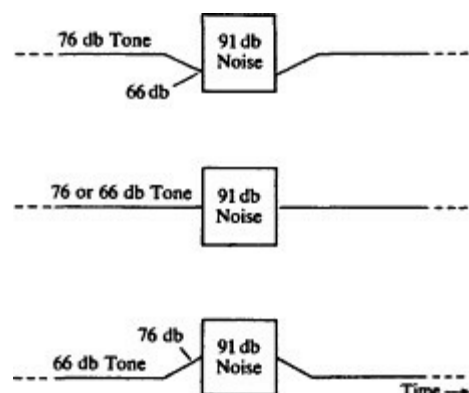

Fig. 2.
The decomposition of an acoustic sequence into smaller and smaller perceptual streams as the frequency separation between the tones or the tempo of the sequence increases. In the latter case, a point is

ultimately reached where one can no longer perceive

individual tonal events; a texture or timbre is heard instead.

and in*Helmholtz's model of the ear as a frequency analyser which coded each discriminable pitch by its specific nerve. Combination or difference tones were thought to be manufactured in the waveform in the ear, rather than neurally. But the four attributes are by no means independent, loudness also depends on frequency, pitch is affected by amplitude, and timbre by frequency. Paul Divenyi (1971) shows that perception of time intervals is affected by the frequency separation between notes, and this has obvious importance for rhythm. Then also, there is no clear distinction between pitch and timbre, but rather a continuous dimension from the unequivocal pitch of pure tones to the spectral inharmonicity of church bells (though their fundamental pitch is distinguishable), to the vague 'pitchiness' of noise within a narrow band of wavelength (Erickson, 1975). Timbre is of course multidimensional, being also affected by fluctuations of harmonics or of pitch (in vibrato), and by the nonpitched starting noises of instruments, or 'transients'. A similar continuous dimension can be traced from the single complex tone to the chord, for if a single harmonic of a complex tone is sufficiently amplified it separates from the fundamental, and a chord is heard. This property is exploited in the chant of a Tibetan monk when he sings alone in twopart harmony. (Smith et al., 1965).

The fact that the fundamental may be perceived when no energy is present at its frequency level,

Page 502

and that the three or four adjacent harmonics which best give rise to this percept fall within a certain middle frequency range (the 'existence region'), whatever the fundamental involved, totally alters the picture of sensory coding inherited from Helmholtz. He held that we have to learn to combine the separately received harmonics of a complex tone, yet most people are unable to regain Helmholtz's supposed primal state of hearing even the first five harmonics separately (the rest of the higher ones, the 'residue', are not separately distinguishable in any case). The problem is to explain how we hear the components of sound as 'belonging' together, whether in hearing the harmonics of a complex tone as fused, or in hearing distinctly each separate stream of all the orchestral instruments in single waveform from a mono loudspeaker. How far does this ability depend on innate neural mechanisms which fuse the spectral components, and how far on mechanisms which have been built up by repeated experience? The limited resolution power of the ear is a psychoacoustic factor which is particularly important to the perception of rhythm. Although hearing is the most accurate temporal

sense, there are nevertheless limits (in milliseconds) to the perceptibility of synchrony, successiveness, and 'flutter', i.e. rapid repetition.

The rise of computer and electronically synthesized music has greatly expanded the vocabulary of music. ?? that, as the American composer Milton Babbitt has remarked, the limits are no longer those of sound production, but rather those of the human auditory system. Rapid changes of timbre are difficult to follow, just as speech recorded syllable by syllable in different voices is incomprehensible. Richard Warren and his colleagues (1972, 1974) have shown that subjects have great difficulty in identifying the order of recurring sequences of sounds which are unrelated in timbre (for instance, a high tone, a hiss, a lower tone, and a buzz) although they are presented at a slower speed than that necessary for auditory temporal resolution. Yet if the two tones are placed adjacently within the four-event sequence, performance is improved. That continuity of timbre is important to perceptual organization is also apparent where a single, pure tone is interrupted by noise, the cessation of the tone being exactly synchronized with the start of the noise, and vice versa. (See Fig. 3.) The pure tone is heard as continuing through the noise, much as in vision one object is seen as existing behind another by which it is occluded. (See ILLUSIONS.) Computer music is easily perceived in the degree to which the sounds resemble or are systematic near distortions of natural sounds. Composers of computer music are able not only to use these parameters of sound from experience but, in collaboration with psychologists, are able also to assess the reasons for the limits to the listeners' perceptual skills (IRCAM Reports).

Fig. 3.

The stimuli used by Bregman and Dannenbring

(1977) consisted of a pure tone interrupted by noise.

The level of the tone leading into and coming out of the

noise burst was varied as shown. The greatest

degree of continuity was found in the centre case

where there was no change in level.

Music as language. The third approach, the grammatical one, treats music as analogous to language, since music also is hierarchically organized and makes selective use of the same neurally closeknit system of voice, ear, and brain. Though without denotative meaning, music is both syntactic and communicative (of subjective states). Its two linguistic elements, melodic phrasing which reflects the intonations of speech, and the formal, syntactic devices of composition, imply that the listener understands both the expressiveness of contour and the 'argument' of musical form. Even the musically untutored listener acquires a musical grammar, a system of rules unconsciously applied, by which he makes sense of music, and would detect 'wrong notes' in an unfamiliar work in the tonal idiom, though unable to name the notes or to state the rules. This grammar implies that the single note is characterized not only by its toneheight, and its chroma (all B flats sound alike), but also by its

grammatical function (e.g. whether it is, at a particular point, functioning as a tonic, leading note, or unaccented passing note). As a word in a sentence is defined by its context, even more so is a note in music.

Formal theories of music and artificial intelligence models seek to define how the listener correctly perceives rhythm, key, tonal modulations, and thematic organization.

Some models are based on traditional music theory and linguistics (Winograd, 1968, LonguetHiggins, 1971), or on Gestalt principles (Tenney and Polansky, 1980).

A more recent theory (Lerdahl and Jackendoff, 1981) covers formal, acoustic, and quasilinguistic aspects, and accommodates the fact that a musical phrase might admit of more than one correct parsing, by distinguishing 'wellformedness' rules from those 'preference' rules which can account for conscious and unconscious organizing principles of

Page 503

musical perception. Its emphasis on the interactions between rhythmic and tonal aspects provides a useful antidote to some research where such interactions have hitherto been disregarded.

Experiments show that, as with language, salience of originally perceived or imposed rhythmic groupings is very strong in subsequent recognition memory; and tunes ending in cadence are easier to remember than those which are harmonically inconclusive. Most musicians would agree that tonal grammar is dominant, that it is not easy to eradicate entirely one's tonal habits of listening when hearing nontonal idioms.

However, the swiftly moving innovations in the history of tonal music, particularly of the last two centuries, undermine the analogy of its grammar with that of language, which is anchored by semantic meaning. Any ancient Greek who conversed with Socrates could equally well have done so with Wittgenstein, but having heard only the musical grammar of the Delphic hymns he would not naturally make sense of Boulez, Beethoven, or even Byrd. Musical style and comprehensibility have increasingly depended upon the listener's developing tolerance of protracted dissonance through his grammatical understanding of its possible resolution in consonance, implicit in his familiarity with past and present idioms. That his longterm memory store, upon which present comprehension depends, is more idiosyncratic than it could ever be for language, presents a difficulty to the psychologist in testing general theories of musical grammar.

In psycholinguistics the experimenter tests a linguistic theory which treats grammaticality as paramount (i.e. whether a string of words constitutes a sentence), whereas ambiguity plays a much lesser role in the whole theory (i.e. whether a sentence is susceptible of more than one meaning and consequently of more than one structural description). But phrases in music frequently admit of differing interpretations and may be ambiguous. Indeed, the performing musician's enduring task is to choose, between the various possibilities of phrasing, the one that to him seems to represent the composer's message most faithfully and eloquently, and his interpretation is to a large extent judged

by its internal coherence. Thus the psychologist of music must work with a grammar which can accommodate the latitude of perhaps many equally

'correct' parsings of a musical structure.

The three approaches outlined here, each concerned with an essential factor operative in musical cognition, remain at present more experimentally distinct than is warranted by their interrelation in the perception of musical structure. In making sense of music, its attributes of contour, interval, tonality, modulation, rhythm, symmetry, repetition, inversion, imitation, and the like, must in turn and at different moments assume different shares of the total cognitive process, and must influence the nature of perceptual grouping or coding processes. Exactly how this fluctuating process operates remains the fundamental question.

Music and performance. Musical perception and performance are both dependent on shortterm memory and expectancy. 'The practically cognised present is no knifeedge but a saddleback, with a certain breadth of its own, on which we sit perched, and from which we look in two directions into time' (William*James, 1890).

From this perch the performer monitors and constantly corrects the flow, shape, and tonequality as it occurs, by a highly integrated system of coexistent codes: auditory, visual, and kinaesthetic. Implicit vocalizing may underlie musical perception, much as Liberman holds that we perceive speech by 'internal generation' at some neural level below that of overt response. But the acquired codes of the musician instrumentalist are more complex, including visual ones for musical notation and for instrumental fingering, and kinaesthetic ones for fingering and more general muscular movement. Kinaesthetic imagery for one's own instrument can also underlie one's perception while only listening. Karl*Lashley (1951) cites the musician's performance when he emphasizes that all human serial behaviour (speech, gesture, and perceptual motor skill) is grammatically structured, on hierarchically ordered levels of organization. Wellpractised sequences occurring too fast for monitoring at the level of individual events are perceived and executed at a higher level of preplanned groups. In music (unlike, for instance, Morse code) the flow of 'information' to be monitored or executed is not constant. Not only the number of consecutive events but also the denseness of harmonic texture may vary from moment to moment, yet the performer maintains a steady flow of action and perception through these variations in information load. The basis here is principally the intrinsic feedback of the nervous system, amplified by the extrinsic feedback of sight and sound, e.g. of the conductor's beat and the sound of other instruments.

Although the appropriate model for research on performance may well be the cybernetic one, it is not surprising that little has yet been done to tease out the components and interactions in this very complex skill. Seashore's research (1938) on intonation and vibrato anticipated the present experimental technique of wiring up musical instruments to computers which record the infinitesimal variations in tone and rhythm that distinguish live performance from computer deadpan accuracy, and one artist from another. Analysis of these recordings shows the variation to be consistent in respect of some general principles of rhythmic displacement, or differences of intonation according to the function of a particular note within a tonality. Some experiments on sightreading indicate that good

sightreaders take in and hold in shortterm memory (the eyehand span) phraselength chunks (see CHUNKING), rather than Page 504

a steady barbybar succession of chunks at the rate of their performance.

A promising source of evidence as to how the components of musical skill may be integrated, is the clinical evidence on amusia, the breakdown of a previously established capability for music due to brain pathology. Although there are strong indications that in righthanded people music is stored in the nondominant hemisphere of the brain, this is by no means invariably so, nor are musical and linguistic functions entirely lateralized. There are many mental abilities common to both speech and language, for instance perception of rhythm and of temporal order, and these seem to be processed in the dominant hemisphere. In lefthanders, either hemisphere can mediate many musical functions, and in some professional musicians a dominant lifework may be stored in the dominant hemisphere. The distinctions between the roles of each hemisphere have been oversimplified in investigations hitherto, although broadly they are apparent. Nevertheless, research which correlates a patient's performance with damage to a particular brain structure, is gradually building up a picture which illuminates our understanding of the nature of musical skill.

An equally promising area is that of developmental psychology, an area which has been largely centred on aptitude tests. The early acquisition of the unconscious ability to operate the rules of musical grammar can be as rich a source of psychological theory as that of the child's acquisition of language. Teplov (1966) finds that children will complete halffinished musical phrases presented to them, with a fine sense of their tonality, rhythmic character, and implied harmonic cadence. The special aptitude of absolute pitch, the possession of which correlates with the early age at which the names of the notes were learned, illustrates the power of category systems in expanding musical intelligence. If more parents were equipped to teach note names as easily as colour names, it is possible that music might more easily resemble an artistic lingua franca.

Music and aesthetics. Most musicians would agree that, as well as the sensory and cognitive aspects we have 'discussed, aesthetic and emotional factors also play a part in perceiving and remembering music, but it is less easy to see how these can be approached experimentally. The belief that memory for melodic contour and implicit harmony is allied to its affective character is well described by Deryck Cooke (1958), whose theory gives general principles why, for instance, we all experience, with Browning, 'those minor thirds so plaintive, Sixths diminished sigh on sigh'. This characterization is, of course, dependent not on pitch intervals alone, but also on rhythm, phrasing, and tempo (for instance, descending coupletphrasing is a particularly plaintive use of minor thirds). The *music* of nonWestern cultures, based on quite different scale systems, no doubt has different aesthetic and emotional significances which are nevertheless experienced to similar degrees in those cultures. In Western music, the factor of musical imagery is partly understood universally by musical people, and is partly idiosyncratic to each composer and listener.

Composers have selfconsistent mood associations with key colour and timbre. Bach's use of the brazen timbre of the D major trumpet associated that key, for him, with jubilation, and the D major open string basis of tone colour enhances this characterization for most composers and hence for most

listeners.

Hitherto experiments on aesthetic aspects have centred largely on subjects' ratings for a certain attribute, or for the more general 'pleasingness'; they were often directed to whole works, or to very large segments of them, rather than to phrases (Schoen, 1937). There are also correlations of measures of autonomic arousal with hearing or performing certain music, including one such study with the conductor Herbert von Karajan as subject (Harrer and Harrer, 1977). Sometimes responses are related to a measure of the information content of a work (Berlyne, 1974). Psychologists may well feel that judgements of whole works do not yield data that are specific enough, and they may be daunted by the great number of confounding variables, such as social, cultural, or fashion determinants of taste.

As yet no systematic experimental study of Deryck Cooke's theory has emerged, relating it to musical education, though a pilot study (Gabriel, 1978) showed that, for twentytwo nonmusician students, Cooke's characterizations of musical phrases were not experienced. This evoked a music theorist's objection to the theory itself (Cazden, 1979), and another to the validity of using 'deadpan' sinewave sequences as an experimental test of a theory concerning real live music (Nettheim, 1979).

To these one must add an objection to the restricted choice of subjects. A study using real live music, and musician subjects, to test Leonard Meyer's theory of the perception of certain melodic characteristics which he calls 'archetypes' attributes the variability of response to the degree of complexity in the underlying hierarchic phrase structure (Rosner and Meyer, 1981). It would seem that experimental musical aesthetics may have to await further progress in the rapprochement between experimental psychology and the theories of musical grammar discussed earlier.

Is it possible for the analytic methods of science to contribute a comprehensive account of the flexible, living performance and enjoyment of music? At the sensory and cognitive levels there has been substantial and illuminating progress. On the other hand, at present the aesthetic level of the musician's use of imagery, particularly with contour, key colour, tone quality, and emotional association seems, like the painter's idiosyncratic choice of palette, to be outside the realm of experimental psychology.

MUSIC PERCEPTION: HISTORY OF THOUGHT. The study of music perception has a fascinating history. From the time of Pythagoras in the sixth century BC, thinking on the subject was heavily influenced by two factors. One was a profound distrust in the evidence of our senses (particularly our sense of hearing), and the other was an obsession with numerology. As Boethius, the leading music theorist of the Middle Ages and a strong follower of Pythagoras, wrote: 'For what need is there of speaking further concerning the error of the senses when this same faculty of sensing is neither equal in all men, nor at all times equal within the same man?'

Therefore anyone vainly puts his trust in a changing judgement since he aspires to seek the truth.'

Matters were made even worse by the strong theoretical link, also stemming from the Pythagoreans, between music and astronomy. It was argued that the planets as they moved must surely produce sounds which would vary with their speeds and their distances from the Earth. It was further argued that the distances between the Earth and the different planets were such that the combination of sounds emitted must form a harmony. Fig. 1 shows the Pythagorean view of the distances of the planets relative to each other, and the musical intervals formed thereby. (This was the prevailing view in ancient and medieval times.) The distance from the Earth to the Moon formed a whole tone, from the Moon to Mercury a semitone, from Mercury to Venus another semitone, from Venus to the Sun a tone and a half, from the Sun to Mars a tone, from Mars to Jupiter a semitone, from Jupiter to Saturn a semitone, and finally from Saturn to the Supreme Heaven a semitone.

Considerable discussion centred on the issue of why, if the heavenly bodies do indeed produce this harmony, we cannot hear it. One suggestion, fielded by Censorinus (*fi. c.* 238), was that the loudness of this sound is so great as to cause deafness. Another, more sophisticated view was that since this sound is present at all times, and since sound is perceived only in contrast to silence, we are not aware of its presence (perhaps this was one of the first suggestions concerning auditory adaptation).

At all events, the link between music and astronomy in ancient and medieval times was so great that the scientific half of the programme of higher education developed into the Quadrivium: the related studies of geometry, arithmetic, astronomy, and music. And even very recently Paul Hindemith in his book *A Composer's World* endorsed this association, writing that Johannes Kepler's 'three basic laws of planetary motion, expounded at the beginning of the seventeenth century, could perhaps not have been discovered, without a serious backing of music theory'.

The Copernican revolution did, however,

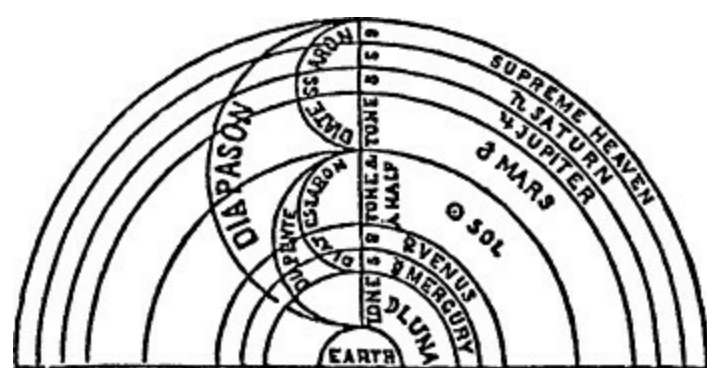

Fig. 1. Pythagorean view of the universe, in musical intervals.

Page 506

Fig. 1.

Pythagorean view of the universe, in musical intervals.

weaken the link between music and astronomy, since it became clear that the planets did not in fact form a harmony. Nevertheless, the strong rationalistic and numerological approach to musical issues persisted. A few enlightened thinkers pleaded for empiricism (notable among these was Galileo's father, Vincenzo Galilei).

However, their writings had little impact; and Hermann von*Helmholtz in 1862 felt impelled to express his concern on this matter in his book *On the Sensations of Tone*. He wrote: 'Up to the present time, the apparent *connection* of acoustics and music has been wholly external, and may be regarded as an expression given to the feeling that such a connection must exist, rather than its actual formulation.' And yet, despite Helmholtz's writings, the numerological approach has prevailed right up to very recent times.

However, we are now witnessing a most interesting phenomenon. The advent of electronic music and the increasing use of the computer as a compositional tool has caused a profound change in the thinking of many music theorists, particularly those who are also composers. If they are to make

effective use of this new technology they need to obtain answers to various questions in perceptual psychology. For instance, they need to know the characteristics of a complex sound spectrum that result in a single sound image, and those that result in several simultaneous but distinct sound images. Given that sounds of any spectral composition can now be generated, they wish to characterize the dimensions underlying the perception of timbre, so that they can create sounds that vary systematically along these dimensions.

Given the potential to generate any sequence of sounds, they need to develop an understanding of the perceptual and mnemonic constraints of the listener, so that their music will not fall on uncomprehending ears.

This same technological development has provided psychologists with the tools with which to explore the mechanisms underlying our processing of music. Such studies, apart from their implications for music, are of considerable value to our understanding of perceptual systems, mechanisms of memory and attention, and even abstract cognitive activity. Music is unique in that it involves an elaborate and highly organized processing system where verbal labelling plays a very minor role.

Given this new interest on the part of both psychologists and musicians, we are at present witnessing an explosion of collaborative work between the two disciplines.

This type of interaction is quite recent, but already it has considerably advanced our understanding of the brain mechanisms underlying music perception.

MYERS, CHARLES SAMUEL (1873-1946), British psychologist, born in London. He qualified in medicine at Cambridge but his interests lay in the natural sciences. After a brief period as professor of psychology at King's College, London, he returned to Cambridge, where he took over the lectureship in experimental psychology from W. H. R. Rivers. With the assistance of members of his family, he founded the Cambridge psychological laboratory, of which he became director in 1913.

His *Text Book of Experimental Psychology* (1909, 3rd edn. 1925) was for long the standard introduction to students of psychology at Cambridge, though it was criticized in some quarters for the perhaps excessive weight which the author placed on the special senses, psychophysics, and the work of Hermann*Ebbinghaus.

During the First World War, Myers served as a physician in the Army. Many years later, in 1940, he published *Shellshock in France*, 191418 based upon his wartime experiences. After the war he moved to London and founded the National Institute of Industrial Psychology, of which he was the first director.

N

NATIVISM. The doctrine that certain capacities or abilities, especially of sense perception, are inherited rather than acquired by learning.

It can be surprisingly difficult to establish what is inherited and what learned, for much that is inherited develops, sometimes over several years, by maturation, and this is hard to distinguish from development by experience and learning. Often there is a mixture of maturation from inheritance and learning from experience—as in the infant's development of crawling and walking. Even for*language development in children there may be innateness, gradually maturing, and—as obviously there is—

learning from experience of adult speech. As is well known, Noam Chomsky has suggested that natural human languages are based on a common 'deep structure', which is inherited and makes the infant's learning task possible (see LANGUAGE: CHOMSKY'S THEORY). Part of the evidence for inherited deep structure is indeed the apparent impossibility of the task with which the infant is faced, that of discovering the structure of language.

There is a similar controversy over how much visual and other*perception develops in the individual by maturation from inherited brain structures and how far (if at all) the physiology is developed or modified by early experience. It has been suggested that linguistic deep structure might be a prehuman, prelanguage, perceptual classifying system developed by natural selection, over hundreds of millions of years, for perceiving and behaving appropriately to various kinds of objects. If that is so, it would explain how the deep structure could have developed so rapidly, on the biological timescale, for human language.

NECKER CUBE. A drawing of a wire cube (drawn without perspective) which spontaneously reverses in depth (Fig. 1). It was first described by the Swiss naturalist and crystallographer L. A. Necker in a letter to Sir David*Brewster in 1832. Necker discovered it while looking at thombold crystals with a microscope and drawing them: the drawings switched in depth and no longer seemed to compare with the crystals as seen with the microscope. There are many other depthambiguous figures.

Fig. 1.

Necker cube. This can be seen as

switching spontaneously in depth,

the front face reversing with the back

face.

A true wire cube will also reverse in depth, and then shows a marked change of shape. The true front, but apparent back as it is reversed, appears too large; though the back and front faces appear almost

the same size when unreversed. This shows that size scaling, normally producing size constancy, can operate from apparent distance, as in Emmert's law for afterimages which increase in apparent size when seen 'projected' on screens of increasing distance, though without any change of the retinal image.

NEGOTIATING, the use of communication between parties to reach agreement, is both a highly specialized social skill and a part of everyday dealings between people. It is a highly complex proceeding, involving the full range of human motives, attributes, and behavioural skills.

At its most commonplace, negotiation can be said to take place in all social encounters. When two people are getting to know each other they are consciously or unconsciously transacting. Each is 'performing' for the benefit of the other, and each is employing cue perception and skills of interpretation to understand the other's meanings. At the same time each conveys to the other the impression the other has created, and each is motivated to conform to the mirrorimage received from the other, or to correct distortions. The continuance of

Page 509

the encounter depends on the creation of a coherent pooling of meaning, albeit one that may be collusive, sustained by deception of self and the other. Each 'actor'

needs two sets of cognitive and behavioural skills: the ability to project or imagine himself in the role of the other, and the ability to improvise a performance that will convey the desired selfimage.

In formal negotiation, this interactive process is embedded in a complex system of rules and relationships. The parties may be bargaining on behalf of constituents, or principals, to secure agreement over some decision, joint action, or form of words. The negotiator's role is then considerably complicated by forces such as the known position of his principals and their expectations of his behaviour, the dictates of wider social norms and values, and the pressure generated by the encounter to reach agreement. The nature of the pressures is unlikely to be the same for both parties: in industrial negotiation the union representative is typically constrained most of all by the demands of his membership. Such negotiation becomes very much a question of mutual attempts at influence, where the 'fate' of each protagonist is dependent on the moves made in the game by the other. The basic ploy usually takes the form of coercive threats, though these have to be exercised with care. Threats of too great a magnitude may well elicit a reaction that terminates the negotiation or engenders an escalating series of hostile exchanges, while threats that are too mild will be ineffective and damage the negotiator's credibility. On the other hand, participants also have the

capacity to reward one another, principally by means of concessions.

The dilemma here for the negotiator is how to make concessions that will not compromise his bargaining position, or damage his image, by indicating weakness or lack of commitment to earlier positions.

The reason why such conflicts, in most cases, do not end in stalemate or breakdown is that parties set out with the aim of reaching agreement and the pressure to settle mounts as negotiation proceeds. Moreover, negotiation takes place in a normative climate of shared expectations. The most powerful expectation is the 'norm of reciprocity': trust and good faith in bargaining, which are highly correlative with outcomes satisfactory to both parties, are dependent on the understanding that the behaviour of one side is likely to be reciprocated by the other.

Most formal negotiations have a strong 'distributive' component: what one side gains the other loses. Each party has a 'target' settlement point and a minimum 'sticking'

point in mind, and each tries to find out about his opponent's targets and limits while concealing his own. If the two ranges within these two points are seen to overlap, both parties will aim at a point closest to their opponent's sticking point. If they do not overlap, then each will strive to shift his opponent's limits or be forced to shift his own; the inevitable alternative is breakdown of negotiations. Since the costs of breakdown are unequal, much tactical behaviour is geared to deemphasizing the cost to one's own side and emphasizing the cost to one's opponent.

The opening moves of a negotiation are crucial. It is common to witness 'blue sky' bargaining, where extreme demands are progressively retreated from by the use of concessions, though this is an extravagant strategy that can lead to considerable 'image loss'. The extreme alternative—a 'finalofferfirst' strategy—is risky: it deprives one's opponent of any credit with his principals for gain in negotiation, and so to be successful it demands that the offer involve a sufficiently large concession in order that a mutually acceptable bargain be struck.

But negotiation is seldom purely distributive: often it also contains 'integrative' components, i.e. the aim is not just to divide up the cake, but also to see if the size of the cake can be enlarged to the benefit of both sides. For this type of objective to be achieved, it is necessary that parties cooperate in a creative, trusting, and open manner—conduct which may be inimical to the distributive goal of preventing one's opponent from acquiring a disproportionate share of the enlarged cake.

A good deal of strategic purpose in negotiating is less palpable. Effort may be directed at changing the attitudes of the other side. The promise of rewards and punishments may be deployed to create changes in the relationship, the level of trust, the motivation of one's opponent, or his legitimacy.

The most difficult and delicate task for the negotiator as representative is 'intraorganizational bargaining': maintaining a positive relationship between the changing parameters of the negotiation and the wishes of his principals. Depending on how amenable his principals are, he may adopt an active or a passive approach to the task; but in any case he will be well advised to set his principals'

initial expectations at a realistic level, for he may need to persuade them into revised expectations as negotiations proceed. He may also need to conceal or rationalize discrepancies between his actions and their demands, and sell the deal at the end. Tacit collusion is common between opposing negotiators cognisant of the pressures to which each other is subject—for example, by engaging in setpiece conflicts and reconciliations in which neither goals nor achievements are highly valued in reality but which will 'sweeten' the principals.

Formal negotiations are generally public affairs, conducted by two teams rather than two individuals. The effect of an audience is usually to make the team wish to appear dominant, and this is likely to lead to aggressive behaviour. Studies of intergroup conflict show how a team tends to overvalue its own products, devalues those of the opposing team, polarizes towards extreme positions, distorts or restricts communication between the teams, and allows 'group think' to dull its ability to search for divergent or creative solutions. Small teams of

Page 510

negotiators who know and like each other are more likely to reach agreement—a fact frequently demonstrated in the conduct and outcome of international negotiations.

Finally, negotiations do not take place in a temporal vacuum, but usually are governed by time pressures. Early in the bargaining process the differences between the sides often appears vast; subsequently, a period of informality develops in which the parties explore for openings and leads, often amid rising conflict within each group. As the pressure to settle increases, the parties concentrate on tractable issues, with (in the case of successful negotiations) a tradeoff of the remainder in a final

'derisionmaking crisis'. Transition through these stages is often helped by the mediation of a third party, associating concessions with minimum loss of face. The process of reaching agreement is never simple, but is often and skilfully achieved for the sake of social order.

NEILL, ALEXANDER SUTHERLAND (1883-1973), British educator, born at Forfar. He described his growing up near Dundee in his last book, *Neill! Neill!*

Orange Peel. His father was a village schoolmaster and they lived in a poor, hardy, farming community. His mother strove for respectability, cleanliness, and godliness. A. S. Neill wrote vividly about his Scottish Calvinistic upbringing: there was the gruesome Sabbath, designed to instil fear of the Lord and guilt about sexual matters. Their mother found Neill and his sister 'investigating' each other's genitals when they were small children and they were severely thrashed and locked up. In Neill's life there are often indications of neuroticism: the 'learning block' as a student, the fact that the Army was prepared to discharge him on medical grounds (an act of compassion that probably saved his life), his psychoanalysis with the educationist Homer Lane and Stekel, his relationship with Wilhelm Reich (1897-1958), and his difficulty in coming to terms with sex and authority. His considerable intellectual ability, together with his intuitive love for children, in whom he probably invested a desire to compensate for his own blighted childhood, produced one of the most influential educators of modern times. His school, Summerhill, was overrun with visitors until the children complained, his books have been read by millions, and there is rarely a debate on educational principles when his name is not mentioned.

Beating children has been declared illegal by the European Court of Human Rights, and in the UK many local authorities have now forbidden the use of corporal punishment. The doubts about beating children and the restraints placed on teachers owe a great deal to the debate first fuelled by Neill's passionate advocacy of the rights of children. He defended the rebellious and the 'problem child'. At Summerhill he took on children expelled from their conventional schools. He saw that the liar, the thief, and the bedwetter had become what they were because they had received no love from their parents or their teachers. When a boy broke a window, Neill stood by his side and broke another window and so seemed to say to the child, 'I approve of whatever you may do; you are more important than a broken window'.

But there were limits to his permissiveness: what a disturbed child might do was not permitted to everyone. There were rules when the safety of children was at stake, and he could get very cross when a child misused his woodworking tools. He did not allow sexual freedom at Summerhill in case a child became pregnant, or, and this was possibly more important to Neill, in case the whole school was closed down by the authorities. The example of Homer Lane's Commonwealth and the allegations of scandal that ended it may have cast a shadow over Neill. He was rarely allowed to work with 'normal' children; most of his pupils came to Summerhill as a last resort.

Educationally the teaching methods employed at Summerhill were overtaken by progressive methods elsewhere. The pupils were largely middleclass and came from families prosperous enough to pay for the education of their children. There was not enough money to pay good salaries and staff turnover was high. Neill seemed much better at understanding the needs of children than those of adults. The great liberator of the young could also be strangely authoritarian with his staff. But the school continues, as does Neill's influence in the world outside, his love for children, his respect for

their needs and rights. His reaction to the unfeeling authoritarianism of the Scottish educational system and the more barbaric aspects of conventional public schools has made a great number of schools less oppressive and more creative. It should be added that there have been times when a false 'permissiveness' has been unjustly ascribed to Neill. It has been used as an abdication from adult responsibility, a sentimental incapacity to accept that children need boundaries and a control which is not necessarily harsh. Excessive indulgence of the child has nothing to do with freedom and can be as destructive as the forces which Neill attacked so effectively in his lifetime.

NERVE CONNECTIONS: HOW THEY ARE FORMED. In the mature vertebrate nervous system there is a very large number of neurones (1012 is the figure frequently quoted for man) and these are extensively interconnected by nerve fibres to form highly complex patterns, which are remarkably constant from one animal to another. These patterns frequently show topographic order, in the sense that one particular set of neurones (for example, the ganglion cells of the retina) 'project'

their nerve fibres to a second set of neurones (for example, the cells of one of the primary visual centres of the brain), in a fashion which preserves the organization of the first set of cells in the pattern of the connections that they form with the second set. In this manner the first set of neurones can be said to 'map' on to the second.

This phenomenon, whereby the neighbourhood relationships of cells in one set are maintained in the connection pattern formed with the other set, is common within the nervous system. It is known that many of the functions of the nervous system depend on the existence of these orderly mappings, and here we are concerned with how such nerve connections may be established during development.

Ideally, we would like to be able to investigate the development of all the individual constituent nerve fibres that comprise a particular set of orderly interconnecting neurones, together with the microenvironment through which they grow and the cells they eventually contact. This sort of approach, where the developing system is followed in detail at a single cell level, is possible only in

certain 'simple' invertebrate nervous systems, where small numbers of individually identifiable neurones exist.

In more complex vertebrate nervous systems, where the numbers of neurones involved may be very large and most of the cells cannot be individually identified, a useful approach has been to study *classes* of neurones which have orderly projections and to try to find general rules which govern the formation of their connection patterns.

The nervous system develops over a certain time, beginning in embryonic life and continuing for a period which depends on the species examined. Within any animal the development of the nervous system is not uniform; different types of neurones develop and form their connections at different times (see NEURONAL

CONNECTIVITY AND BRAIN FUNCTION). At any particular time a neurone can only form connections with other neurones that have already developed sufficiently to be able to receive such connections. As a neurone develops, its surrounding environment of glial cells, other neurones, and axons, will be unique at any given instant, and the role of this environment is crucial. What are the cues in the environment which tell the axonal growth cones where to grow and ultimately how to find their correct target structures? Various mechanisms have been proposed to account for the specific patterns of axonal outgrowth that may be observed in development. For instance: (i) There may occur the expression of particular sets of molecular components in the cell membranes of certain cells along the fibre pathway, which are recognized and preferentially responded to by the growing axons. (ii) Fibres may grow preferentially along specific extracellular substances in the environment which are manufactured by cells along the appropriate pathway and not, or to a lesser extent, elsewhere. (iii) There may be passive guidance by certain structural or spatial aspects of the environment which could lead axons towards the correct target regions. (iv) The direction of outgrowth of nerve fibres may be influenced by the differential distribution in their local environment of substances produced elsewhere in the system.

The recognition by growth cones of certain cell surface molecular markers is the basis of the chemoaffinity hypothesis expounded by Roger Sperry in the 1940s (see BRAIN SCIENCE: SPERRY'S CONTRIBUTION) and foreshadowed by the work of Cajal and Langley at the end of the nineteenth century. This idea is that fibres are guided to their targets along specific pathways by recognizing cellular cues expressed on either glia or other neurones. At the simplest level, these cues need only be expressed at a very few choice points along the pathway to be followed by the fibres. Once the fibre has reached the general region of its target structure, the recognition of a specific set of cell surface molecules could determine which cell, or cells, the fibre will synapse with.

The observations which led to this hypothesis involved the remarkable precision with which the optic nerve fibres of lower vertebrates are able to regenerate, after injury, to their original target sites in the main visual centre of the brain, the optic tectum. In these experiments the optic nerve fibres became disorganized at the point of the lesion and regrew as an abnormally ordered array, yet they nevertheless returned to their original target sites. Although numerous studies have evoked this hypothesis as a controlling mechanism for development, there is still very little direct evidence to

support it. A major argument cited against the idea of individual cytochemical labelling of neurones is the vast array of molecules which could be needed to specify all connections in the nervous system. More plausible are the ideas that specific molecules are expressed in gradient fashion such that comparatively few molecular types would be needed to establish any one topographic projection.

An alternative idea is that, by modulating the expression of surface molecules, target neurones could be made

transitorily attractive to particular ingrowing axons at an appropriate time in development.

Some of the best examples of cell recognition by neurones exist in invertebrate nervous systems. Studies in the developing insect nervous system have shown that growing axons do respond to specific cells in their immediate environment. Axons growing in the developing limb are found to contact and positively respond to a series of cells which lie along their route. It has been postulated that these cells may form a series of 'steppingstones' guiding the axons towards their targets in the central nervous system (Bate, 1976). It is as yet unclear whether these cells are specifically responded to by particular axons or whether they form a more generalized set of pathway cues which could be used by any axon which might encounter them. It has also been found that, in some cases, although selective destruction of individual 'steppingstones', or 'guidepost' cells can prevent the normal sequence of fibre growth at that time (Bentley and Caudy, 1983), it may still be possible for an approximation to the normal connection pattern to be achieved by other mechanisms (Berlot and Goodman, 1984). Thus it is likely that there is an overlapping series of contingency plans available to the system, whereby if one mechanism fails, another can take over.

Another variant on the concept of specific cytochemical recognition is the idea that subpopulations of the growing neurones may have different cell surface, and thus axon surface, properties. By recognition of these differences, a growing axon could select an appropriate route along neighbouring axons, within a common nerve pathway. Some good evidence exists for this idea of selective fasciculation. An example, again from the insect nervous system, is that the growth cones of certain fibres called the G axons in the locust are able to distinguish between the neurones they encounter. These growth cones grow as a part of a bundle of axons, but within the bundle they preferentially contact only one particular type of axon, the P axon. If the preferred P axons are eliminated before the G growth cone reaches the bundle, the growth cones will not fasciculate with other axons in the bundle and cannot extend to their targets (Raper et al., 1983). A good example of selective fasciculation within growing fibre populations has been found in the chick visual system, where experiments in tissue culture have shown that fibres from temporal retina tend to fasciculate with other temporal fibres, whereas fibres from nasal retina have no such selective preferences (Bonhoeffer and Huf, 1985).

An extension of the selective fasciculation hypothesis is the idea that ingrowing axons could establish a topographic projection by referring only to information expressed on the surfaces of adjacent axons. In other words, each axon would be able to recognize the axon surface of its neighbour neurones, and terminate in adjacent positions. For the correct orientation of a projection formed in this manner, some form of cue would be required in the target structure. This could simply be the sequence of growth or maturation of the target cells, the position at which the first axons enter the target field, or a

simple gradient function complementary to a particular subset of labels in the population of growing axons.

In the spaces that surround the cells of the developing nervous system there exists a matrix of various secreted molecules. This extracellular matrix (ECM) has been found to contain molecules which form very favourable substrates for axonal growth and for cell migration. Of these, laminin and fibronectin have been most extensively studied. Isolation and purification of these substances has enabled their axonguiding properties to be investigated in tissue culture. More recently, with the development of appropriate monoclonal antibodies, the roles of various ECM components in the guidance of axons in certain parts of the intact developing nervous system have been investigated. Since these are secreted molecules, variations in the levels of production by cells which lie along pathways subsequently to be followed by growing axons, could induce and later guide the outgrowth of the axons. The transitory expression of certain ECM components along the migration routes followed by cells from the neural crest (Thiery et al., 1982), and along axon pathways in advance of the growth cones, provides compelling evidence for such a guidance system. However, the cellular mechanisms which underlie the production of these molecules, the blueprint which would be necessary to define the positions of enhanced secretion, and the orchestration of the expression of these molecules by the cells lying along a particular pathway, are still largely a mystery.

The development of the nervous system occurs as a series of closely timed events and, as discussed above, for a particular set of axons the pathway along which they normally grow is unique for that instant. It is therefore possible that, in some cases, specific and orderly nerve connections could be formed by defined sequences of axonogenesis. Thus for a particular system the neurones could differentiate in an orderly sequence, producing waves of growing axons which then pass along a specific pathway delineated by those cells which exist at that particular time of nervous system development. This pathway could then lead the axons towards a simultaneously and sequentially differentiating target population of cells, with which they could connect in the sequence of their arrival. In this fashion the first arriving axon would connect with the first differentiated target neurone, the next arriving axon would connect with the next differentiated target neurone, and so on throughout the development of the system. The delineation of the boundaries of the pathway could rely on the physical arrangements of cells. It is known that the physical morphology of the substrate of a growing axon may influence the direction in which the growth cone extends. Alternatively, the

Page 513

cells that line the pathway may transiently express ECM components which are favourable for axonal growth.

This idea of spatiotemporal control may seem oversimplistic, but there is good evidence for such a system in the formation of ordered connections by optic axons in the water flea *Daphnia magna* (Flaster et al., 1982). In the more complex systems of higher animals, where extensive rearrangements of axons have been shown to occur, such ideas may seem improbable. However, in many 'complex' systems the initial formation of connections occurs over a relatively short distance, through a relatively uncomplex terrain, and involves few axons. Once an initial pattern of topographically ordered pathways and connections has been established, then subsequent growth of the vast numbers

of axons in such systems could follow, using selective fasciculation as the main guidance mechanism.

A further possibility, particularly in early development, is that direction of outgrowth of nerve fibres may be partly controlled by the influence of substances released from the target structure. It has been shown that embryonic mouse sensory neurones in tissue culture may grow selectively towards their appropriate targets, cultured in the same dish, and ignore inappropriate target tissue (Lumsden and Davies, 1983).

Once a growing axon has reached its target structure, how does it know precisely which cell to make contact with? We have already outlined one widely accepted theory, that each axon recognizes a specific set of cell surface molecules on the appropriate target cell. However, there is considerable evidence that nerve connections are not that specific. Indeed, each incoming axon will form many synapses with a variety of target cells, each of which will receive contacts from numerous incoming axons. Furthermore, there is good evidence to show that these connections are continually being broken and reformed, not only as systems develop, but also in what, in the past, has been considered to be the adult, 'hardwired' system. The idea of specific connections must therefore be seen as relative and not absolute. It seems that axons are directed to certain regions of their target structures, producing there a roughly ordered array. When the axons reach the region of their target group of cells, some unknown signal instructs them to stop extending as single axons and to produce multiple branches, each of which bears a mini growth cone. These axon arborizations explore the target region, forming connections with many cells in the appropriate area. This initial exuberant pattern of connections will be topographically ordered, but only at a somewhat coarse level. As development proceeds, the pattern of connections is refined by retraction of the most exuberant branches and the consolidation of synaptic contacts with cells in a very localized region. In this fashion each axon will form contacts with target cells also contacted by axons which arise from its neighbouring neurones.

The mechanisms which are responsible for this fine tuning of the initial connection pattern are believed to involve the function of the system. One idea is that synchronous nerve impulse activity may stabilize connections. If an array of neurones is locally stimulated, neighbouring neurones will initiate impulses at the same time, while other cells in the array will be silent. If several of the stimulated neurones contact the same target cell, then it will receive an increased number of simultaneous impulses and it is highly likely to respond. In contrast, a target cell which has only few contacts from the stimulated neurones and many contacts from unstimulated neurones, will remain silent. In time, contacts which rarely cause their target cell to respond may become redundant to the function of the system and eventually be withdrawn, so that each neurone then concentrates its contacts on those cells where it achieves maximal effect. Such a mechanism could gradually consolidate the contacts made by neighbouring neurones on neighbouring target cells.

Evidence for these ideas comes from studies of the development of nerve connections in the mammalian visual system. Initially the fibres from each eye form superimposed (Rakic, 1977) but topographically ordered projections to the lateral geniculate nucleus. During the early life of the animal, these overlapping projections segregate to form eyespecific bands of terminations. If nerve impulse activity is blocked during this phase of development, the normal segregation of optic axon terminal arbors does not occur (Schmidt and Tieman, 1985). More evidence comes from studies of

regeneration in the lower vertebrate visual system. As previously discussed, regenerating optic axons in fish are able to reform precise retinotopic connections. This process occurs gradually, with the initial connections forming a grossly retinotopic projection which is refined over a period of weeks. The blocking of nerve impulse activity during this period has been shown (Meyer, 1983) to impair the normal sequence of refinement of the retinotectal projection map.

NERVOUS SYSTEM. For the neurologist, there is no such thing as the mind. There are certain activities of the brain endowed with*consciousness that it is convenient to consider as mental activities. Since one expects to find a noun adjoined to an adjective, one supposes that there must be a mind expressing itself in a mental way. But the requirements of language and of logical thought are not always the same; demands of syntax may lead to errors in thinking.

The central nervous system is the physical substance that provides its possessor with genetically determined ways of behaving and also ways of changing this behaviour. What has been inherited is structure, studied as anatomy, and the working of this structure, studied as physiology. It is often convenient, and often misleading, to categorize some parts of the functioning as mental activities. But this does not imply that behind this functioning is a structure that could be called the mind.

The life of animals consists of receiving and responding to information. In animals made up of more than a few cells, this requires a nervous system. In vertebrates, the nervous system consists of three parts: afferent nerve fibres with their receptors, efferent nerve fibres with their muscles and glands, and the central nervous system, formed by the spinal cord and the brain.

The neurone. The nervous system is made of cells, like every animal tissue. The essential cell is a nervecell or neurone. Neurones are the largest cells in the body. A small neurone may measure about 3 micrometres, but a large one stretches for over 1 metre, and far more than that in a whale or an elephant.

Fig. 1.

Photograph of a three-dimensional model

of a neurone, showing the cellbody and

dendrites.

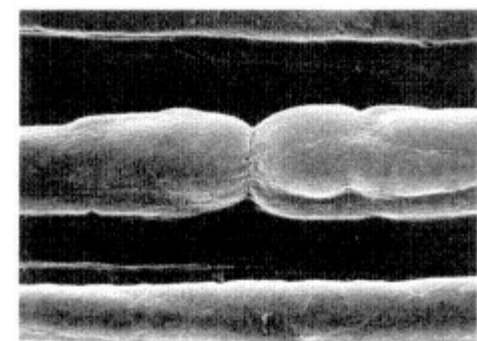

The neurone is considered to have three parts: the cellbody, the dendrites, and the axon. The dendrites are thin prolongations of the cellbody (shown in Fig. 1). Most sorts of neurone have one prolongation far longer than the others; this is the axon, the telegraph wire of the neurone, taking the message from one neurone to another or else to the muscle or gland that it supplies. The boundary of the neurone is a membrane, having certain properties on which the functioning of the nervous system depends. The axon with its surrounding membrane is called a nerve fibre. The ending of the nerve fibre is called, quite simply, the nerve ending or nerve terminal.

Fig. 1 is a photograph of a scale model of a neurone; it gives a better idea of the three dimensions of the cell than does a photograph taken down a microscope. The cellbody and the dendrites in actual fact would be covered with the nerve endings of other neurones.

All the neurones in the central nervous system of man are present at birth. As the baby grows, they enlarge and grow, the dendrites spread further, and the axon lengthens; but neurones, unlike most cells, do not divide and reproduce. Thus they are irreplaceable; and any neurones that we lose from accident or disease are lost for ever and we are so much the poorer.

Vertebrates have two kinds of neurones, those with myelinated and those with nonmyelinated nerve fibres. Myelinated fibres have layers of a lipoprotein called myelin folded round the axon; nonmyelinated fibres do not have these layers of insulating material. The myelin sheath is not continuous throughout the length of a nerve fibre;

it is broken at little gaps, called the nodes of Ranvier or just nodes (shown in Figs. 2 and 3). Fig. 2 shows a myelinated fibre dissected out of a nerve of a baboon. It is the same as one from a human being. The arrows point to the nodes of Ranvier. Myelinated nerve fibres are shown at far greater magnification and with a good indication of three dimensions in Fig. 3. This photograph is focused on the external surface of a node of Ranvier, which is in the large fibre in the middle.

Receptors. The way into the central nervous system is through the receptors. They are connected to

the central nervous system by peripheral nerves; and peripheral nerves also connect the central nervous system to the muscles, to allow the animal to stand and move. The central nervous system of vertebrates is made up of the spinal cord and the brain. The spinal cord does not fill out the length of the vertebral column, for it is only about 40 centimetres long. The brain is an immensely complex and convoluted development of the cranial end of the spinal cord.

Receptors are natural transducers, converting the kinds of energy that they can receive into electric current. They can be classified as exteroceptors, reporting events in the outside world, and interoceptors, reporting the inside world of the body itself. They include receptors in muscles, tendons, and joints, the alimentary canal, and the bladder. There are receptors recording a steady state and changes occurring in that state; these include thermoreceptors, which report warmth and cold. Other receptors are silent until something new occurs. Among these are the receptors of the skin, which take notice of pressure and touch, pulling and stretching. All over the body are nociceptors, receptors reporting events that are liable to damage the body. There are chemoreceptors. Some of these are in the alimentary canal, including the nose and tongue. They report the arrival of molecules of substances that provide us with*smell and*taste. Further along the alimentary canal, they work without involving our conscious awareness; they serve to adjust the correct enzymes for the digestion of food.

Some receptors are formed of special cells; others are the nerve fibres themselves, unattached to any special endorgan. In the skin many receptors are naked nerve fibres, others are nerve endings surrounded by capsules of cells, looking like the layers of an onion surrounding the growing tip. Some receptors are massed together to form a sense organ, such as the eye or the ear. Others are scattered over a large area, for instance those of the skin or the viscera. If it is desirable to know the source of distant stimuli, one needs to have two separated sense organs. They then form the base of a triangle, the apex of which is the distant stimulus. When we are uncertain where a sound is coming from, we alter the angles of the base of the triangle, by turning first one ear and then the other in the supposed direction of the sound (see BINAURAL HEARING).

Not everything that a receptor receives is sent on to the higher levels of the central nervous system. Processing of the data begins in the sense organ and continues at the entrance to the spinal cord or brain and throughout the central nervous system. The brain itself controls its own input. The manner and purpose of this control is not yet known and can only be guessed at. It may be that if a certain location of the input is important at a particular moment—say something is damaging or hurting Page 516

the back of the left hand—then the input from this region might have to be facilitated and that from other regions reduced or blocked. A mechanism such as this could form the first link in the chain of mechanisms of paying*attention.

All that the receptors report does not come to consciousness. Because we are occupied with what is happening around us, we tend to forget that many parts of the spinal cord and the brain are being informed about stimuli which reach no conscious level. Merely to maintain an upright posture depends on the reporting of the receptors of joints, muscles, the skin, and the organs of balance in the

inner ear; this is going on all the time and none of it usually becomes conscious.

Not all of the information that the eye supplies to parts of the central nervous system makes us see something. There are visuomotor reflexes that contribute to walking. In many birds and mammals, the cycles of life depend on the amount of light received. Lengthening periods of daylight or the days drawing in have their effects on the arrival of puberty and periods for procreation. They also cause hibernation or aestivation, and tell the animal when it is time to wake up and get moving.

Somehow the amount of light is recorded and appropriate behaviour is brought about.

The sense of smell is so important to many animals that it is used for communication. Odoriferous substances, put out by animals in order to signal to others, are called pheromones. Sex pheromones are very commonly used. They may play a minor role in human sexual signalling. Certainly the attraction of the female rhesus monkey for the male depends entirely on her smell, and the male monkey emits a smell attractive to the female. Man has about thirty million olfactory receptors in each nostril, and they can respond to about twenty to thirty primary odours. The other smells that we can smell are thought to be mixtures of these primary odours.

How the nervous system sends messages. The behaviour of the central nervous system consists of passing messages from one lot of neurones to another. The message itself is sent in the form of a Morse code consisting only of dots. As the dots are always grouped together, they are usually referred to as a volley of nerve impulses, or just as a volley. The nerve fibre conducts impulses in one direction only. Afferent nerves outside the central nervous system conduct impulses towards the spinal cord and brain, and efferent nerves conduct them away from the central nervous system to the muscles and glands. Within the central nervous system, each nerve fibre is a one-way street.

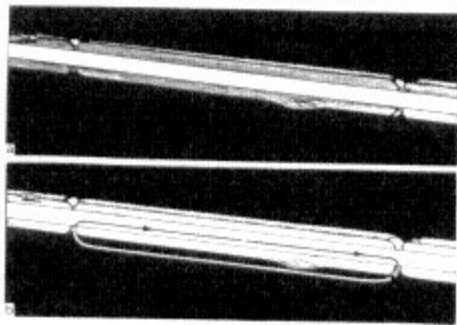

One can talk of taking messages, for the nerve impulse is an instruction to the cell that receives it to do something. The message or impulse is an electric current, somewhat like the current sent along a telegraph or telephone wire. In the system invented by man, the electrical events take place in metal, in long thin wires. In natural systems, the electric current is carried by a flow of ions in fluid. In the telegraph, the current is carried passively along the wire; in the natural system, the nerve fibre itself generates the current that spreads along the fibre. The nerve impulse depends on the physical characteristics of the membrane surrounding the axon. This membrane is a semifluid lipid, permeable to certain hydrated ions and not to others. It is very permeable to potassium ions, less permeable to chloride ions, and far less permeable to sodium ions. These differences in permeability cause a different concentration of ions on the two sides of the membrane; and the different concentration gives rise to a difference in potential between the inside and outside of the axon. This potential difference, the inside being electronegative, the outside electropositive, is called the *resting potential*. The nerve impulse is a sudden, rapid, transient change in the permeability of the membrane to sodium ions. These positively charged ions pass through the membrane of the axon from the extracellular fluid, reversing the charge on the membrane from negative to positive. In this state, the membrane is more permeable to potassium ions, and so they flow out of the axon, through the membrane into the extracellular fluid—a process that brings back the former state with the inside negative and the outside positive. If this did not occur, the membrane could not be excited again. The passage of

sodium ions carrying a positive charge is referred to as depolarizing the membrane, and the return to resting conditions is called repolarizing the membrane.

What has so far been described is how a nerve fibre at rest is excited. The next question is how this minute region of excitation spreads along the nerve fibre. The transient increase in permeability is induced by a potential change coming from a receptor or from the nerve endings of another nerve fibre. The increase in permeability causes current to flow between the spot that has become more permeable and the adjacent region of membrane. This circuit of current allows positively charged ions to pass through the membrane at the adjacent region; and so the cycle of events occurs in these neighbouring regions of the membrane. By such minute steps, the current spreads along the membrane of the axon. This spreading depolarization is called the *action potential*. The process takes place in one direction only, ahead of the region that has just been activated. The reason is that the membrane cannot be depolarized until it has been repolarized: in other words these electrochemical events cannot be repeated until the previous resting state has returned. Thus it is inevitable that the spreading permeability change will pass along the membrane only in front of the region that has just been active.

Similar events occurring at the receptor are called the generator potential or *transducer potential*. They are set off by the stimuli to which that receptor is sensitive.

The generator potential starts

Page 517

off the action potential along the afferent nerve fibre.

The most primitive and smallest animals consisted of only a few cells with nervenets formed of only nonmyelinated fibres. The faster conduction of impulses that became necessary as animals became larger, was not achieved by making nerve fibres with greater diameters: a new step in evolution occurred, the covering of nerve fibres with myelin sheaths. The conduction of the nerve impulse in myelinated fibres is different from that in nonmyelinated fibres, and the continuous spreading of the current so far described is the mode of conduction in nonmyelinated fibres. Conduction in myelinated fibres is called *saltatory conduction*, as the current jumps from node to node.

In saltatory conduction (illustrated in Fig. 4b) the current is also due to the passage of ions through the membrane; but in this case the membrane is covered by lengths of insulating material, the myelin sheath. The nodes are little breakages in this insulation. The current spreads along these fibres by

passing through the noninsulated nodes, in through one and out through the next. This is a much faster way of conducting impulses than continuous conduction.

Once the electrical events have been started in a nerve fibre, they spread along it to its end. They are selfpropagating, and nothing stops them, short of damage to or cutting the nerve fibre. A nerve fibre always produces the same amount of current; for the current is related to the resistance, and the resistance is inversely related to the radius of the fibre. The rate at which the impulses are conducted is between 0.5 and 2 metres per second in the case of nonmyelinated fibres and from 2 to 120

metres per second in the case of myelinated fibres.

There are two ways in which nervous systems differ in principle from telephones and cables. They consist of inhibitory as well as excitatory neurones; and they are spontaneously active. The communication systems invented by man are excitatory: either you send a message or you don't. If you were to receive an inhibitory telegram, it

Fig. 4.

Propagation of the action potential in a myelinated

nerve fibre. a. Diagram of the axon with its myelin

sheath and two nodes of Ranvier. b. Current circuit

through the nodes.

would just say 'Keep quiet!' In the central nervous system, excitation and inhibition tend to cancel each other out. A neurone fires off an impulse when its threshold of excitability has been exceeded. Excitatory neurones tend to fire an impulse, inhibitory ones tend to stop it firing.

The nervous system starts being spontaneously active from an early moment *in utero* and continues until death. In manmade communication systems, nothing is happening until a message is sent. Into the mass of active neurones of the central nervous system, volleys of impulses are sent. It will be seen that inhibitory neurones are needed: the spontaneous activity may need to be quietened down as well as be increased.

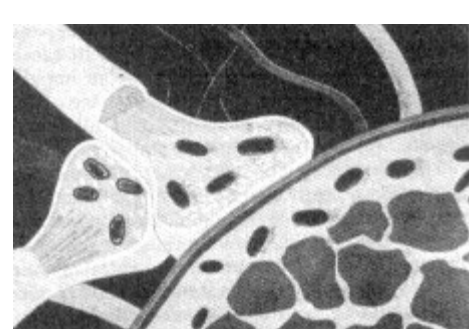

Between the nerve endings of one neurone and the cellbody and dendrites of the next, there is a minute gap; it is about 200 nanometres wide in most cases. This region where the message is passed from one neurone to the next is called the synapse, after the Greek word for 'clasp', and the gap is called the synaptic gap or cleft.

Structures and functions are spoken of in relation to the synapse as presynaptic and postsynaptic. The synapse is like a diode, conducting in one direction only. Any change in a message has to be made at a synapse, for once the impulse is travelling along a nerve fibre, it generally continues to the next synapse.

Many factors have an influence on the firing of a neurone: there is its threshold of excitability, its local chemical environment, and the sum of excitatory and inhibitory impulses it receives within a brief period of time. Each nerve impulse delivers a constant amount of excitation or of inhibition. The amounts of both are increased by increasing the number of impulses sent in a brief time. Once the postsynaptic neurone has fired an impulse, its excitation has to be raised to make it fire again. The excitatory effect of an impulse arriving on a motor neurone that works a large muscle of a cat's limb lasts 5 milliseconds. In this neurone, the relation between the intensity of current supplied to the neurone and the neurone's rate of firing off impulses is linear. In some other neurones, the relation is that of an Sshaped curve. In some places in the central nervous system, arriving excitatory impulses keep the postsynaptic neurone always ready to fire; only a few more impulses arriving will then fire it off.

The cellbody, like the human body, is not equally excitable all over. Out on the ends of the dendrites, the membrane is relatively inexcitable. Excitation delivered there may never fire the neurone but it may be sufficient to increase the excitability momentarily; thus impulses continually delivered far out on dendrites may keep the membrane of the cellbody at a certain threshold of excitability.

The kinds of excitation and inhibition discussed so far are called *postsynaptic potentials*. Another kind of inhibition is presynaptic inhibition. It is named presynaptic as it stops a nerve fibre delivering

Page 518

Fig. 5.

A model of nerve terminals to show presynaptic inhibition. The nerve terminal coming from the left lower corner inhibits the nerve terminal on which it is ending before this nerve fibre can deliver its impulses to the cellbody on which it is ending.

its full amount of excitation just before it reaches the synapse where it ends. It is illustrated in Fig. 5. The fibre coming in from the bottom left corner inhibits the fibre on which it ends before that fibre

delivers its quantum of excitation to the cellbody. Its effect is to cause partial or even complete blocking of the message. This blocking of the message in a fibre is an exception to the statement made above—that once the nerve impulse is travelling along a fibre, it continues to the end. As far as is known, presynaptic inhibition is a function only of excitatory neurones; there is no presynaptic inhibition of inhibitory neurones. Recent investigations lead one to conclude that dendrites of different neurones in juxtaposition can also influence each other.

With such a limited repertoire of interaction between neurones, it is surprising how complicated the total picture of neuronal activity can be. There are two common patterns of relations between neurones and groups of neurones. Messages can be spread far and wide from a few neurones or they can be channelled into a few pathways and sent on to only a few neurones. The first is called divergence and the second convergence. To give some idea of the figures involved, one might take as an example the large neurones known as Purkinje cells, after the anatomist who first described them early in the nineteenth century. On to each of these neurones there come 200,000 nerve endings from many other neurones: this is convergence. And a single neurone called a granule cell sends branches to 300450 Purkinje cells: that is divergence.

There are other patterns of organization. One is surround or lateral inhibition. When a central or linearly arranged group of neurones is excited, there is concomitant inhibition of the surrounding neurones. This inhibition is strongest for the neurones immediately adjacent to those being excited and becomes weaker for the more distant neurones. The more strongly the central group of neurones is excited, the stronger will be the inhibition of the surrounding neurones. This kind of organization has the effect of emphasizing contrasts. It was first discovered in the retina, where it is probably used to accentuate the edges and boundaries of what is seen. This reciprocal organization is not static. If the source of the central excitation is, for instance, a stimulus moving along the skin, then the line of excitation and surrounding inhibition will move; the moving stimulus on the skin excites new neurones as it moves, and these excited neurones inhibit different surrounding neurones as they themselves are turned on and off.

Excitation and inhibition at the synapse are electrical occurrences similar to those in the nerve fibre. There is a sudden increase in permeability of the postsynaptic membrane, and hydrated ions pass through it. Presynaptic inhibition is due to the flow of ions into the presynaptic fibre just before the nerve ending.

The response of any neurone depends on the following factors: the region of the membrane that receives nerve impulses, the temporal scatter of arriving impulses, the previous effect of hormones and endogenous peptides, and the chemical composition of the fluid surrounding the neurone. All these factors together determine the binary response of the neurone, to send an impulse or to remain silent.

Even though inhibition and excitation of the next neurone at the synapse depends on the passage of ions through the membrane in a fashion similar to the events of transmission along the nerve fibre, there are important differences. When an impulse reaches the end of a nerve fibre, a chemical substance is put out into the synaptic gap. This substance unites with the protein of the postsynaptic

membrane, and the membrane with this substance becomes permeable to some hydrated ions and not to others; according to which ions pass, depolarization or excitation, or hyperpolarization or inhibition occur. The regions of the postsynaptic membrane where these chemical substances act are known as receptor sites; and the substances are called neurotransmitters or transmitters. The transmitters are synthesized in the cellbodies of neurones; they are then passed along the nerve fibre and stored in vesicles in the nerve endings, remaining there until a nerve impulse arrives. The impulse liberates a constant amount of neurotransmitter into the synaptic gap; this passes across the gap and unites with the receptor site of the postsynaptic membrane. Whether excitation or inhibition occurs is determined by the size and shape of the pores of the receptor site. Smaller pores allow potassium and chloride ions to pass, resulting in inhibition, and larger pores allow sodium and chloride ions to pass, resulting in excitation. Once the transmitter has reacted with the postsynaptic membrane, it is inactivated and/or taken up again into the presynaptic nerve ending.

Neurones and their nerve fibres are often named according to the transmitter substance they syn

Page 519

thesize and emit at their endings. So, for instance, one has cholinergic neurones, releasing acetylcholine, and noradrenergic neurones, releasing noradrenaline.

Acetylcholine is the transmitter that works the muscles of the body; noradrenaline works muscles of the uterus and the blood vessels. The muscles of the alimentary canal are made to contract by many transmitters, including acetylcholine, noradrenaline, and many peptides.

In vertebrates, it appears that all nerve fibres act by putting out transmitters at their endings. At the various synapses in a chain of nerve fibres in the central nervous system different transmitters will be emitted. Also, outside the central nervous system, different neurones exert their effects by putting out their transmitters, making muscle fibres contract or glands secrete. A purinergic neurone, which has a short axon about 1.5 centimetres long, may be excited by a cholinergic nerve fibre, secreting acetylcholine; and the cholinergic neurone will have been excited by noradrenaline.

Parts of the nervous system working together to carry out a certain function often use the same transmitter for all the neurones concerned. Dopamine, for instance, is secreted by neurones concerned with waking the brain from sleep. Noradrenaline is the transmitter used in the hypothalamus for controlling body temperature.

Neurotransmitters are being discovered all the time, and an important research territory is that of peptides and hormones formed in the body that can act as neurotransmitters. (See DOPAMINE NEURONES IN THE BRAIN, AND NEUROPEPTIDES, for further discussion.) **Moving.** Plants are fixed, animals move. Here we discuss the activities of animals and the movements of various parts of their bodies.

Movement is due to the contraction of muscle fibres, and muscle fibres are caused to contract by impulses arriving in the peripheral nerves. If the nerve running to a muscle is cut, the muscle is

paralysed. The nerve fibre goes to the neuromuscular junction, which is a synapse between the nerve ending and the membrane covering the muscle fibre. From this region, electrical events similar to those of the nerve impulse spread over the membrane of the muscle fibre, causing the proteins of muscle to contract.

In vertebrates, the basic patterns of movement are organized in the spinal cord. For most quadrupeds—and this includes the crawling baby—the spinal cord arranges the basic pattern of running or walking: when a forelimb flexes, the opposite hindlimb extends, the other forelimb extends, and the remaining hindlimb flexes. During a movement, the muscles around a joint work according to a pattern of reciprocal innervation; when the limb is used for standing, the muscles around the joint tend to keep contracting together. Reciprocal innervation is organized so that as one group of muscles, say the flexors, contract, the antagonist group, say the extensors, are relaxed. It is the same with the muscles used for breathing. When the muscles used for breathing in, contract, those for breathing out are relaxed.

Whether we stand, run, hop, or crawl, all the activity of the central nervous system finally ends with activating, or not activating, motor neurones. For this reason C.

S.*Sherrington called the motor neurone the final common path. Whatever happens to the body, impulses are sent to the central nervous system, they go round and round in the brain, and they come out there, at the final common path of motor neurones.

All animals have inherited certain ways of responding to the situations they are likely to encounter. The more simple an organism, the more inevitable the behaviour will be; and the observer would not think of the animal as choosing how to behave. A minute organism endowed with positive phototaxis must go towards a light; another species, inheriting negative phototaxis, must escape from it.

The simplest and most automatic response to stimulation is a reflex movement. The word 'reflex' was introduced early in the nineteenth century by a British neurologist, Marshall Hall. He chose this word as he thought of the muscles as reflecting the stimulus, much as a wall reflects a ball thrown against it. By 'reflex' he meant the response of a muscle or several muscles to a stimulus that excites an afferent peripheral nerve. Since that time the meaning has been enlarged. It is now used to mean an inborn, immediate response of muscles or glands to a particular stimulus, involving the central nervous system.

Even a simple reflex, with only one synapse, such as the monosynaptic stretch reflex, is not the same on every occasion. This has been realized, and often forgotten, for about a hundred years. There are many factors influencing the one synapse between the afferent and the efferent nerve. There is the local and general state of excitability, and the number of reflex responses that have preceded the one being observed. For instance, if an identical stimulus to evoke a reflex response is repeated regularly several times a second, the response either increases or decreases. If the stimulus is repeatedly applied for many minutes, the local reflex response decreases and finally stops altogether.

There are many kinds of behaviour seen in animals lower in the evolutionary scale than mammals that

in fact are reflex responses, though they appear not to be. The toad, for instance, has only two kinds of behaviour in its repertoire towards any moving object that it sees: it either turns towards it to snap it up, or else it turns away to escape. These are both reflex responses; which one occurs is related to the size of the object seen. Snappingupfood behaviour is the answer to small objects moving in the field of vision, and avoiding and fleeing is the answer to large moving objects. To the naive observer, these actions might well

appear as behaviour based on choice, the animal making a decision what to do.

Most kinds of behaviour of the higher vertebrates are neither entirely reflex nor entirely subject to deliberation and decision: they have elements of both. When someone inadvertently burns you on the leg with a cigarette, a volley of impulses is sent off to the spinal cord from the skin, and nerve impulses continue to fire off for thirty minutes or so. From the local region of spinal cord, impulses are sent to many other parts of the spinal cord and brain. Some regions get the information before others, and some centres react automatically while others react only after impulses have been received from various higher parts of the brain. The sending of information to various parts of the brain is the physiological substratum for the functions classified as psychological, such as making a decision after pausing for deliberation. The first response to the burning cigarette is likely to be a flexion and withdrawal of the burnt leg with extension of the opposite limb to support the weight of the body. The lower parts of the brain are informed of the rapid movement of the lower limbs so that they adjust the posture for standing on one leg to remove the other from the damaging stimulus. A further necessary part of the reaction is to cause pain. In the brain all sensory information is integrated, the input from the eyes, the ears, the nose, the skin. The brain recognizes that the object causing the burn is a cigarette. The highest levels of the brain are needed to arrange behaviour related to the circumstances. The brain relates the new event to remembrances of things past.*Memory is used. Parts of the brain compare this new event with previous experience and note whether it is new and unfamiliar or something already known.

The first reflexes develop in the womb, as the structures are formed. The very earliest reflex responses occur around the mouth; the lips are turned towards the point stimulated. After birth, other reflex responses are added to the repertoire.

The essential reflex for maintaining posture is the stretch reflex; it is a servomechanism used to keep the muscles contracting to the right degree. When the muscle is pulled on and stretched, receptors within the muscle are excited and send impulses to the spinal cord. The nerves from the receptors of these muscles go to the motor neurones working the muscle and make it contract. When the stretch is removed, the receptors stop firing, the stimulus to the motor neurones of the muscle has gone, the motor neurones stop firing, and the muscle relaxes. Thus stretching a muscle makes it contract, and releasing it allows it to relax. In the stretch reflex, there is only one synapse, that between the afferent nerve fibres from the muscle receptors and the motor neurones working the muscle.

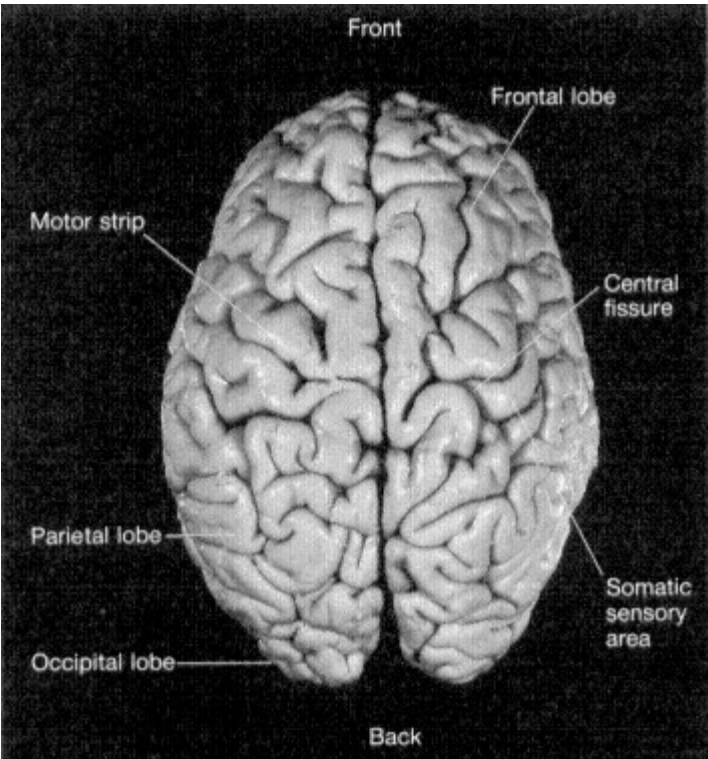

A baby learns to sit up when the organs of balance in the internal ear have established reflexes with the motor neurones working the muscles of the trunk and limbs.

The basic reflexes for standing, crawling, sitting, walking, and running depend on builtin circuits of neurones in the spinal cord, connected to circuits in the centre of the cerebral hemispheres and the cerebellum. The cerebellum is kept informed about the activity of all muscles, about acceleration and deceleration affecting the whole body, and about all other inputs to the central nervous system. As soon as the spinal cord starts performing a movement, impulses are sent up to the cerebellum and continue to be sent throughout the movement, so that the cerebellum is kept informed how the movement is progressing. For the cerebellum is an error-measuring device that compares the actual performance with the programme which it receives from the cerebral hemispheres.

Most movements are programmed by the brain, and they use lower-level reflex arrangements as their components. When you do touchtyping, the impulses leave the brain, programmed in time and place to hit the keys in order. Once the impulses are on their way, they cannot be interrupted. You know when you are going to type the wrong letter or the letters in the wrong order, and out they come, wrong; the knowledge comes too late to interrupt the planned movements. (See CHUNKING.) The movements organized by the cerebral hemispheres depend on impulses sent down tracts of nerve fibres to the spinal cord. Some of these tracts have synapses on the way; others have no synapses until they are near the motor neurones. There is one large tract called the corticospinal tract; it is shown in Figs. 9 and 11. It is mainly a motor tract, though some of the fibres go to the posterior horn, which is an afferent part of the spinal grey matter. A recent development in evolution, it has reached its highest development in man and is used for carrying out the finest and most delicate movements of hands and feet, fingers and toes.

The spinal cord and brain. It is now necessary to describe some of the anatomical features of the spinal cord and brain. The spinal cord consists of a central region of grey matter, made up largely of the cellbodies and dendrites of neurones, and a surrounding ring of white matter. The white matter consists of tracts of nerve fibres descending from and ascending to the brain. The input from the peripheral nerves of the body is delivered to neurones of the grey matter of the spinal cord. These data are then processed at this level, and the resultant nerve impulses are sent along the spinal tracts to various regions of the brain. The input from the organs of the special senses—as vision, hearing, smell, and taste are called—goes to the grey matter of the brain. The brain, like the spinal cord, consists of grey and white matter, but most of the grey matter is on the outside and the white matter inside; though there are some large masses of grey matter inside the cerebral hemispheres and cerebellum as well.

The brain is really an enlargement and opening out of the cranial end of the spinal cord. The first,

Page 521

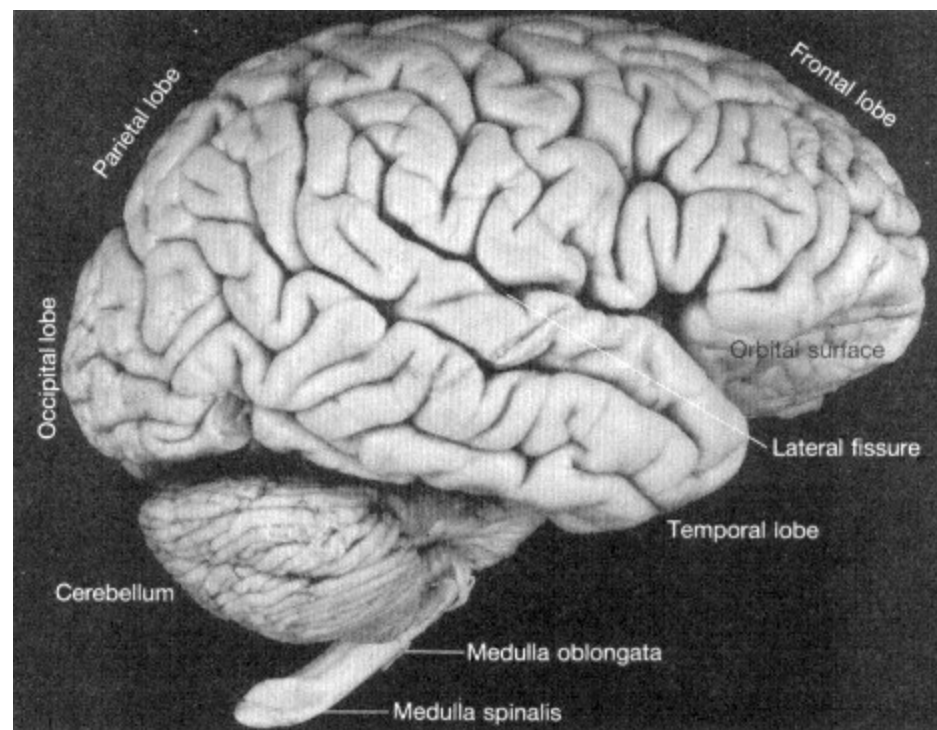

Fig. 6.

Human brain seen from above.

slightly enlarged part is called the medulla oblongata (Figs. 7 and 8); the Latin term for the spinal cord is medulla spinalis. The medulla oblongata and the pons (Fig. 8) make up the hindbrain. From the roof of the hindbrain the cerebellum developed, first becoming large and important in birds. Further forwards or, to use the anatomical term, further rostrally (towards the beak) is the midbrain, and rostral to the midbrain comes the forebrain. When you take the brain out of the skull, what you first see are the two cerebral hemispheres. Each cerebral hemisphere is divided into lobes; they are called frontal, temporal, parietal, and occipital. Many anatomists also recognize a limbic lobe, which will be referred to later. The lobes are shown in Figs. 6, 7, 8, and 11.

The most posterior ridge or gyrus of the frontal lobe is the motor strip; it is the main source of the corticospinal tract. Most of the fibres of this tract go to the opposite side of the spinal cord, for each cerebral hemisphere mainly controls the opposite limbs. Many of the fibres marked as going to and coming from the cerebral cortex in Fig. 9 would be the fibres of the corticospinal tract. As they descend through the brain, they become collected into a narrower space; most of them cross over from one side to the other as they enter the spinal cord. The gyrus from which most of these fibres come is called the precentral gyrus; behind it is the postcentral gyrus, and between the two is the central fissure (marked in Fig. 6). The postcentral gyrus is the most anterior part of the parietal lobe. It is the somatic sensory area, a primary area for tactile and kinaesthetic input. There is another fissure, more prominent than the central fissure, the lateral fissure, shown in Fig. 7. It is the boundary between the temporal lobe below, and the frontal and parietal lobes above.

Once the cranium has been sawn through, the brain is easily lifted out of the skull. To remove it, one has to cut through the stalk of the pituitary (Fig. 8) and all cranial nerves, and also divide the medulla oblongata from the spinal cord. The cranial nerves were described and numbered from the front backwards by Thomas Willis in the seventeenth century. The first nerve cannot be seen in Fig. 8, as it was cut through when the brain was removed. It is the olfactory nerve, and is made up of thousands of nerve fibrils running vertically up from the cavity of the nose into the olfactory bulb (shown with most of the structures mentioned here in Fig. 8). From the olfactory bulb, impulses for smell are sent along the olfactory tract to the deeper parts of the temporal lobe. In Fig. 8, the second or optic nerve and the fifth or sensory nerve from the face can be seen. The pituitary gland is

Page 522

Fig. 7.

Human brain seen from the right.

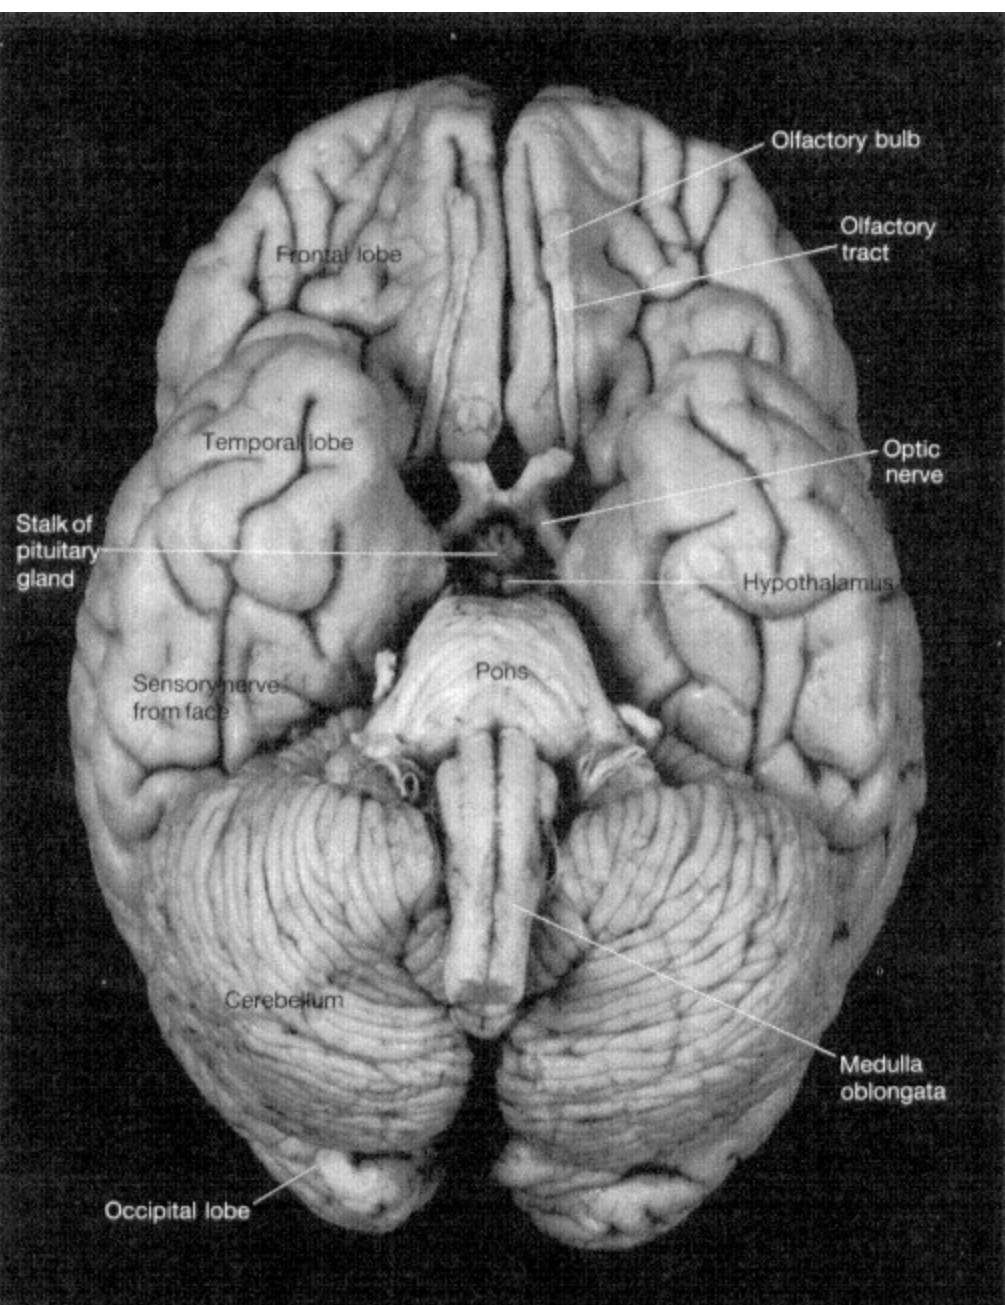

just behind the optic nerve. Tumours of the pituitary are liable to press on the optic nerve fibres and cause disturbances of vision, and, if they are not removed, blindness.

The cortex of the cerebral hemispheres is made up of six layers, the neurones being arranged in most places in columns of six. Vast numbers of nerve fibres run into these layers, and similar vast numbers leave them. The tracts in which these bundles of nerve fibres are collected are shown in Fig. 9. This figure shows another large mass of fibres, the optic radiations, passing backwards from the midbrain to the occipital lobe, to reach the primary visual area of the cortex. The pons is cut through the midline in this dissection; it is a bridge taking fibres from one side of the hindbrain to the opposite cerebellum. The great mass of fibres going to and coming from the cerebellum is also seen in this figure, as a large white band in the centre of the cerebellum.

There is a mass of interconnecting neurones with short axons throughout the core of the brain, named the reticular formation; a part of it is shown in Fig. 9. This is a very old part of the brain, being an essential structure for working vital functions. It organizes breathing, controls the heart, blood vessels, bloodpressure; it is concerned with sleeping and waking, with relaxation, and with the opposite state—vigilance and alertness. This system stops all the input from receptors reaching the anatomical substrate of consciousness during sleep; wakens us when the input is apparently urgent.

The two cerebral hemispheres are not equal and identical, neither morphologically nor physiologically. There is probably an inborn propensity for the two hemispheres to develop differently, and these differences are increased by experience and learning.

Each cerebral hemisphere organizes the movements of the opposite limbs, and the activity of each is coordinated by fibres passing across the large bridge, formed of nerve fibres, called the corpus callosum (shown in Figs. 11, 12, and 13). The two hemispheres are not equal partners in organizing movements; the left is the leading one, just as it is for speech. It keeps the store of learned skills. It programmes most movements, and it directs the right hemisphere to control the right limbs while it controls the left ones. If the great bulk of nerve fibres through the corpus callosum is divided, the movements of the right limbs, controlled by the left hemisphere, remain normal, but programmed movements of the left limbs become abnormal in a strange way. The afflicted person cannot comb his hair when asked to do so, for instance, but makes vague movements similar to combing movements, perhaps in the air above his head. When asked how he would point the way, he

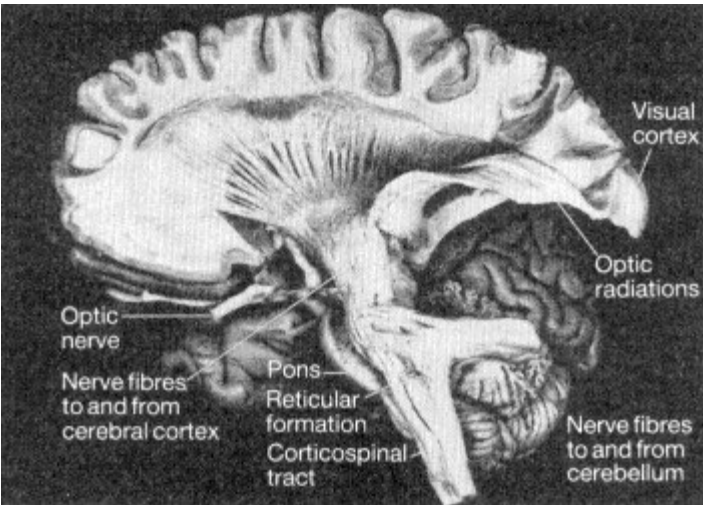

Page 523

Fig. 8.

Human brain seen from below.

may move his arm in an inadequate manner or just raise it vaguely in some direction. Although he can carry out more automatic and reflex movements, such as standing and sitting, quite normally, he cannot trace a circle on the ground with his foot nor point his toe when asked to do so. But all of these movements are performed quite normally by the right limbs. As the right hemisphere does not direct the left hemisphere, a lesion of the right hemisphere causes some paralysis of the left limbs but

Page 524

Fig. 9.

The human brain dissected to show the tracts of nerve fibres going to and coming from the cerebral cortex and the cerebellum, and the optic radiations, which are fibres running from the midbrain to the visual cortex of the occipital lobe.

has no effect on the limbs controlled by the left hemisphere. (For further discussion, see **SPLITBRAIN AND THE MIND.**) **Types of muscle.** The movements of the body are not only the movements of the whole body in space; there are the movements of organs of the body, movements of the heart, the intestines, the bladder, the pupils of the eyes. The muscles working these organs are different from those making up the trunk and limbs.

There are two main kinds of muscle, smooth muscle and striated muscle, the names describing their appearance under a light microscope. One may make the generalization that smooth muscles work entirely automatically, without our having much influence on them; and striated muscles are the muscles we use when we intend to do something like getting out of bed or jumping over a fence. As we have seen, muscles are made to contract by receiving impulses from nerve fibres.

Striated muscles are supplied by somatic nerve fibres, and nonstriated muscles by nerve fibres of the autonomic nervous system.

The autonomic nervous system. This consists of two parts, the sympathetic and parasympathetic systems, which cannot be classified as being either central or peripheral, as they are both. The autonomic system is always active, though at any time one part may be more active than the other, each being activated by emotion and behaviour depending on emotion. The sympathetic system is responsible for temperature regulation, contributes to the behaviour of threat and aggression, dilates the pupils and makes the hair stand on end, and controls the distribution of blood throughout the body by dilating or constricting blood vessels. When the person has to be active, it distributes the blood, so that the muscles of the limbs get a lot and those of the alimentary canal little. When the body is active,

the sympathetic system cools it by making the sweatglands secrete sweat, for heat is lost by evaporating sweat. The parasympathetic system organizes micturition and defecation, and it is the main controller of the alimentary canal. Sexual functioning is mainly parasympathetic, with minor, but in the male essential, contributions from the sympathetic system.

Perception. Animals are active; they are not usually sitting around waiting to be stimulated. They spend a lot of time seeking information, engaging in what ethologists call exploratory behaviour; they are curious and are trying to satisfy their curiosity. They ask the question, 'What is this?' as we can see from cursory observation of domestic pets and of cows in the field. But curiosity has to be tempered with caution, the amount of each depending on the species of animal, and mainly on whether it is a herbivore or carnivore. Some sorts of stimuli are prepotent, particularly the dangerous ones. The first question to be answered is whether the newly found object is familiar or strange, something the animal knows about or something that has to be approached with circumspection. Such perception may need knowledge, and knowledge involves memory. A rose is a rose only when compared with the memory of previous roses; but recognition usually takes place so quickly that we do not know we have put up the hypothesis—this is a rose—and have then confirmed or refuted it. Even so, just as we may need time to test a hypothesis, so a cat or a dog faced with a strange object may be seen to exercise caution in determining whether it is familiar or

Page 525

new, related or unrelated to something already known, before reaching a decision on what to do with it.

Sometimes we behave as if we know about certain objects and situations when we have had no previous experience of them. How much of such builtin knowledge the human being has is only just being found out. In many higher vertebrates, visual patterns passing across the field of vision produce behaviour. When a young animal has never seen a shape before and yet knows what to do about it—this is the essence of knowledge. The human baby has more interest in human faces than in random lines and shapes and takes more notice of the sound of human speech than that of passing motor cars or the wind in the trees. The brain is constructed so as to receive and respond to the more significant kinds of stimulus. (See INFANCY, MIND IN.) So, from the mass of stimuli always affecting it, the animal selects those that are important to its needs of the moment. When it is hungry, it neglects background noise and looks for food and all the signs that indicate food.

The brain can increase one sort of input and play down another. Selection starts at the receptors, continues where the nerve fibres enter the brain and spinal cord, and can operate at any synapse within the central nervous system. In order to concentrate on listening, we may find it helpful to close our eyes; to concentrate on a pain, we may want people to stop talking. One can learn to neglect an input habitually. When researchers used to use microscopes with one eyepiece, they did not close the eye that was not looking down the eyepiece, they just did not record what it was sending into the brain. Balletdancers learn to suppress the input from the organs of balance in the inner ear, in order to avoid vertigo when pirouetting.

All inputs to the central nervous system, gustatory, auditory, visual, and from the skin, the organs of balance, the bladder, the alimentary canal, the muscles and joints, go to the cerebellum, the reticular

formation, and the thalamus (Figs. 11 and 13). Those that can eventually become conscious and cause a sensation go to certain neurones of the thalamus and thence to the cortex. In the thalamus each input has its own territory, though there is also some mixing, with different sorts of inputs going to the same region.

Each kind of sensation depends on a primary sensory area of the cortex. Next door to or surrounding the primary area is its secondary sensory area. After the secondary sensory areas, there are the association areas; and finally the motor areas. Nerve fibres of the primary areas go to the secondary surrounding areas and nowhere else. Each secondary area connects with the corresponding area of the other hemisphere, with every other secondary sensory area of its own hemisphere, and with association areas. The association areas would seem to be concerned with elaborating sensory information, and with joining the various kinds of input to make a meaningful whole. It looks like a fish, it smells like fish, it tastes like fish, and so it must be a fish. The association areas are interconnected; and finally they are connected to motor areas. The motor areas also receive other inputs—for example, to the neurones of the corticospinal tract there come fibres from the thalamus and from the somaesthetic area of the postcentral gyrus, as well as fibres from other motor areas of the frontal lobe. The connections are laid down when the central nervous system is formed, according to the pattern of the species. They are then elaborated further during the experience of living.

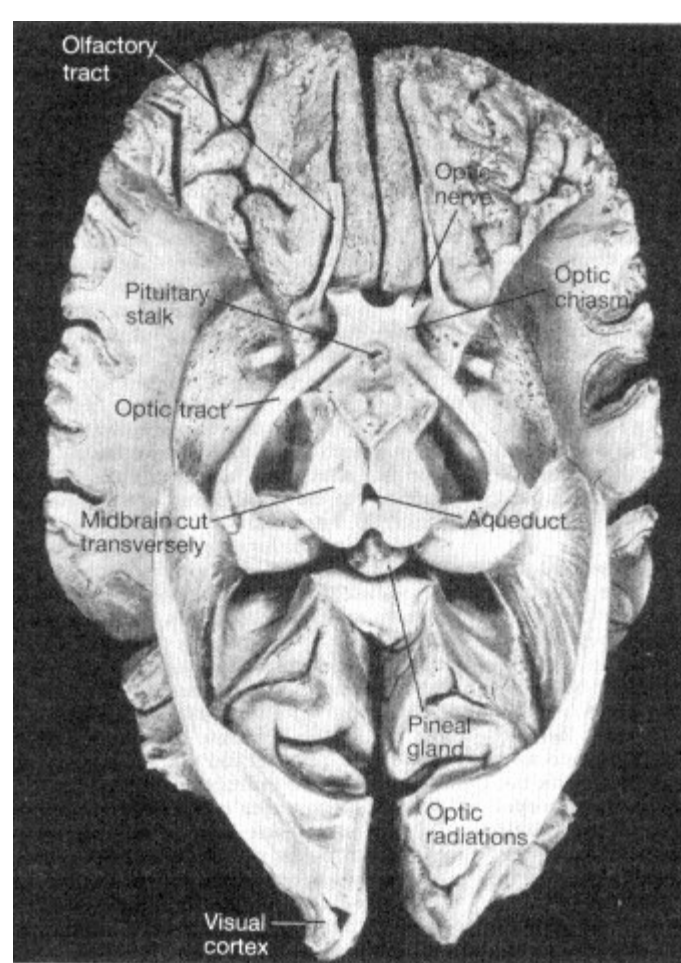

Fig. 10 is a photograph of the brain dissected to show the optic pathways. The two optic nerves meet in the optic chiasm. There, half of the optic nerve fibres cross over to the opposite side and half remain on the same side as the retina from which they arise. The fibres then continue posteriorly, as the optic tract, going to a part of the midbrain. There is a relay there, and then fibres continue posteriorly to the visual areas, as the optic radiations (Figs. 9 and 10).

The primary area for hearing is in the upper part of the temporal lobe and cannot be seen until the brain is dissected. Near this region is the area for vestibular sensations, sensations which occur only under unpleasant circumstances, as when we feel giddy after spinning round and round or when we are rocked mercilessly on the sea. The area for smelling is also in the temporal lobe, and also in an older part of the forebrain, near the septal and preoptic areas (Figs. 11 and 12). The primary area for tactile feeling is in the postcentral gyms.

When a primary area is destroyed in man, the sense served by that area is not completely removed. In a few unusual cases, the primary visual cortex has been destroyed without damage to the surrounding visual parts of the cortex. The patient is blind but he can still point quite accurately to things he is shown. He knows where something is in the visual field, but he cannot say what it is. This produces the amazing situation of the patient being unable to see something but being able to put a finger on it, at the same time insisting that he sees nothing. In a sense, we may conceive of vertebrates as having two visual apparatuses, one to tell what a thing is, and another to tell where it is (see BRAIN FUNCTION AND AWARENESS).

In front of the secondary visual areas are the visual association areas. That in the right hemisphere is essential for the recognition of people's faces. In this region or in nearby regions of the cortex, the position of things in the environment in relation to ourselves is appreciated by means of connections

with other parts of the hemispheres, parts concerned with knowledge of right and left, first on our own bodies and then in the world around us. If this region is badly damaged—and we know more about the effects of lesions than about how parts of the cortex normally function—then the patient cannot get any meaning out of the hands and numbers of a clock and thus cannot tell the time; neither can he understand the meaning of

Page 526

Fig. 10.

The human brain dissected from below, especially to show the visual pathways. The two optic nerves fuse at the optic chiasm and then continue as the two optic tracts to the midbrain. From relays in the midbrain, fibres run posteriorly as the optic radiations to the visual area of the occipital lobes.

the points of the compass, or of maps, or of the plans of architects. Nor can he plan a journey, for he cannot visualize the route and has no idea which road to take whenever there is a choice. For this region of the right hemisphere of the brain is the bump of locality—and note that we still use the terms of *phrenology.

Destruction of the primary area for hearing does not cause complete deafness; there is only a loss for high tones. Bats, for whom hearing is essential for life, can hear quite well with the primary auditory area destroyed.

The association areas are the important ones for all the activities we call thinking, remembering, imagining, or working things out. The ability to calculate, for instance, depends mainly on an association area of the left parietal cortex and the nerve fibres connecting to that area. This region is also essential for appreciating the relations of the fingers one to another. When this region is destroyed, the patient gets muddled in showing which of his fingers is which, and he cannot recognize, say, the index or the ring finger of the right hand of someone else. In addition, he gets confused about right and left. It is very likely that our ability to calculate is related to our knowledge of our own digits; and it is not coincidence that as we have ten fingers we use a decimal system. The cognizance of spatial relationships comes into arithmetic as well as into geometry. There are congenital defects of the cerebral cortex in which a child can learn to deal with figures up to ten but is unable to transfer a figure laterally to the next column.

Most parts of the brain are paired. For paired structures to work together, they have to be connected; the connecting links in anatomy are called commissures. The largest of the commissures connects the two cerebral hemispheres together; it is the corpus callosum, and it is made up of about 145 million nerve fibres. It is shown in Figs. 11, 12, and 13.

Page 527

From this rapid survey it will be realized that the brain is divided into separate regions with separate functions. This was first proposed by F. J. Gall, who founded phrenology on this concept in the early nineteenth century. He called the different regions of the cerebral cortex the organs of the brain.

Needs and desires. For an animal to carry out correct behaviour, it is provided with drives, desires, emotions, rewards, and punishments—functions which are a feature of the working of the brain. Correct behaviour means satisfying not only the demands of metabolism but also the demands made on the individual by other members of the group—it means correct social behaviour. Both kinds of demands, or needs, are always changing. At one moment food is required, at another drink, or shelter; at some stage a mate of the opposite sex is needed; after mating, life has to be adjusted to care for the offspring. The reward for proper behaviour is pleasure and satisfaction; the penalty for not seeking and not finding stimulation is boredom. The punishment for biologically wrong behaviour is unhappiness, and failure to satisfy essential needs is followed by discontent, which may be demonstrated in agitated activity. Thus the behaviour of human beings, like that of all other gregarious animals, is aimed at satisfying the desires that have come from the needs of both the individual and the group. Being aware, consciousness of purpose, thought, and programming and planning for the probable future are to be seen as a part of fulfilling these aims. The development of these higher cerebral mechanisms reaches its greatest extent in man.

There are many experiments showing how mammals that do not think and plan make correct choices. For instance, rats choose a correct diet when they are presented with a large variety of substances to

choose from. They are placed in a sort of cafeteria where they can choose what to eat from a large variety of foodstuffs. When deprived of an essential ingredient of diet, they choose those foods that supply the missing elements. Deprived of a certain vitamin, they choose foods rich in that vitamin. Female rats take more fat when they are lactating, and return to their usual amounts when the litter has been weaned. When pregnant, they take more calcium and phosphorus, protein and fat. Human babies and young children behave similarly when they are left to their own devices. Thus, in rare cases of atrophy of the adrenal glands, in which the body cannot retain salt, the child demands salt and eats great quantities of it. That the brain can make the child choose the right food comes as a surprise, for we tend to think of it as the organ of thought; and a two-year-old cannot work out what food it requires when deprived of a necessary hormone.

The needs of individuals are not only the usual ones stressed in biology and physiology. There are the needs that one may call social: the need for companionship, the need to be part of a group with a hierarchical structure, the territorial needs of the group of which one forms a part. To satisfy these needs, the brain provides feelings and emotions, instinctual drives, and it puts energy at the disposal of these drives. Knowledge of what parts of the brain are involved in these social needs is still inadequate; our conceptions of the physiological and anatomical bases of behaviour await improvement as further knowledge is gained.

Just as some regions of the brain produce sensations and others organize movement, so parts of the temporal lobes are involved in generating emotion. The main evidence for this comes from the electrical stimulation of the brains of patients with epilepsy during operations under local anaesthesia. In some cases of epilepsy, fits are caused by scarring in the cortex of the cerebral hemisphere, and occasionally good effects come from removing the scar tissue. During the operation, the surgeon has to stimulate the brain electrically so as to know if he is operating in the right part of the hemisphere. Excitation of certain parts of the temporal lobes produces in the patient an intense fear; in other parts it causes a strong feeling of isolation, of loneliness; in other parts a feeling of disgust; and in others sorrow or strong depression.

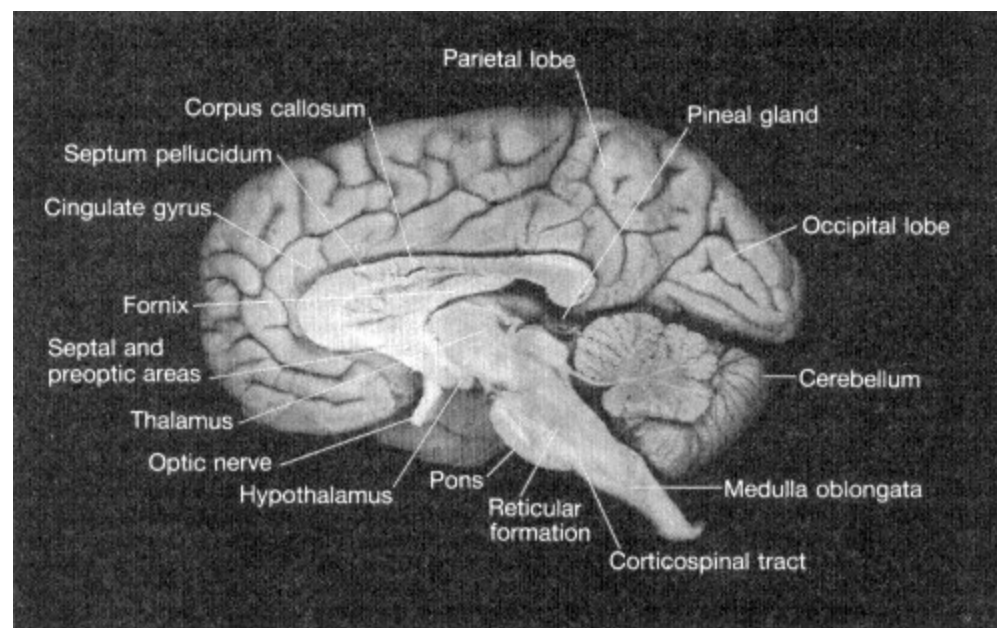

Stimulation of some parts causes a feeling of dread rather than of fear, a dread without object, the patient being unable to explain what it is he dreads. Sometimes there is intense anxiety and sometimes a feeling of guilt. Often such stimulation causes stronger and purer emotion than occurs in real life. Whereas it is the nature of the human situation that feelings of delight and joy come more rarely than feelings of misery, an ecstatic feeling that all problems are soluble can be brought about by electrical stimulation of parts of the temporal lobe.

Certain total acts of behaviour are organized by the hypothalamus. This small region (Fig. 11) organizes the metabolism of the body, heat production and the control of body temperature, the production and circulation of hormones, and the states of being awake or asleep and of aggression or timidity. It organizes mating and sexual behaviour and it controls the sympathetic and parasympathetic nervous systems.

But the hypothalamus does not initiate behaviour. The cerebral hemispheres do this—in so far as one may abstract one part from the whole and see it behaving independently. The cerebral hemispheres

receive information arriving from all input channels, form a total and meaningful picture of it, the meaning including emotion, and organize a programme of behaviour. In response to such and such an occurrence, one must threaten or even attack; to a different one, be submissive or hide or flee. Stereotyped patterns of response organized by small groups of neurones in the hypothalamus can be modified or totally changed by the cerebral cortex.

The parts of the cerebral hemispheres most directly connected to the hypothalamus are regions

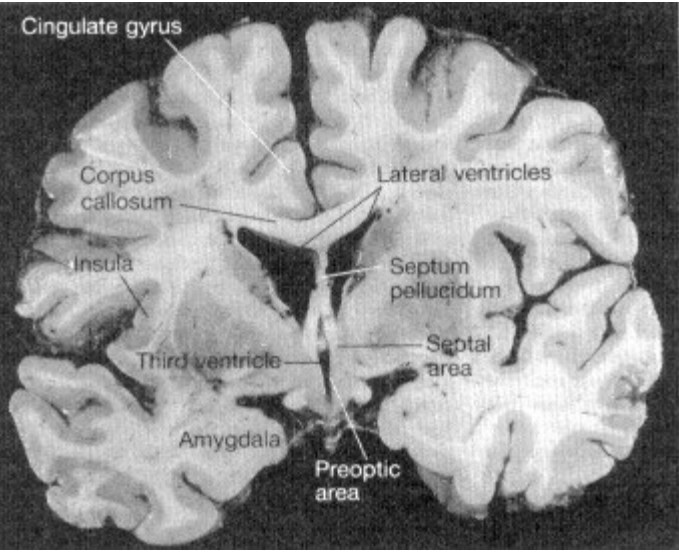

Fig. 11.

Sagittal section through the human brain; it is cut through the midline and seen from the left.

within the temporal lobe sometimes called the limbic lobe. The limbic lobe is the most ancient part of the cerebral hemispheres and is already well developed in primitive fish. In mammals, it includes the hippocampus, the amygdala, the cingulate gyrus, the fornix, and the septal and preoptic areas (shown in Figs. 11, 12, and 13). The amygdala is a large mass of neurones deep in the anterior part of the temporal lobe; this mass of grey matter, like other masses of archaic origin, lies within the white matter of the hemispheres. The cingulate gyrus surrounds the corpus callosum. The fornix is a connecting band of nerve fibres between the amygdala and hippocampus, and the septal and preoptic areas and hypothalamus. Beneath the corpus callosum there is a septum Fig. 12.

Coronal section through the human brain; the brain has been cut through from ear to ear.

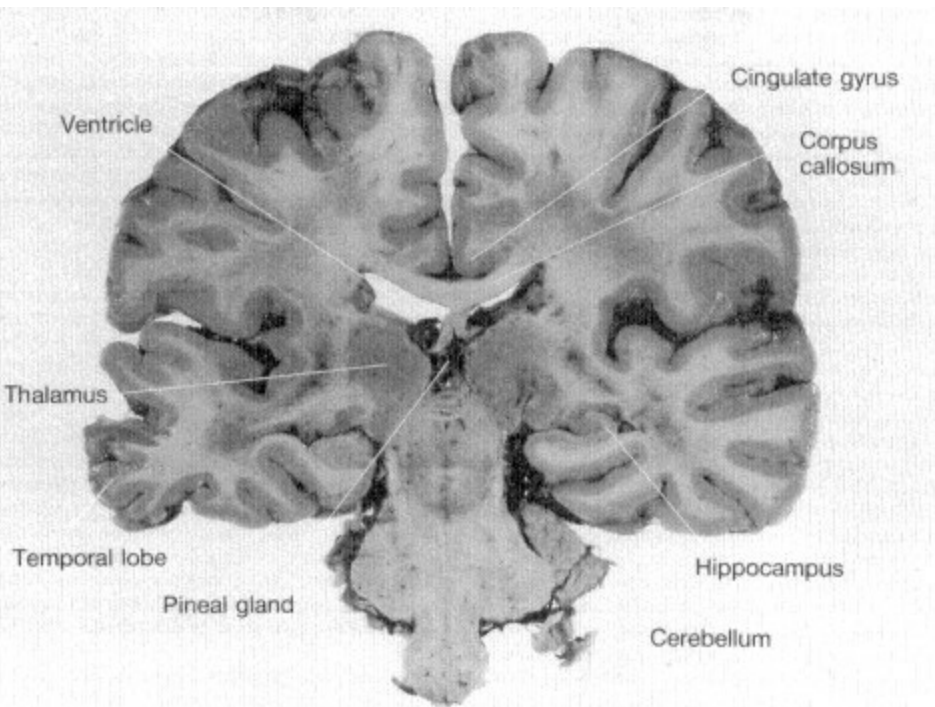

Fig. 13.

Coronal section through the human brain; it is cut in the same plane as Fig. 12 but further posteriorly.

which is almost transparent, hence its name of septum pellucidum. It separates the two ventricles of the hemispheres (Figs. 12 and 13). Beneath the septum, the two ventricles connect through a hole to the third ventricle, which divides the hypothalamus into two. In front of the third ventricle are the septal and preoptic areas. The main centres of the autonomic nervous system are in the hypothalamus.

R. G. Heath, operating on conscious, psychotic patients in New Orleans, stimulated the septal area by means of electrodes and also by dripping in neurotransmitters.

In some patients,

Expressions of anguish and despair changed precipitously to expressions of optimism and elaborations of pleasant experiences, past and anticipated. Patients could calculate more rapidly than before stimulation. Memory and recall were enhanced. One patient on the verge of tears described himself as somehow responsible for his father's nearfatal illness. When the septal region was stimulated, he immediately terminated this conversation and within fifteen seconds exhibited a broad grin as he discussed plans to date and seduce a girl friend. When asked why he had changed the conversation so abruptly, he replied that the plans concerning the girl had suddenly come to him....

Another patient, an epileptic, was one day agitated, violent and psychotic. The septal region was then stimulated without the patient knowing it. Almost instantly his behavioural state changed from one of disorganization, rage and persecution to one of happiness and mild euphoria. He described the beginning of a sexual motive state.

Heath's patients could not account for their changing the subject to sex; they would say that the ideas just came into their minds. Now, electrical or pharmacological excitation of the parts of the brain related to certain functions causes the subject to have the thoughts and emotions associated with those parts of the brain, and the act of copulation is organized in the front end of the hypothalamus and the nearby septal area. The neurones organizing this behaviour and accompanying emotional states do so only when they receive the right hormones in their blood supply. Somehow the hormones must change the neurones, but it is not yet known what they do or how they do it. The septal area inducing sexual thoughts, emotions, and action is either the same region or quite near the region that causes pleasure when it is excited. This region may be damaged in professional boxers, as it is vulnerable to head injuries. Some boxers become impotent and lose any interest in sex. The neurones are near those organizing micturition; and some boxers also have difficulty in controlling their bladders.

Neurones of the hypothalamus organize aggression with the accompanying emotions. When these neurones have been stimulated electrically in experiments in various kinds of animals, the

animals show manifestations of rage and attack any living being in sight. A pigeon stimulated in this way and alone in a cage behaves as if it sees another bird; it circles threateningly round the hallucinatory bird, preparing to attack it.

The brain and spinal cord are not isolated within the body, encased within walls of bone though they are. They are bathed in blood; and the constituents of the blood reach all parts of the brain and have an effect. The food and drink we take soon reaches it: not only alcohol but fish and chips, and hamburgers—all contribute. The hypothalamus controls the production of hormones, which are taken by the blood to the spinal cord and to all the tissues of the body. It is a part of the brain and functions in relation to the rest of the brain. It is related closely to the parts of the cerebral hemispheres that organize emotions and total acts of behaviour such as aggression, fear, and sex. Acts such as these need hormones with their effects on neurones and other tissues of the body.

If we think of nerve fibres as like telegraph wires, we can think of hormones as like radio messages. The programme is sent out; it can be picked up by anyone who has a radio to receive it. The hormone is poured into the bloodstream and it can be picked up by any cell capable of receiving it. Most hormones are made by endocrine or ductless glands. The glands are controlled by nerve fibres from the central nervous system and also by circulating hormones of other kinds. The brain orders and controls the secretion of hormones; and the brain itself is subjected to the action of hormones.

Many factors influence the secretion of hormones. The pineal gland (Figs. 11 and 13) is affected by light. In most animals, nerve fibres connect it to the retinae. In those few species that have a third eye in the top of the skull, the nerve fibres connecting the pineal with this eye are very short; the two structures are almost touching.

Light affecting the pineal gland makes it release the hormone melatonin into the bloodstream. The pineal also prevents the pituitary from secreting gonadotrophic hormones. When this control is relaxed, these hormones act on many tissues of the body, including the central nervous system, and bring about the physical and psychological characteristics of adolescence. In some birds and some small mammals, the cycle of reproduction depends on the duration of daylight. Long days allow the parents time enough to find food for the young. When autumn comes, the days draw in and the pituitary rearranges its release of hormones. With shorter days, birds fly off to a warmer climate and small mammals settle down to a quiet and boring winter of chastity and hibernation.

Some hormones act on the genes. As genes control and organize the structure and function of cells, they can change the character of the cells completely. When the gonads secrete their hormones at puberty, most of the tissues of the body are changed: the genital organs enlarge and, in the male particularly, the larynx enlarges too.

These hormones also act on the neurones of the nervous system, changing the function of cells. And so one sees that the male dog, reaching puberty, cocks a leg to urinate; if he is castrated, he never does this, but passes urine in the semisitting position common to puppies. Hormones acting on certain neurones in the brain give us mental pictures. The amount of sexual desire is much influenced by the secretion of hormones acting on neurones of the brain.

Thinking. When one is asked what part of the brain does the thinking, one has to answer in the usual way that appears to prevaricate: it all depends on what you mean by thinking. For the word is used to mean solving problems, remembering, planning what one is expecting to do, planning what one is about to say, imagining things, considering opinions, and making judgements. Much thinking makes use of words, of internal speech. But one can have auditory thoughts, thoughts without words. The composer conceives a melody without using words. The painter pictures things without using words, seeing them in his mind's eye. One remembers faces, things one has seen, and can imagine shapes and scenes when closing the eyes. Thinking of a smell is not helped at all by speech.

The parts of the brain concerned with the activity we categorize as mental are the cerebral hemispheres. The various kinds of intellectual activities are carried out by different parts of the cerebral hemispheres. The ability to think spatially depends on a region of the right hemisphere between the occipital, parietal, and temporal lobes;

and a main region for mathematical thinking is in a similar part of the left hemisphere. Neurologists imagine that the higher levels of the brain make a model of the actual world, a mental picture that parallels the world, though no doubt with distortions; it is a symbolic representation of reality (see CRAIK, KENNETH). The model is made by the neurones, and the connections between the neurones, of the cerebral hemispheres. There are more than ten billion neurones in the human cerebral cortex.

How connecting up regions of the cortex actually brings a memory into consciousness or allows us to imagine an event that has never occurred, we really do not know. We may conjecture that, in remembering a scene, the regions of cortex that were active when the original external stimulation occurred are brought into activity again. If this is so, and it is likely to be at least a part of the truth, there has to be some difference between the original activation of the region and the later pale image of the memory. It is obvious that a main function of the brain is to provide higher vertebrates with such mental images derived from the surrounding world. And it is customary to say that when one evokes these images, one has the picture in one's mind. Why we are unable to put all of this together is that our methods of research are apt for analysis but very poor at synthesis. (See the articles on

Page 531

MEMORY and THINKING: HOW IT CAN BE TAUGHT for further discussion.)

Speaking. A baby starts by listening to the sounds of speech. Endowed as he is with acute hearing for the frequencies and overtones used in speech, he comes to notice the subtle differences between these sounds. He then learns to associate meanings with the sounds; he also imitates and learns to make the sounds himself and to stop the babbling that has no meaning to those around him. Just as he moves his limbs, he makes controlled movements with the muscles of the larynx, palate, lips, and tongue.

One supposes that something like this is happening. Volleys of impulses from the inner ears reach the lower centres for hearing in the lower parts of the brain. From there, volleys are relayed to various specific parts of the brain, including the auditory regions of both temporal lobes. Surrounding each primary auditory region is a secondary auditory region in which heard phonemes are turned into

sound symbols. These are sounds with meaning. The secondary auditory regions of the temporal lobes are connected to many other cortical areas that contribute to speech. One is an area of the frontal lobes that organizes the actual movements of the respiratory muscles, larynx, and mouth to produce speech.

When a child learns to read, he organizes connections to the visual cortex, where recognition of the seen shape of letters and words occurs. Reading is associating the visual representation of the word with its auditory representation, and associating the auditory representation with the actual object. 'Associating' is a psychological term for the physiological activity of sending volleys of impulses between various cortical areas. When the child learns to write, he says the sound out loud to himself, and then draws the visual representation of that sound that has been accepted by the conventions of his society. This entails learning sequences of movements needed to draw the agreed symbols. All of it happens in milliseconds once it has been practised.

Neurologists have had to learn from observing the effects of damage to parts of the brain. When certain regions are destroyed, then such and such defects are found.

From deducing what a destroyed region might have done, tentative guesses are made as to how the brain works. Learning about the brain in this way provides answers to many anatomical questions; but given the structure one still needs to understand how the rapid passage of nerve impulses results in all the activities we call thinking.

Total behaviour. The kinds of people we are depends primarily on our brains. The parts of the brain making each of us ourselves and different from everyone else are the higher levels of the brain: higher anatomically, towards the top of the head, and higher physiologically, in that their operations are least automatic and reflex, and most delayed in action and complicated. One spinal cord, one medulla, one brainstem is much like another. But we differ in our cerebral hemispheres. They certainly start different; and they become more different on account of everything we have put into them or not put into them.

The temporal lobes are the main regions of the cerebral hemispheres for memory. The limbic lobes are the main parts for organizing the essential drives, which are kindled by emotions. They have rapid connections to both parts of the autonomic nervous system: sympathetic for activity and parasympathetic for relaxation. The hypothalamus has many functions. It organizes hormonal control of the body, total acts of behaviour, circadian rhythms, food and drink intake, and excretion and elimination among other things. It seems far too small a structure and to have far too few neurones to do all these things. Its smallness contrasts with the size of the cerebral hemispheres with their row upon row of neurones. From the whole extent of the hemispheres, one imagines, commands are sent to the limbic lobes, and from there are funnelled down to the hypothalamus. One supposes that a situation is apprehended by the cerebral hemispheres, is then related to previous experiences, probably in the hippocampus, and labelled as familiar or novel and strange. What is likely to happen next is then anticipated, and behaviour to meet it is planned. This requires not only action, but also emotions, desires, and the entire mental state that is necessary for the programme.

The more rostral parts of the frontal lobes and their connections to the thalamus, to the hypothalamus, and to the septal areas are the regions of the brain most concerned with social behaviour. Maturation of these regions takes years, and development of the anatomical connections continues until puberty. Experiments on dogs and monkeys in which connections between the frontal lobes and other parts of the brain were cut through, has demonstrated that animals losing social knowledge cannot relearn social behaviour. Animals subjected to the operation would go casually up and take food away from animals of higher rank, and would fail to learn not to do this in spite of being repeatedly punished by the other animals. Man's case is similar, though seldom extreme since lesions are not usually extensive.

Large lesions in the front parts of the frontal lobes lead to lack of attention to the feelings and the behaviour of others. In 1868, Harlow of Boston reported a famous case in which a crowbar was blown through a man's frontal lobes without killing him:

His equilibrium, or balance, so to speak, between his intellectual faculties and animal propensities, seems to have been destroyed. He is fitful, irreverent, indulging in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating....

Page 532

Early attempts at leucotomy cut many of the connections between the frontal lobes and the thalamus and resulted in apathetic beings with no energy, no interests, and no ability to concentrate on anything for long. The patients became uninhibited, their behaviour insensible to its effect on other people and unaltered by criticism. Less extensive operations resulted in less damaging effects.

The frontal lobes play an important role in determining our energy, and thus our interests, but are not primarily concerned with intellectual functions. They are concerned with mood, and with inherited and acquired behaviour in social groups, as we have seen. Connected as they are with the septal areas, it is likely that fight behaviour is learned, by both man and other gregarious animals, from reward with pleasure. Conversely, wrong behaviour must be corrected, and there must therefore, also be connections with aversive centres, if there are such centres in the limbic lobes. It may be that without such connections learning would not occur.

Total conceptions of the central nervous system. It has been apparent to investigators of the nervous system that one learns a few things about a small part, even about many different parts, but one comes no nearer to a conception of the functioning of the total system. A broad view of its anatomy, physiology, and pathology was the achievement of the clinical neurologist John Hughlings*Jackson, whose conception took into neurology the ideas about evolution current in the second half of the nineteenth century. Renaissance thinkers had removed man from the centre of the universe; he was put back by Charles*Darwin and Herbert*Spencer. In Jackson's concept the nervous system has evolved, both anatomically and physiologically, in hierarchical stages. When it becomes impaired or damaged by pathological processes, it degenerates in the reverse order to its

evolutionary development; Jackson called this degenerating process dissolution. Evolution and dissolution accounted for its functioning in health and decay. The lower levels are the older, more primitive and simple; the higher levels more complex, less firmly established, and so more liable to suffer from toxic or pathological processes. This organization decreed that a higher level was constantly suppressing or inhibiting the functioning of its immediately lower level. During dissolution the higher level was seen as being damaged first and most, leaving the next level manifesting its activity in an uninhibited and excessive manner.

The lowest level was the spinal cord; above it were the lower levels of the brain, and above them the higher levels. It is unfortunate that Jackson indicated precise anatomical levels in the hierarchy, as his conception could otherwise be maintained. For example, he regarded the motor strip of the precentral gyrus together with the kinaesthetic region of the postcentral gyrus as the middle level, and the frontal cortex rostral to the precentral gyrus as the highest. But the frontal cortex is not a sensorimotor region; most of it is concerned with behaviour in relation to the social group and with the totality of behaviour. Such ideas could not have entered into Jackson's nineteenth-century view, however, for the prevailing concept of psychology of the time was one of stimulus and response, of the sensorimotor reflexes of a single, isolated human being.

Jackson conceived of the lower levels as the most automatic, with stereotyped reflex behaviour, and proposed that the highest levels—with mental, intellectual, and psychological functions—be regarded as the least automatic and least stereotyped. One of the canny features of his conception was to see differences between neural levels as differences of degree rather than as of kind. It fitted in with the material of biology; and it enabled him to avoid the difficulties inherent in using terms such as 'voluntary', a term derived from the will, or terms such as 'psychic'.

Jackson saw a baby's life as ruled by primitive reflexes. As the baby grew and developed, more complicated and less stereotyped behaviour was superimposed on the stock of reflexes. Finally, in the adult, reflexes formed only a small and hidden part of the repertoire of behaviour, the rest relying on consciousness, apparent choice, and accompanying emotions. When dissolution occurred, the parts oldest in evolutionary terms survived longest, while the most recently acquired degenerated first.

The early signs of dissolution of the cerebral hemispheres are a loss of finer sensibilities and indifference to social requirements. The senile person does not become different; he becomes more like himself than before. The choleric person loses his temper more readily, the obsessional becomes bound by compulsive rituals, the humorous becomes fatuous. As the higher levels of the cerebral cortex degenerate, an early loss is the ability to think with symbols. This may be detected in such banal examples as a person being unable to see the meaning of a proverb. He will explain that a rolling stone gathers no moss because the conditions during rolling are unsuitable for the growing of moss: the meaning, as a proverb, is not understood.

Jackson's way of thinking about the nervous system was based on the reflexes that Charles*Sherrington was investigating at the time. But reflexes, no matter how elaborate they become, do not constitute even a small part of the behaviour of higher animals. Even moving is not organized

only by reflexes. Most of our movements are organized from above, being programmed by the cerebral cortex, though this was not known to Sherrington and Jackson. If something as essential to Jackson's conception as the organization of movement is not hierarchically built up, then his scheme falls to the ground. What also appears unsatisfactory today is that the conception was based, as it could only have been at the time, on a simple stimulus-response

Page 533

idea of neural organization. This view of behaviour saw an organism as waiting for events to occur. Something in the outer world eventually stimulates the animal, and the animal responds. It was not then realized that occurrences originate mainly from within. What was being neglected in psychology and neurology was the makeup of the nervous system itself. That the stimulus to behave originates within the central nervous system has been realized by twentieth-century biologists, though more from the contributions of ethologists than from observation of spontaneous activity within the system. We higher animals continually show purposive behaviour, seeking to satisfy internally originating needs. Animals are goal-seeking organisms.

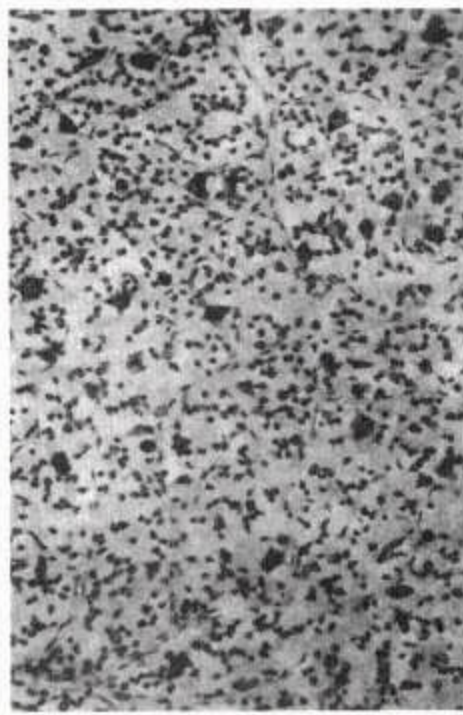

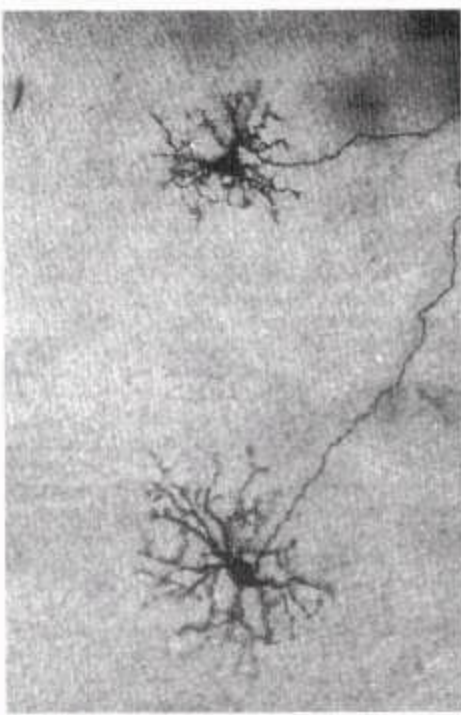

A less all-embracing way of seeing the nervous system was that of W. R. Hess (1881-1973). His view took its origin from the basic behaviour of the animal. He was the first anatomist or physiologist to investigate the anatomy of the central nervous system in relation to total acts of behaviour such as attacking, escaping, digesting, and defecating. He implanted electrodes in small regions of the hypothalamus and produced total acts, as mentioned, when he stimulated them electrically. Thus he found that there are centres for rage, for fight and flight, for threatening and submissive behaviour, for digestion, for repose, sleep and maintaining wakefulness, for micturition, defecation, and copulation. These centres are in the hypothalamus and they are excited and inhibited by the cerebral hemispheres. What is meant by a centre in neurology is a small region of the central nervous system devoted to one function. Hess thought of the functions as consisting of two opposite forms of behaviour; he called them ergotropic and trophotropic. Ergotropic behaviour is going out and actively doing things; it includes both parts of the defence reaction—that is, fighting and fleeing—seeking food, and looking for a mate. When it is maximal, the pupils are dilated, respiration is increased, and blood pressure rises. Ergotropic centres are in the more posterior part of the hypothalamus. Trophotropic behaviour is reposing and building up the body. It includes sleep with the anabolic functions that occur during sleep, the activities of the alimentary canal and the bladder, replenishing the supply of glucose, and the building of the cells of the body from protein and fat. When trophotropic behaviour is maximal, the pupils are small, respiration is slow, and the glands of the alimentary canal are secreting. The centres of trophotropic organization are in the rostral part of the hypothalamus and the septal and preoptic areas. The regions of the cerebral hemispheres most closely concerned with trophotropic behaviour are the posterior part of the orbital surface of the frontal lobes (Fig. 7), the insula, which is a part of the cerebral hemisphere (Fig. 12) lying deep to the temporal, frontal, and parietal lobes, and the anterior parts of the temporal lobes, with the evolutionary regions of old grey matter within them, including the amygdala (Fig. 12). The trophotropic system works mainly via the parasympathetic nervous system, whereas the regions of the cerebral hemispheres more closely concerned with ergotropic behaviour are the anterior nucleus of the thalamus, the hippocampus, and the connections of these structures, working mainly via the sympathetic nervous system.

Hess's scheme, like Jackson's, was developed before there was an adequate view in biology of man as a gregarious animal; and so it also is a scheme that describes the nervous system of an isolated person, as if he had no social relationships and no inherited social instincts and ways of behaving. Any total conception of the nervous system must rather see man as genetically endowed to function as a member of a group, with builtin drives and propensities to behave as we know human beings do behave. To omit an animal's relations with other members of its group is to leave out almost everything.

The mind? Should one think that the materialist view of the neurologist is inadequate or wrong, the best way to criticize it may be to attack it on its own ground. Such criticism would go something like this: 'Although you have explained the anatomy and physiology, you have said almost nothing. You tell me that when you hear me speaking, pressure waves reach your inner ear, and that they cause the physicochemical events called nerve impulses in the auditory nerve. Further groups of nerve impulses finally reach the speech area of the left cerebral hemisphere, you say, and from there more impulses go to other parts of the brain, to regions where strangeness or familiarity are recognized, where memories are evoked, and where various emotions are induced. But you have chosen to leave everything out except the structure, the anatomy of the brain. *How does the activation of neurones at synapses make me feel frightened?* You answer that if during an operation the electrical stimulation of parts of the limbic lobes makes the patient feel frightened, then we may assume that fear is normally caused by the excitation of that part of the brain. But that is merely showing me a location, a bit of anatomy. Your explanation is no explanation at all.'

As we should have no preconceptions about what effects the activation of groups of neurones have, we can merely take note of what effects they do have. In one n

case, we have the feeling of fear; in another case, we hear a sound. These experiences are a part of the constant effort of an animal to remain alive, a station on the pathway towards activity in the world. Thus attacks on the present attempts of students of the nervous system to understand behaviour are most effective where ignorance of neural events is greatest; and they tend to fail where knowledge of neural functioning is adequate. In the example of movement, we know much of the neural events that occur,

although of course gaps in our knowledge remain. Neurologists can point to the physical and chemical events that occur when we put our right foot forwards. Nerve impulses pass from the left frontal hemisphere along various circuits of neurones in the brain; and finally they come down to motor neurones working the muscles of the right lower limb, exciting some and inhibiting others. The result of this is that muscles used in putting the foot forwards are caused to contract, and opposing muscles to relax, the muscles of the trunk and upper limbs behaving similarly. There are no occurrences but physical and chemical ones, nothing but the events we study in anatomy and physiology, chemistry and physics; and therefore, in this case, the critic cannot say that the neurologist has not shown him everything. It follows that if what happens when we move can be more or less explained, any inadequacy in the ability to account for what happens when we feel fear or remember a past event is likely to be due only to insufficient knowledge of the physiology concerned.

Put at its most superficial, it is a matter of vocabulary. In the context of neurology the adjective 'mental' is in order but the noun 'mind' is not; so it is acceptable to say that perception is a mental occurrence but bad terminology to say that perception occurs in the mind. Once one is aware of the dangers of using the word 'mind', however, one may use it most acceptably. For 'let me not to the marriage of true minds admit impediments'.

NEUROANATOMICAL TECHNIQUES. Although it is possible and productive to study the mind without knowing anything about the structure of the brain, rather as one can drive well and be knowledgeable about the performance of motor vehicles without understanding the internal combustion engine, few doubt that mental events are related to the activity of the brain and that the

structure can give clues about how the brain works. Unfortunately, however, the brain is so complex that its detailed structure is only beginning to be understood. For example, in humans it contains about ten thousand million nervecells, and each one may make and receive several thousand contacts with other cells. The following describes the principal methods of obtaining information about the most complex circuit in existence.

Even before the invention of the microscope it was possible to say something about gross brain structure by postmortem dissection. The nerve Fig. 1.

Left. Two Golgistained nervecells in the retina of the eye of a rat. Each has a cellbody with branching dendrites that make connections with other cells. The long thin process is the cell's axon. The hundreds of other cells are unstained and therefore invisible. *Right.* A photograph of a similar region of the eye using a conventional stain, which shows up all the cellbodies but none of the dendrites or axons.

Page 535

bundles carrying information from the eyes, ears, nose, and skin can all be followed to their first and major destination in the brain. But from here we are lost, and in any case dissection has never revealed the course and connections of individual nerve fibres, which are often less than onethousandth of a millimetre thick. The first great step forward came in 1873 when Camillo*Golgi discovered that a small proportion of nervecells could be stained with black silver chromate so that they became readily visible against the background of unstained, transparent cells. Why the Golgi method selects a few cells apparently at random is still unknown, but for over a hundred years it has been the principal tool in revealing their precise shape. It was the only method that let us see the trees instead of the wood (Fig. 1), and showed that most nervecells, or neurones, consist of a cellbody and an axon (fibre) which may vary in length from less than a millimetre to several metres in large mammals.

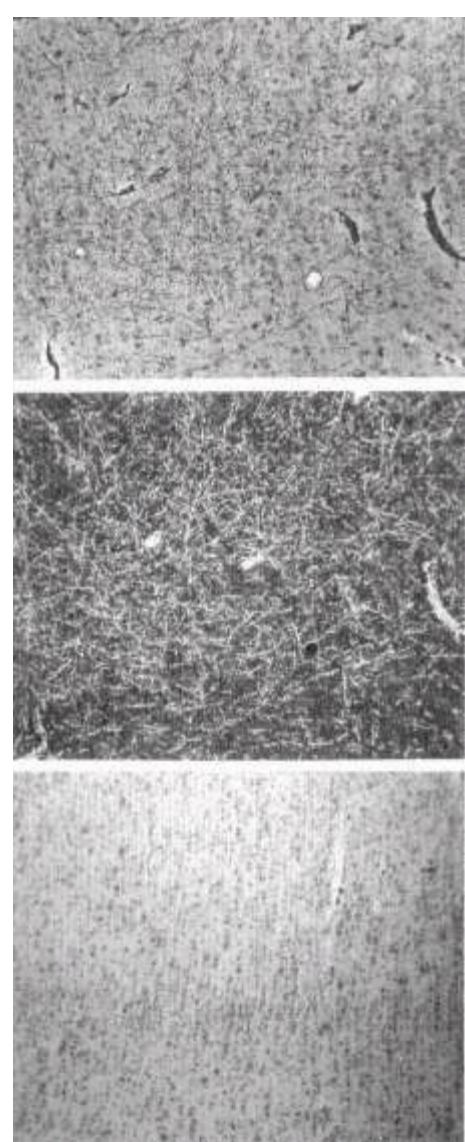

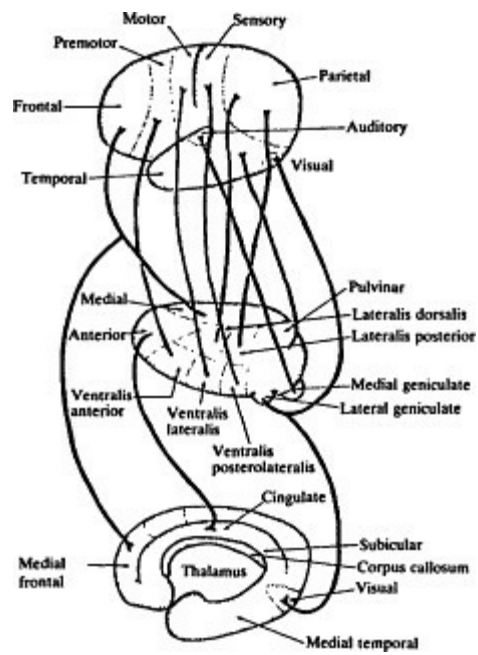

Although the Golgi method is excellent for revealing local details, it is highly impractical for showing whether two widely separated areas of the brain are directly connected by nerve fibres. A solution to this problem was that of 1870 by Gudden, who observed that when axons are cut their cellbodies often die and disappear.

When the tissue is sectioned and stained, the cells that gave rise to the cut axons are conspicuous by their absence (Fig. 2). The method of retrograde cell degeneration was widely used in the early part of the twentieth century to show which parts of the thalamus in the centre of the brain sent axons to particular parts of the cerebral cortex on the surface of the brain. The resulting map is shown as Fig. 3. But the method produces too many false negative results. Some cellbodies do not die when their axon is cut, perhaps because of regrowth of the axon. Other axons may branch, and only if all branches are cut will the cell die. Therefore the absence of cell degeneration following axon cutting does not prove that two regions lack connections. Nerve cells may also degenerate in the opposite direction—that is, when the cellbody is damaged the axon and its terminal connections die. In the 1950s Nauta and his colleagues at the Massachusetts Institute of Technology developed what are known as the Nauta techniques for selectively staining degenerating axons and their terminal branches with silver, and an entirely new set of nerve connections was discovered. For example, the visual cortex at the back of the brain is now known to send axons to at least eight different regions of the cerebral cortex and subcortex (Fig. 4). None of these pathways is demonstrable by retrograde degeneration.

So far we have mentioned only histological methods. But nerve cells can be stimulated by a natural agent such as light in the eye, or by brief pulses of electricity delivered through electrodes in the tissue. The electrical activity evoked in the nerve cells can then be recorded as it is propagated in the brain along axons. For more than fifty years

Fig. 2.

Section through part of the thalamus in a monkey's brain showing the lateral geniculate body, whose cells send axons to the visual cortex. The cells in the centre have disappeared because a small part of the cortex was damaged. This method of retrograde degeneration shows which thalamic cells send axons to the damaged area.

Page 536

Fig. 3.

The thalamus of the brain (shown much enlarged in

the centre of the figure) consists of discrete groups of cells. By the method of retrograde degeneration the parts of the cerebral cortex to which they send their axons have been discovered.

The lines show these pathways from the thalamus to the lateral surface of the brain (*top*) and to the medial surface of the brain (*bottom*).

this method has been used to map pathways in the brains of animals. One notable advantage of it is that the electrical activity crosses the junctions or synapses between cells, so that the entire route can in principle be revealed. For example, the impulses from the eye travel to the dorsal lateral geniculate nucleus of the thalamus, thence to the primary visual cortex, and from there to several other so-called secondary visual areas.

Such physiological methods reveal a great deal about the general route followed by axons of a particular sensory system and about the areas where the axons terminate, but they reveal little about the connections of individual cells. One way of overcoming this is to record the activity of a cellbody with a micropipette and then inject the cell with a dye. When the tissue is then sectioned the dyed cells and all their processes are visible microscopically. This method is tedious and can never reveal more than a few cells at a time, but it has successfully shown, for example, which of the thousands of cells in the visual cortex are the first to receive impulses from the eye, and how many braincells an incoming fibre can contact.

The methods described so far had reached their peak by the early 1960s, and radically new discoveries about the connections of the brain seemed impossible. How wrong this was!

Neuroanatomy

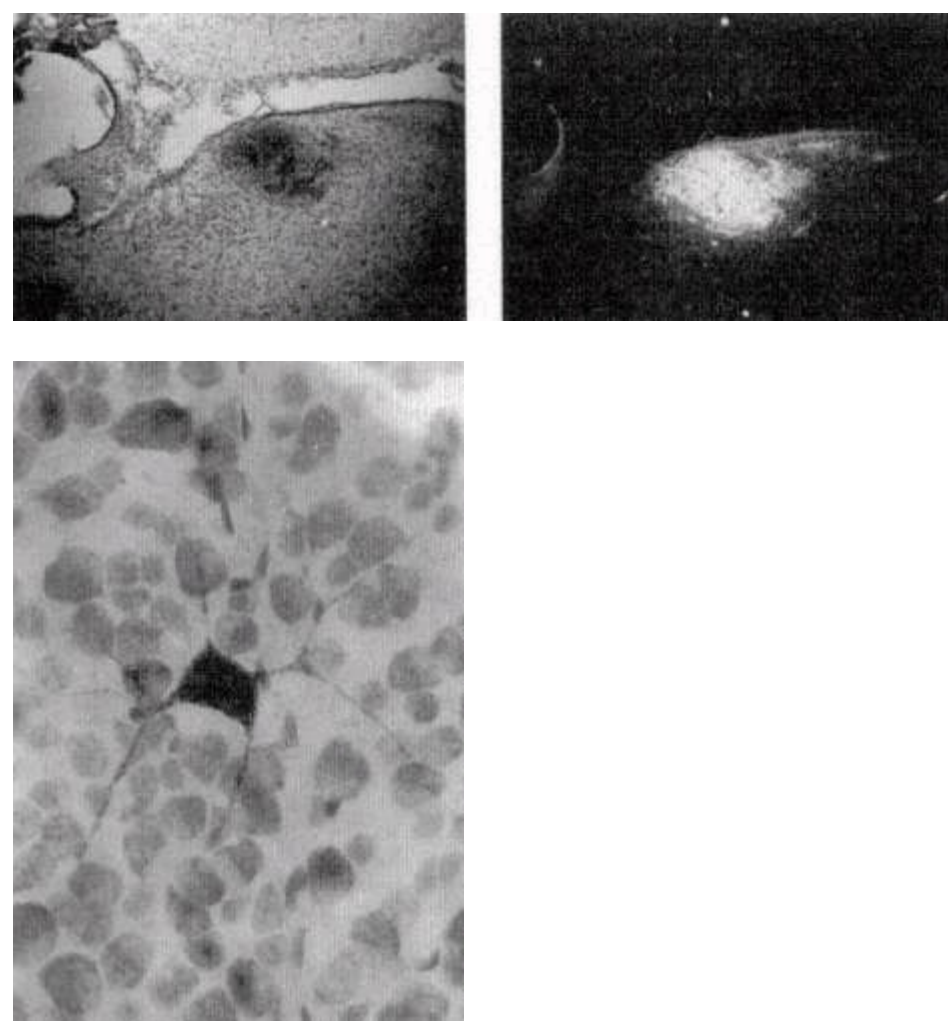

Fig. 4.

same region of cortex stained conventionally.

Only cellbodies are visible.

was on the threshold of major advances. Since 1948 it had been known that the axoplasm inside a nerve fibre flows along the fibre. By injecting radioactive amino acids inside the eye of a mouse it was shown in 1965 that the amino acid was absorbed by nerve cellbodies and incorporated into proteins, which were then passed along the axons. In 1968 it was

Page 537

Fig. 5.

is reversed.

shown that if the brain tissue was sectioned and the sections coated with photographic emulsion, the radioactivity that had reached the axon terminals could be detected by its effects on the photographic film. Since then, this technique of autoradiography has been widely used to study the course of axons from several groups of cells that have been bathed in minute injections of radioactive chemicals, which can now be delivered through a micropipette to any part of an animal's brain. Not only does the technique take advantage of a normal biological process without damaging the injected cells, it is far more sensitive than degeneration techniques. For example, autoradiography has shown that the nerve cells in the eye send fibres to at least six different parts of the brain, whereas only four were known previously (Fig. 5).

When a nerve fibre is squeezed tight, axoplasm accumulates on *both* sides of the obstruction, implying that there is active transport in both directions. If that is the case, it should also be possible to apply chemicals to the terminals of axons and trace them back to the parent cellbodies elsewhere in the brain. Such a technique, called retrograde marking, has been in use since 1970. The commonest tracer is horseradish peroxidase, which is rapidly conveyed from nerve axon terminals back to the cellbody, where its presence can be revealed by histochemical treatment. of thin slices of the tissue (Fig. 6). However, a variety of materials can be used so long as they can be chemically attached to a transportable substance. For example, colloidal particles of gold, which show up well in light and electron microscopes, can be attached (conjugated) to transportable wheatgermagglutin.

New transportable substances are continually being discovered, and one class has already proved to be especially useful. When bathed with light of a particular wavelength some chemicals absorb the light and emit light of a very different colour, i.e. they fluoresce. It is now known that several fluorescent dyes are transported in the axoplasm. If such labelled nerve cells are observed under a fluorescence microscope where they are illuminated by light of one wavelength (which, like ultraviolet, may be invisible to the human eye), they fluoresce at visible wavelengths—for example, blue—and stand out against a dark background. By injecting two different fluorescent tracers in separate parts of the brain it was first shown in 1978 that some cellbodies accumulated both tracers because they glowed red or blue according to the

Fig. 6.

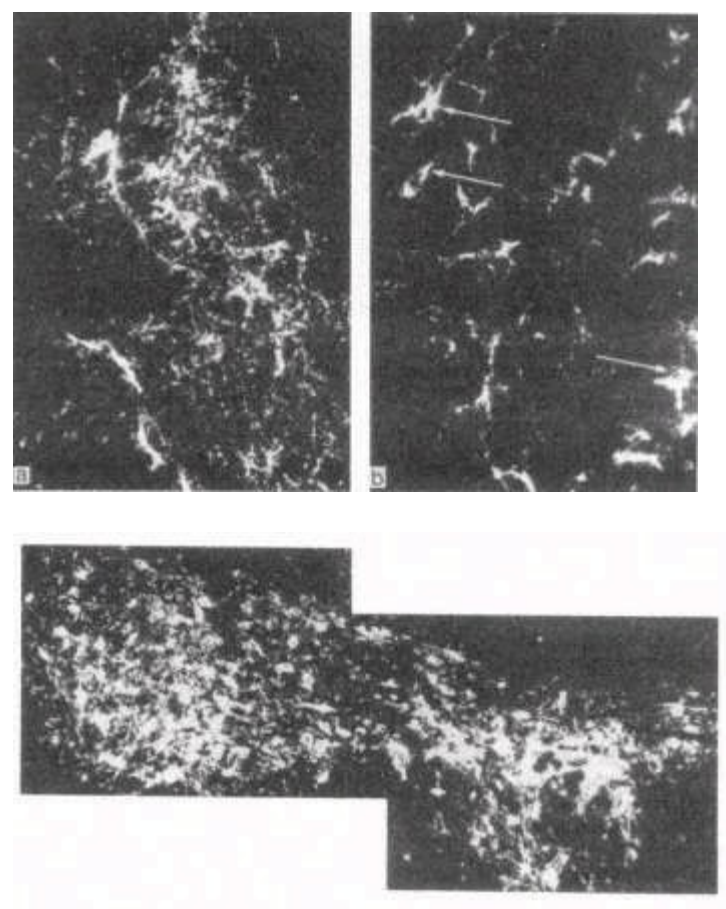

Photograph of part of the retina of the eye of a rat.

The dark cell in the centre has accumulated horseradish

peroxidase tracer injected in minute amount into

a small part of the brain, showing *that* this and other

similarly labelled cells send their axons to this part of the brain.

The same region from a different brain treated to make the fluorescence specific for a different transmitter, dopamine. The arrows show that the transmitter is concentrated round cellbodies.

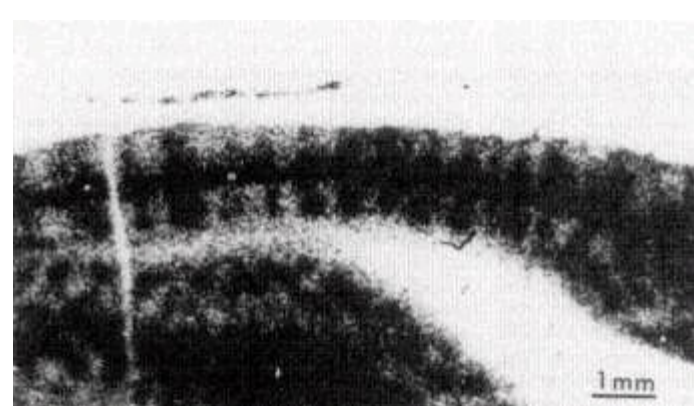

wavelength of the illuminating light. This proved conclusively that some cells give rise to an axon which branches and reaches entirely different areas of the brain.

Although nervecells transmit information as electrical impulses along their axons, the communication between cells at their points of contact, or synapses, is chiefly chemical. The terminals of an axon release minute quantities of the chemical, or transmitter, which then stimulates the membrane of adjacent cellbodies. Although many different transmitters exist, any cell releases predominantly only one type. If that type can be selectively stained in some way it should be possible to display all the pathways which use that particular transmitter. This was achieved in 1962 by the discovery that nerve

terminals secreting catecholamines fluoresced with a greenish hue after the tissue was treated with formaldehyde vapour (Fig. 7). Since then several other transmitter-specific pathways have been demonstrated, but the most precise and exciting development is the technique called immunohistofluorescence. When cells containing a particular transmitter are injected into another animal of a different species, the host develops antibodies to the transmitter just as it would to other foreign tissue like bacteria. These antibodies can be isolated from a blood serum sample taken from the host. A fluorescent dye is now chemically attached to the antibodies, which are then applied to fresh sections of brain tissue, where they attach themselves to the type of cell producing the original transmitter (Fig. 8). In this way several cell groups and their fibres have recently been shown to act by secreting dopamine, adrenaline, noradrenaline, substance P, or tryptamine, a discovery that could not be made simply by studying their structure or electrical activity.

Nor is the discovery of mere academic interest. Disturbances in the metabolism of specific transmitters have been implicated in several neurological and psychiatric conditions, for example dopamine in Parkinson's disease, acetylcholine in senile dementia, and gammaaminobutyric acid in epilepsy. To pinpoint such pathways is therefore of great potential value to medicine. (For further discussion see DOPAMINE NEURONES IN THE BRAIN.) So far the brain has been discussed as if it were a fairly static piece of machinery. The connections Fig. 8.

Immunofluorescence in the substantia nigra of a rat brain after incubating the tissue with fluorescent antibodies to an enzyme which controls the metabolism of the transmitter tyrosine.

Page 539

may be discovered by a variety of means, but what do they do and under what behavioural circumstances are they active? If only the brain were semitransparent with pathways that lit up when they were in use, we might more easily relate structure with mind. This dream is not as outrageous as it may seem, as two examples show.

Nerve cells need glucose, and the more active they are the more glucose they use. The glucose is normally metabolized rapidly but, if an injection of a closely related radioactive chemical, carbon-14 2deoxyglucose, is given to an animal, the brain cells fail to detect the disguise and absorb it as if it

were glucose, but they fail to metabolize it. The chemical sticks in the cells and can be demonstrated by the autoradiographic method described earlier. By these means it has been shown which cells in an animal's brain are the most active when it looks through one eye, gazes at vertical lines, moves about, or listens to sounds (Fig. 9). This is a drastic and irreversible procedure, of course, because the brain has to be sectioned. However, regional activity at a grosser level can be demonstrated in the living brain without harming it. If a subject inhales radioactive xenon, the gas enters the bloodstream, where it circulates for a few minutes before gradually being lost again in the breath.

As those parts of the brain that are most active at any particular time receive the greatest blood supply, they contain the most radioactivity, which can be detected by sensors outside the skull. The method is used clinically to pinpoint brain abnormalities that may require surgery, but it also successfully shows which regions are most active when we are looking, listening, talking, moving a limb, problemsolving, or just daydreaming.

To describe the bare bones of some of the techniques now available for studying the structure and connections of the brain may seem a far cry from understanding the mind. It is. But we are certainly much closer to saying something about the physical counterparts of perception, action, and mood than was St Thomas Aquinas, who saw mind as those faculties which in their operation dispense entirely with matter.

NEUROLINGUISTICS. This term is used mainly in Europe and in some centres in the USA, to describe the application of linguistic theories to the classification and analysis of acquired disorders of language or speech in patients with brain damage (for example, aphasia). Some work has also considered the corresponding developmental disorders of speech, reading, and writing in children (see LANGUAGE DEVELOPMENT IN CHILDREN), as well as the dissolution of language in dementing diseases.

While ideas from linguistic theories have been applied to aphasia for many years (e.g. Steinthal, 1871; Pick, 1913; Isserlin, 1922; Jakobson, 1956), the term neurolinguistics and more systematic application of linguistic ideas has only become widespread since 1970.

In 1969, the neurologist Henri Hecaen and the linguist Armand Dubois declared the object of neurolinguistics to be, first, the establishment of 'a purely linguistic typology' of neurologically caused verbal disorders, and second, the achievement of an experimentally verifiable correlation of lesion sites with the linguistic types. In practice, however, it has proved difficult to use solely linguistic criteria of classification, and Hecaen's own 1972 scheme classifies patients on the basis of

clinical and psychological, as well as linguistic features: 'sensory aphasia', for example, has three aspects—a disorder of semantic relations, a failure of auditory decoding at a phonemic level, and a disorganization of attention.

Neurolinguistic researchers have used various types of linguistic theory: e.g. *Luria's (1947) linguistic theories come from the structuralism of the Prague school (see following entry); Lecours and Lhermitte (1979) use Martinet's theories, while Weigl (1981), Whitaker (1971) and others adopt Fig. 9.

Deoxyglucose autoradiograph of a section through the visual cortex of a monkey after the animal was looking at a pattern of stripes. The array of vertical stripes in the cortex shows which groups of cells were activated by the stimulus.

Page 540

the perspectives of transformational generative grammar (see LANGUAGE: CHOMSKY'S THEORY).

Progress towards the secondary aim of discovering the anatomical substrates of various functions has not proved impressive, partly because of the lack of agreement on what constitutes a proper classification of aphasia in linguistic terms. It is becoming clear that the relationship between linguistic theories and brain structures will not be simple; many workers would now see the development of a neuropsychology of language as a prerequisite for the further advance of neurolinguistics.

NEUROLINGUISTICS, LURIA ON. During the last few decades the sciences of language and speech have undergone a remarkable development.

A few decades ago linguistics was supposed to be a science concerned with general laws of the formal codes employed by language—its phonetic (or phonemic), lexical, syntactical structures. The goal of comparative and structural linguistics was to describe ideal codes of the language, their interrelations, and their formal organization. During the 1950s and 1960s the development of transformational grammar converted linguistics into a very precise science using systems of basic rules which could be expressed by mathematical means.

The discovery of these rules brought linguistics very close to basic psychological questions. The way in which initial motives and thoughts lead to inner speech, abbreviated in its structure and predicative in its function, and then towards extended speech utterances, appeared as a fundamental problem. The process of encoding the initial thought (generation of the speech utterance) and of decoding it (understanding of the speech utterance, its general meaning, and its deep sense) became the most important area for investigation. Leo*Vygotsky's classic work *Thought and Language* appeared, and started the development of a new branch of language science—that of psycholinguistics, which abandoned the formal description of the basic laws of the language and began to follow up carefully the steps of the semantic rules of speech, the conversion of the thought into a verbal intention. Problems associated with the actual psychological generation of verbal utterances, of dialogue and monologue, and of verbal and written speech (as well as their decoding) appeared, and a group of gifted scholars (among them G. Miller, D. E. Broadbent, J. Mehler, T. Bever, R. Brown, T. Fodor, D. McNeill, and D. Slobin) made a series of really important contributions to this field.

In spite of the considerable progress associated with psycholinguistics, one important question remained unsolved. Psycholinguistics was scarcely able to single out basic factors in speech; nor was it able to analyse basic forms of speech composed of separate units, each dealing with a different factor underlying the form. To solve this problem a new step was needed, and this step was provided by a new branch of linguistic science—that of neurolinguistics.

The general method of neurolinguistics is to follow all changes in language and speech that are associated with local lesions of the brain, and to describe as carefully as possible the different forms of breakdown of the processes of encoding of verbal utterances and of their decoding which appear in

cases of differently localized brain lesions.

It is thought that speech, as well as other kinds of mental activity, is really a functional system based on the cooperation of many cortical and subcortical regions, each contributing its own part to the whole processing of information or the establishing of plans and programmes of behaviour. This is why analysis of the derangement of speech processes associated with separately localized brain lesions provides a unique opportunity to single out factors included in language and speech, and to describe different kinds of language disorders each involving different factors in its manifestation.

Observations have shown that the process of speech, which includes mastering language codes and processing their encoding and decoding, can be impaired differently with lesions of different parts of the brain. As a rule, in lesions of posterior ('gnostic') regions of the major (left) hemisphere the process of acquisition of language codes can be disturbed. Lesions of the verbalacoustic areas of the left temporal lobe evoke a derangement of phonemic organization of the sounds perceived, and as a secondary result considerable disturbance of the lexical units of the language is seen: words which are acoustically similar can be confused, and

'alienation of word meaning' takes place. This can

Page 541

result in marked difficulty in understanding single words, while the whole prosodic and partly syntactic structure of the phrase is preserved, and the patient remains able to understand the sense of the whole phrase in spite of lacking stable recognition of single lexical units.

It was found that lesions of the most complex 'tertiary' regions of the left hemisphere (inferoparietal or parietooccipital regions of the cortex) are associated with different forms of impairment of language. Phonemic organization of language remains intact and the understanding of separate lexical units is preserved. Trouble appears when separate lexical parts are related in simultaneous 'paradigmatically' organized structures which require processes of simultaneous synthesis and perception of logicogrammatical relations. This is why in patients with lesions of these regions, fluent 'syntagmatically' organized verbal utterance, or simple

'communications of events' (such as: 'The house is burning', 'The boy hit a dog', 'Mother went to a movie and the children remained at home') are preserved, while complex 'communications of relations' resulting in logicogrammatical structures (such as: 'Brother's father', 'The triangle under the circle', 'Mary is fairer than Ann'), phrases, or complex distant constructions that need a series of additional transformations for their understanding, are severely deranged.

A careful description of these disturbances makes it possible to divide all utterances into two basic groups—one which is 'syntagmatically' organized and remains intact, and a second which is 'paradigmatically' organized and breaks down.

The general statement of neurolinguistics is that in differently localized brain lesions, verbal utterances can be broken down into different links (phonemic, lexical, logicogrammatical, etc.). This

is of great importance for increased knowledge of the basic rules involved in language acquisition and linguistic performance, and is the reason why neurolinguistic studies can contribute to a better understanding of the basic structure of language. What we have described here are new ways of studying some linguistic structures, their components, and the basic types of their breakdown.

But speech comprises more than the mastering of the codes of the language. The generation of speech utterances, as well as their understanding, requires a long journey, starting from motives and intentions, including inner speech, and ending with extended verbal utterances—or, in the case of understanding, starting with perception of extended utterances and finally arriving at an understanding of the basic sense. Last, but not least, there is the motive of the whole verbal communication.

This complex journey includes some important psychological, extralinguistic factors, such as: retention of motives and intentions; constructing plans and programmes of verbal constructions ('realizations') of these plans; and building a 'closed semantic system' which has to remain stable and which can resist distracting factors.

This requires an adequate 'tone' of the cortex (it is impossible to retain goal-linked programmes in dreamy states) and an active participation of the frontal lobes of the brain, which should be considered as a special apparatus for retaining stable programmes and for permanent control of the information processing. If the mechanisms ('apparatuses') of the brainstem are deranged and the 'tone' of the cortex becomes low, or if the frontal lobes are injured and do not provide the control needed,

'closed semantic systems' are broken down and replaced by 'open semantic systems', i.e. by systems open to every distraction, or to inert stereotypes (perseverations). These extralinguistic conditions result in a special kind of pathology, in which the subject becomes unable to use syntactical codes of language, or to generate extended verbal programmes, or to single out the meaning of complicated verbal constructions, which easily become deranged by external influences of immediate impressions, fixed stereotypes, etc.

The application of neuropsychological methods (i.e. the careful study of change in behavioural processes associated with local brain lesions) opens up new techniques both for linguistics and for the psychology of speech. This new field of science can be used with success to improve our knowledge of the inner mechanisms of language.

NEUROMODULATORS. See NEUROTRANSMITTERS AND NEUROMODULATORS.

NEURONAL CONNECTIVITY AND BRAIN FUNCTION. The nervous system is made up

largely of nerve cells (neurons), with their associated neuronal processes, and glial cells. The role of the glial cells in the mature brain is believed to be supportive to the neurons, but in development their involvement in establishing organized connections, and in the formation of differentiated brain structures, appears to be most important. Here we concentrate on the neurons, which, with their axons and dendrites interconnecting the cells in a formidably complex fashion, are thought to carry out the main business of the nervous system. This business, the primary function of the nervous system, is information processing in the most comprehensive sense of the term. For many years there has been discussion on the relationship between the structure (here meaning connectivity) of the nervous system, and its function. If this discussion is to be more than a series of guesses and counter-guesses, we need to have a clear idea of what the structure and function of the system actually are; and here, because of recent advances in neuroanatomical techniques, we are in a much stronger position in relation to neural structure than to function.

Page 542

We have a fairly extensive, though far from complete, knowledge of the connections that exist within both the vertebrate and the invertebrate nervous systems. About parts of the system in various vertebrates (the main sensory pathways, the main motor pathways, the cerebellum, the hippocampus, and certain regions of the spinal cord) our knowledge of connectivity is pretty comprehensive; about other parts of the system (many cortical regions of the cerebrum, the reticular core of the brainstem, and numerous other parts) our knowledge of the patterns of connectivity, although increasing rapidly, is still very limited.

Many invertebrate nervous systems have a relative simplicity, in which not only are the classes of neurons fewer, but also the total numbers of cells, and concomitantly of connections, are less than in vertebrates. In such invertebrate systems this reduced complexity has enabled a fuller picture of connectivity to be obtained. As a result of technical advances in recent years investigators are now in a relatively strong position to start examining how connectivity in small circuits, in which the identities of the individual constituent neurons are known, is related to their function. The extent to which such systems model the circuitry of the more complex vertebrate nervous system, awaits clarification.

In contrast to these 'simple' nervous systems, those of the vertebrates are impressively complicated. The brain of man is often quoted as comprising some 10¹²

neurons. Since, at any given time, an unknown number of these are probably altering their connections, and may be altering their basic characteristics, our attempts to obtain any sort of complete description of neural connectivity are fraught with practical and also theoretical difficulties. The numbers being dealt with are so large and so uncertain that, as was pointed out by Hottridge (1968), no statement of the complete structure of the nervous system can ever be correct; by the time the statement is made, it will be out of date.

This gloomy thought need not deter us, however. In practice, we can get a long way by concentrating on *classes* of connections. When we do this, a most significant fact emerges. To the extent that we are

able to demonstrate patterns of neural connections from one part of the nervous system to another, or to the rest of the body, we find that these patterns are closely similar from one animal to another within the same species, and in some instances are found to be remarkably similar in animals of widely different species.

These similarities in neural connection patterns between different animals indicate two things. First, they tell us that neural connections are not random but are formed in a controlled fashion. Second, they suggest that orderly connections have relevance for the function of the system. Teleologically speaking (and teleology is, after all, essential in any meaningful consideration of the nervous system), it would seem pointless for evolutionary mechanisms to perpetuate and refine the vastly complicated (and highly ordered) networks of neural connectivity, if these were purely decorative, so to speak.

When we consider neural function we find ourselves beset with far greater difficulties than in the study of neural structure. This is because, except for its most obvious roles, we do not really know what the function of the nervous system actually *is*. The above definition of neural function as 'informationprocessing' merely hides our ignorance behind a term which is presently popular without explaining anything. With manmade informationprocessing machines we know what the mechanism is and the nature of the operations performed by it, because we construct the machines in a particular way and for a particular purpose. With the nervous system we did not construct the mechanism, and we have not been able, so far, even to define some of its operations.

There are multiple levels of function in the nervous system and the only ones we know much about are those at the bottom. Some of the simpler spinal*reflexes we can both understand in terms of function and account for (almost) in terms of the connectivity underlying this function. At a higher level of complexity, we also have a fairly good understanding of many of the connection patterns that underlie the arrangement of sensory inputs and motor outputs. It is readily demonstrable at these levels of the nervous system that there is a close relationship between structure and function.

In the adult nervous system it is customary to consider that function is highly dependent upon structure. However, there is now good evidence that it also works the other way round, that structure may depend upon function, particularly during development. Experiments have shown that the refinement of the connection patterns formed between arrays of neurones is dependent upon normal stimulation of the system. If the normal pattern of stimulation is altered during crucial stages of development, the connection pattern can be modified, which in turn changes the functional capabilities of the circuitry.

The existence of a relationship between structure and function in the formed nervous system is readily demonstrated experimentally. Thus one can alter spinal reflexes in an accurately predictable fashion by switching nerve pathways; one can cause people to feel bodily sensations, to hear or see things by electrical stimulation of the appropriate parts of the brain; and one can alter the position of the apparent external stimulus by altering the point of stimulation in the brain. Observations such as these tell us that there are maps of the outside world, as perceived by our various sensory apparatuses, which extend across specific parts of the brain. The visual world, the auditory world, the sensitive surface of the body, are all represented in particular areas of the*cerebral cortex. All this is common

knowledge and has been for many years; yet to a large extent the central mechanisms which

Page 543

are responsible for the motor outputs we associate with these sensory inputs remain unknown.

Even at the relatively low organizational level of sensory inputs and motor outputs, however, things are only fairly straightforward as long as we confine our attention to the threedimensional geometry of the nervous system; as soon as we try to include the fourth dimension, taking into consideration the effects of such things as *learning, *memory and previous experience, the study of sensory inputs moves into another class of complexity.

The main difficulties we find in attempting to relate highlevel neural functions to neural structure are tied up with the problems we have in defining these functions. *Pattern recognition is an easy one and we can almost see how it could work. *Intelligent behaviour is more difficult. We all know what we mean by the term intelligent, but there are almost as many definitions as there are people prepared to define it. Perhaps the most difficult function is language, since it may be very closely related to the very mechanisms of thought. What indeed *is* thought?

The brain is the organ of the mind. There can no longer be any doubt about this in the light of recent neurosurgical observations. The intimacy of the relationship between the brain and the mind is very clearly brought out by the personality changes which occur following surgical lesions of the frontal parts of the brain; and perhaps even more dramatically by the occurrence of two separate minds, or spheres of consciousness, one related to each side of the brain, in patients who have undergone *'splitbrain' surgery (Sperry, 1966).

What we do not yet know is whether a form of inbuilt connectionist mechanism exists to underlie the highest neural functions. Here, the mind boggles (and we would indeed be far advanced if we knew what we meant by mind and if we could usefully define the term 'boggle'). However, while it is in no sense explanatory, a computer analogy may be useful. Simple computers can be wired up to do specific jobs. The larger the computer, and the wider the variety of tasks it can perform, the smaller is the emphasis placed upon specific patterns of wiring and the greater the emphasis on the programming. In the most powerful machines the wiring is in essence relatively simple, whereas the programs are highly complex. We may look on the brain as a form of computer, extensively hybrid, and containing many more elements, more complexly interconnected, than any manmade machine. It seems likely that, in the brain, connections are not prespecified for the highest orders of function.

Perhaps these latter depend upon programs which may themselves be either built in or, maybe more likely, acquired during the development of the individual, through the interaction of environmental factors on a genetically transmitted potential.

Although we do not know the nature of the relationship between neural connections and, for instance, intellectual and linguistic activities, we do know that such a relationship exists. It seems likely that many of the intractable difficulties we encounter in attempting to find out about the relationship

between the brain and the highest neural functions, follow from the self-referential nature of the inquiry. The brain is the organ of the mind, of intelligence, and yet we use the brain to investigate its own activity in these fields. Since modes of thought (including modes of perception) are conditioned by the structure of the brain, it is hardly surprising, in principle, that we find that our thoughts on these matters tend to run in tight philosophical circles.

NEUROPEPTIDES. The study of neuropeptides, i.e. peptides occurring in the nervous system, is one of the fastest growing areas in neurobiology today. Novel peptides from the brain with actions related to functions such as pain, analgesia, sleep, etc., are being discovered at an increasing rate. There are probably two reasons for this neuropeptide 'explosion'. One is that methods for the identification of peptides in very small amounts, such as are present in the brain, have been developed and greatly improved in recent years. The other is the growing realization by neuroscientists of the importance of peptides in brain function, based on the ability of neuropeptides to relay messages selectively between particular groups of cells.

Peptides are made of amino acids joined together to form a chain, and since eighteen different amino acids are found in animals there are 306 ways of putting these together to make a dipeptide and, theoretically, there is an astronomical number of different decapeptides (with ten amino acids). Different peptides can be distinguished because many brain cells, and cells elsewhere in the body, have receptors on their surface which can 'recognize' a particular peptide. Thus each peptide used by the brain can carry a particular message if it can travel to a nearby or distant site to interact with its receptor. The combination of the peptide with its receptor will induce a change in the cell, for example a nerve cell may be excited or inhibited. In this way a peptide can be used by one group of cells to influence or control another group. There are several types of control. A peptide which is released into the bloodstream and acts on distant cells is a hormone: this type of action tends to be slow and longlasting. A peptide released from the fibre terminal of one neurone into the synaptic cleft to act on the Page 544

membrane of another neurone is a neurotransmitter: this type of action is relatively fast and shortlasting.

The first important neuropeptide to be identified chemically was the hormone vasopressin, shown by Vincent Du Vigneaud and his colleagues at Cornell Medical School in 1953 to be a peptide with nine amino acids. Vasopressin is made by a particular group of neurones in the hypothalamus and is

transported to their terminals in the posterior pituitary gland, or neurohypophysis. When these hypothalamic neurones are activated, vasopressin is released from their terminals into the bloodstream and is carried all round the body. Reaching the kidney it recognizes receptors and acts on them and, in effect, commands the kidney to conserve fluid. Thus its function is to act as a messenger between the brain and the kidney in the control of water balance in the body.

Following this discovery, it was some years before it was realized that there are peptides which can relay messages within the brain. Evidence is now accumulating that some peptides act as neurotransmitters at synaptic junctions. It is also possible, though by no means established, that some peptides are released into the cerebrospinal fluid to act at a variety of distant neuronal sites. Research into these possibilities is being eagerly pursued.

The strongest evidence for a neurotransmitter role for a peptide comes from the study of substance P, which was known to be a biologically active peptide, present in brain extracts, as long ago as 1936, although its chemical identity was not established until 1970. Substance P is present in fine sensory fibres which inform the nervous system of painful stimuli, for example it is found in fibres from the tooth pulp. There is a body of evidence to suggest that it is released from the terminals of such fibres at synapses, where it excites sensory neurones which transmit the message that noxious stimulation has occurred to higher parts of the brain concerned in pain sensation and in behavioural responses to pain.

There are also peptides which can produce analgesia. These are the enkephalins and endorphin, which are known as opioid peptides because their action resembles that of morphine and other derivatives of opium. Their discovery in 1975 was a major advance in our knowledge of brain function. These peptides occur in particular groups of neurones and their best-known action is to produce analgesia by inhibiting neurones which are attempting to transmit the message that pain-producing stimulation has occurred.

Is there a sleep peptide? This intriguing possibility has spurred the activity of several research groups. Certainly a substance of peptide composition with sleep-inducing activity can be extracted from the brain, or cerebrospinal fluid, or cerebral venous blood, of sleeping or sleep-deprived animals. However, different groups of workers are not yet in agreement on the identity of this peptide, and identification is necessary before its role in sleep can be determined.

One group of peptides made in hypothalamic neurones are transported via local vascular channels to influence the release of hormones from the anterior pituitary gland. These include thyroid hormone releasing factor (TRH), luteinizing hormone releasing factor (LHRH), and growth hormone releasing-inhibiting factor (somatostatin). These three peptides are also found in neurones in many other areas of the central nervous system, where their functions are as yet unknown.

Peptides that occur in the alimentary canal and various other naturally occurring peptides have been found to be distributed in particular groups of neurones in the central nervous system, but little is known about their possible functions. Some peptides have been shown to influence behaviour, and a recently discovered tripeptide, containing pyroglutamate, histidine, and glycine, has been obtained

from the urine of patients with one type of anorexia nervosa: given to mice it acts to reduce food intake, but it is likely that this peptide is only present under pathological conditions.

How are neuropeptides made? Nerve cells are different from other cells in that they possess large amounts of RNA (Nissl substance) in the cytoplasm. The RNA makes proteins with a sequence of amino acids that depends on the sequence of bases in the RNA in each cell; these proteins are then cleaved at particular points by peptidases. The short-chain peptides thus produced can be transported to the fibre terminals of the neurone and released when required. During evolution, mutations occur which change the base sequence in the DNA in the genes, and therefore in the RNA, and this results in changes in the amino acid sequence in the proteins and peptides. These changes may be unimportant, resulting in minor differences between species in closely related peptides with the same function. Alternatively the changes may be more significant, resulting in the development of different peptides which, although related to their ancestral peptide, have become specialized for different functions. Thus vasopressin has the same function in different mammals even though in some species a particular amino acid in the sequence has been changed. On the other hand, vasopressin and another hypothalamic peptide, oxytocin, are related in that they both have nine amino acids, seven of which are identical, but the difference is sufficient for them to have different actions. Some mutations may throw a spanner in the works by preventing the formation of a particular peptide or by producing a peptide which interferes with normal function. In this way some pathological defects of genetic origin may arise.

For the future, we know that there are many peptides in the brain and spinal cord whose chemical identity and actions remain to be determined. Since some peptides have been shown to have actions related to specific functions we can specu

Page 545

late that this may be true also for many other peptides. Does each peptide supply the chemical code for particular types of activity? Within the next decade we can expect to know much more about the role of peptides in brain function. For better—it is hoped—or for worse, this work will lead eventually to the development of important new drugs with effects on brain and behaviour. One might also hope that better understanding of the functions of neuropeptides in the brain will yet produce a nonaddictive analgesic. For example, endorphin, when injected, has effects similar to those of morphine. Unfortunately tolerance to and physical dependence upon both endorphin and met-enkephalin have been demonstrated as well as cross tolerance between these peptides and exogenous opioids.

NEUROPSYCHOLOGY. The first issue of the international journal *Neuropsychologia*, in January 1963, contained an editorial which defined the term

'neuropsychology' as 'a particular area of neurology of common interest to neurologists, psychiatrists, psychologists and neurophysiologists'. It added that 'this interest is focused mainly, though not exclusively, on the cerebral cortex', that 'topics of particular concern are disorders of language, perception and action', and that 'although certain of these disorders can, of course, be studied only in man, we are none the less convinced that information of great value to human pathology is to be obtained from animal experiment, which may be expected to throw valuable light on the basic mechanisms of cerebral organization'. An editorial in the same journal nearly twenty years later commented that 'there is still no better definition available'. The developments which led up to the emergence of an autonomous discipline of neuropsychology have a long and chequered history and provide insights into the perennial issues which still occupy neuropsychologists.

Attempts to localize mental processes to particular bodily structures can be traced back at least to the fifth century BC, when Hippocrates of Cos identified the brain as the organ of intellect and the heart as the organ of the senses. Empedocles (about 490/430 BC), concerned with the same central and enduring philosophical problem of the relationship of mind to body, located mental processes in the heart. For the next two thousand years, the relative merits of what have been called 'the brain hypothesis' and the 'cardiac hypothesis' were debated. The natural successor to Hippocrates was the anatomist*Galen, who, in describing aspects of brain anatomy, argued for the brain hypothesis. There is little doubt that both Hippocrates and Galen drew heavily upon their experiences as physicians. Galen as a surgeon tending gladiators was doubtless well aware of some of the consequences of brain damage. His views contrast with those of*Aristotle, who, having decided that the heart was warm and active, saw it as the source of mental processes, whereas the brain was relegated to the minor role of serving as a mechanism cooling the blood of the heart. Galen believed that the mind was located in the fluid found in the large ventricles of the brain, a view which continued to be canvassed until it was refuted by Vesalius (1511/64). *Descartes, continuing the debate, adopted a quite explicit dualist position, seeing the body and the mind as separate but nevertheless able to interact. By the eighteenth century, some of the issues that were to represent major viewpoints in what was to become neuropsychology were already being identified—the principal one being whether, and to what extent, particular mental functions could be localized in particular parts of the brain.

The detailed argument for localization of function is usually associated with the phrenological theory

of Gall and with his contemporary J. C. Spurzheim (1776-1832).

Both Gall and Spurzheim were anatomists and made important contributions to their discipline by which they were assured a place in the history of science.

Regrettably, once they went beyond anatomy and attempted to locate functions in different parts of the brain, they indulged in speculation which led them wildly astray.

From their observations of the external structure of the skull, they developed the view that such external features might correlate with important aspects of behaviour.

Despite the conceptual ingenuity of their views, they failed to produce evidence which was even reasonably objectively based and could be regarded as convincing support for their main hypothesis. The demolition of their views was brought about by the work of the French anatomist Pierre Flourens, who ablated parts of the brains of pigeons and studied the changes that occurred postoperatively in their behaviour. He concluded that there was no evidence for localization of function within the cerebrum but that any loss that was observed simply reflected the extent of damage to brain tissue.

The possibility of demonstrating localization of function took a decisive step forward on 21 February 1825, when J. Bouillaud (1796-1881) read a paper to a scientific meeting in France in which he argued from his clinical studies that speech was localized in the frontal lobes, a view already suggested by Gall. Shortly afterwards, in 1836, Marc

Page 546

Dax read a paper in Montpellier, also reporting a series of clinical cases; these he believed demonstrated that speech disorders were linked with lesions of the left hemisphere. It was not, however, until 1865 that Dax's manuscript was published, by his son. Meanwhile, in 1861, Paul Broca, founder of the Anthropological Society of Paris, heard Bouillaud's son-in-law report the case of a patient who had ceased to speak when pressure was applied to his exposed anterior lobes. Soon afterwards, he saw a patient who had lost his speech and could say only one word, 'Tan', and utter oaths. Results of the post mortem on this patient indicated left frontal pathology. It is usual to credit Broca with describing this syndrome, which consisted of the inability to speak despite normal understanding of language, and also as the person who elaborated the concept of cerebral dominance of language in the left hemisphere. The other outstanding figure at this time was Wernicke. To him is attributed the discovery that there is more than one language area in the brain.

The history of thought on aphasia over the past 150 years and more illustrates the continuing debate about how mental functions are related to brain structure. Thus, one group of workers on aphasia, taking their lead from the early phrenologists, maintained that specific mental functions were subserved by separate areas of the brain. Those who opposed this 'localizationist' view believed that mental capability reflected total intact brain volume. While Broca and Wernicke lie in the localizationist tradition, Hughlings Jackson and Kurt Goldstein represent the so-called holistic

approach to aphasia.

In view of these early observations on the relations between brain and behaviour, it remains something of a puzzle why a separate discipline of neuropsychology did not develop by 1900 rather than by 1949. Perhaps part of the reason was the intervention of the world wars, part was the suspicion of any views that seemed to indicate a retreat to the localizationist views of the phrenologists, and part was the strong presence of the so-called Gestalt theories in psychology. All of these, it would seem, led to the localizationist approach being abandoned in favour of a more holistic approach. Henry Head (1926) was dissatisfied with the classical neurologists' attempts to deduce schemes from clinical observations, believing that they were, as he put it, 'compelled to lop and twist their cases to fit the procrustean bed of their hypothetical conceptions'. He attempted to bring some order to the field by devising a standard list of tests to be used in the study of aphasia, an idea developed by Weisenberg and McBride (1935). Earlier (1933), Weisenberg and McBride had made the important discovery that individuals who do not understand spoken language, although their hearing is intact and they can identify nonverbal sounds (e.g. a telephone ringing), may have damage in two different locations. Around the same time, the influence of Karl Lashley, who published his paper 'In Search of the Engram' in 1938, is usually seen as significant. Lashley proposed a theory of mass action, contending that the behavioural result of a lesion depends on the amount of brain removed more than on the location of the lesion.

During the second half of the twentieth century and, in particular, immediately after the Second World War, there was a reawakening of interest in the brain/behaviour relationship, and, as often happens in science, it was not so much the discovery of new ideas but the rediscovery of old ones. In this case it was the views of some of the classical neurologists, combined with the development of the new behavioural techniques of the experimental psychologists which were to give the necessary impetus to lead to the development of neuropsychology as such. Recent research (Bruce, 1985) suggests that the term 'neuropsychology' was first used in 1913 by Sir William Osier in an address he gave at the opening of the Phipps Clinic at the Johns Hopkins Hospital. In his address entitled *Specialism in the General Hospital* Osier expressed the hope that 'time may be found for general instruction of the senior class in the elements of neuropsychology'. Bruce speculates that Lashley, who was appointed research professor of neuropsychology at Harvard in 1937, may have heard Osier give his address at the Phipps Clinic since Lashley was a graduate and postdoctoral student at Hopkins from 1911 to 1917. Subsequently in 1949 the term 'neuropsychology' was given wide publicity when Donald Hebb published a book under the title *The Organization of Behaviour: A neuropsychological theory*. Nine years later, Heinrich Klüver, in the preface to his book on *Behaviour Mechanisms in Monkeys*, suggested that it would be of interest to 'neuropsychologists'. In 1960, Karl Lashley's collected writings were published under the title *The Neuropsychology of Lashley*. At no point, however, thus far, was the term 'neuropsychology' used systematically, nor was it carefully defined in the text. Hans Lucas Teuber, one of the early pioneers in neuropsychology, argued that the task of neuropsychology is twofold. First, to help the patient with the damaged brain to understand his disease and, secondly, by carefully studying such experiments of nature, to provide essential insights into the physiological basis of normal brain function. Although such study draws information from several disciplines, including anatomy, biophysics, ethology, pharmacology, and physiology, nevertheless its central focus

continues to be the development of a science of human behaviour based upon the study of the function of the human brain. Teuber showed elegantly and convincingly how the precise methods traditionally used by experimental psychologists in the study of psychophysics could be applied to problems in neuropsychology.

His monograph entitled *Visual field defects after penetrating missile wounds of the brain*, published in 1960 and written jointly with Page 547

Battersby and Bender, illustrates the success of such methods.

Thus by 1963 the time seemed ripe for the launching of *Neuropsychologia*. The editorial of the first issue traced its background to regular meetings of a small group of European neurologists and psychologists who had first gathered in Austria in 1951 to discuss disorders of higher mental functions associated with injury or disease of the brain.

Today there are several different approaches to the study of the brain/behaviour relationships, but the method which has figured most prominently is the one that is the natural successor or complement to the work of the early neurologists, namely study of the effects of lesions in specific areas of the brain by carefully observing associated changes in behaviour. It is noteworthy that the results of carefully controlled animal studies have been very important in the development of neuropsychology. In studying patients, one must, for obvious ethical reasons, take what comes and thus accept that the limits of any brain damage are not precisely known. By contrast, in animal studies, the locus and extent of lesions can be precisely defined and pre and postoperative behaviour carefully studied and measured.

In human studies, experimental psychologists have contributed significantly by devising ingenious techniques to be used under controlled conditions and by proposing theoretical concepts to account for the deficits in behaviour observed in braindamaged patients: for example, the distinction between shortterm memory and longterm memory and models of their interrelationships.

Neuropsychologists study our awareness of the world in which we move. What we see, hear and touch are dependent upon the proper functioning of the intact central nervous system. Likewise, how we respond by taking action is dependent on the intactness of those parts of the nervous system concerned with initiating and sustaining coordinated motor activity. But it is not only sensory and motor processes that may be altered by changes in the nervous system: higher functions such as language, thought, and memory may also be changed. The human brain is well endowed with so-called association cortex. These are regions of neocortex not specialized as primary sensory or motor regions. Thus, *memory, for long a topic of interest to philosophers, was a central concern of Lashley, who, after years of animal experimentation, concluded that 'it is not possible to demonstrate the isolated localization of a memory trace anywhere in the nervous system'. Only three years after Lashley reached this conclusion, a neurosurgeon, William Scoville, in 1953, operated on a patient known as H. M. and left him unable to remember virtually anything that occurred after his operation. It appeared that the surgical bilateral removal of the hippocampus and adjacent structures had not touched H. M.'s stored memories but had made it impossible for him to store or retrieve new

memories. The detailed study of H. M. changed the emphasis in the study of memory from searching for a location for memories to analysing how memories are stored and retrieved. Today, the roles of the temporal, frontal, and parietal lobes in memory form part of a wider study of the complementary specializations of the left and right hemispheres, to which we now turn. Since studies of cerebral asymmetries have been a major part of research in neuropsychology for several decades, they illustrate well the methods used by neuropsychologists, how their results are presented, and the controversies and uncertainties that remain.

Cerebral asymmetries. The discovery by Dax and Broca in the nineteenth century that damage to the left hemisphere resulted in inability to talk, whereas damage to the right hemisphere did not affect speech production, led to the general acceptance of the view that the left hemisphere plays a special role in language which is not shared by the right hemisphere. Language, however, is not the only special function of the left hemisphere. At the beginning of the twentieth century, H. Liepmann demonstrated that the left hemisphere has a special role in controlling complex movements. Nevertheless, the special functions of the right hemisphere remained a comparative mystery until the early 1950s when, following the work of Zangwill, Hécaen, and Milner, it became clear that it was more involved in the analysis of visual and spatial dimensions of the world than was the left hemisphere.

The potential for some behaviours, it would seem, is virtually wired into the structure of the nervous system. These include not only reflex and instinctive behaviours, but also behaviour as complex as language. In this sense, psychological asymmetry is based upon microanatomical asymmetry. In 1968, Geschwind and Levitsky reported gross anatomical asymmetries following their study of a large series of human brains. They reported that the part called the 'planum temporale' was larger on the lefthand side of 65 per cent of the brains they studied and that it was larger by nearly 1 cm than on the right. Subsequent studies have confirmed Geschwind and Levitsky's findings and have shown, moreover, that these structural differences are in evidence very early in life.

In addition to those studies of neurological patients with lesions on one side or other of the brain, there are studies of those who have had the brain stimulated during surgery and of those receiving temporary anaesthetization of one side of the brain before surgery. Most recently, studies of regional bloodflow have added another technique for the study of functional asymmetry. Studies of healthy people have also added significantly to neuropsychological knowledge. One widely used technique is to present sensory information selectively to one or other cerebral hemisphere and to ask for some kind of verbal or nonverbal response. Electrical recordings from the two hemispheres

Page 548

have also been studied. Even so, the method that has proved most powerful in demonstrating lateralization is that called, by Teuber, 'double dissociation'. Having demonstrated that lesions in the left hemisphere of righthanded patients produce difficulties in language, including speech, writing, and reading, and that such difficulties do not follow from lesions in the right hemisphere, we may say that the functions of the two hemispheres are dissociated. By contrast, difficulties which follow righthemisphere damage are found with spatial tasks, with singing, and with playing musical

instruments; such abilities are thus more disrupted by damage to the right than the left hemisphere. It is then said that the two hemispheres are doubly dissociated.

Another approach which has proved important in identifying cerebral asymmetries has been study of the results of an operation carried out on a small number of patients to whom epilepsy had become a problem unresponsive to other forms of therapy. In some such cases, neurosurgeons resorted to cutting through the major fibres which interconnect the two cerebral hemispheres, known as the neocortical commissures. These include the corpus callosum and the anterior commissure, and their complete sectioning is known as 'total commissurotomy'. After the operation, the two hemispheres behave as if they are virtually independent. Because of the particular way in which sensory inputs are connected to the cerebral hemispheres, we know that information coming from the left visual field or the left hand is directed to the right hemisphere, and vice versa for the right visual field and the right hand. From numerous studies of such so-called 'splitbrain' patients, it is now acknowledged that when the left hemisphere has access to information it can initiate speech and thus talk about the information, whereas the disconnected right hemisphere cannot. The right hemisphere apparently is good at recognizing things but is unable to initiate speech because it cannot get access to the speech mechanisms in the left hemisphere. By presenting stimuli such as pictures or words to the left visual field and thus the right hemisphere, or the right visual field and left hemisphere, and asking the patients to name or otherwise act upon what is seen, it has been possible to carry out careful studies of the functions of the isolated right and left hemispheres (see SPLITBRAIN AND THE MIND).

The technique of selectively presenting information to one or the other hemisphere, whether through the eyes or through the ears or through the sense of touch, has also been applied to normal people. The results indicate relative differences between the two cerebral hemispheres, but it is difficult to repeat such experiments and get the same results each time.

Another approach to the study of brain function arises at times in the course of major brain surgery when a neurosurgeon may briefly stimulate the exposed surface of the brain electrically in order to ascertain which part of the brain he is treating and also to establish with as much certainty as possible on which side of the brain speech is lateralized. Using such stimulation and asking the conscious patient to report what he feels or to answer questions, further information is gained about the functions of particular areas of the brain.

There is yet another source of neuropsychological knowledge associated with the study of neurological patients. To discover as precisely as possible in which hemisphere speech and language are lateralized, a neurosurgeon may temporarily inactivate one or the other hemisphere by injecting sodium amobarbitone selectively into the carotid artery supplying one or other side of the brain. In this way, it is possible to study what one side of the brain is able to do in the temporary absence of help from the other side. Recently it has been assumed that the flow of blood to the neocortex increases in areas where the neurones are particularly active, and in this way, by injecting a solution of a radioactive substance into the blood, it has been possible to examine where it accumulates when particular cognitive activities are taking place. (See IMAGES OF THE BRAIN IN ACTION.)

The auditory system (see HEARING) is not completely crossed, as both hemispheres receive

projections from both ears. It appears that the connections from each ear have a preferred access to the opposite hemisphere, so that sounds to the right ear are principally handled by the left hemisphere and vice versa. Kimura showed that when words are presented simultaneously to the two ears through headphones, the material that is entering through the right ear is more easily analysed than that coming in through the left ear. The converse seems to be true with musical material similarly simultaneously presented. Observing this difference, it has been inferred that the left hemisphere specializes in the analysis of language and the right hemisphere in music. A similar technique can be used to study sensation through touch. For example, two flat stimuli can be represented simultaneously, one to each hand, and the subject is asked to identify the objects that are being palpated. In all such experiments the results show that in normal subjects, hemispheric asymmetry is relative rather than absolute. In the normal subject, since the two hemispheres are intimately interrelated through the corpus callosum, any information that is put into one hemisphere can rapidly be transferred to the other hemisphere. Thus, the most likely reason for the observed asymmetries is that the direct route into the left hemisphere is much more efficient than the indirect interhemispheric route.

Neuropsychologists recognize that such talk about lateralization of function begs a number of important questions. What, for example, is it that is lateralized? On this issue there are a number of competing theoretical arguments. For example, there are those who take the view that the two hemispheres are organized differently. Thus, Page 549

Josephine Semmes in 1968 suggested that the left hemisphere functions as if there is a collection of discrete regions, whereas the right hemisphere functions in a much more holistic and diffuse manner. Others take the view that the two hemispheres have distinct ways of processing information, and they argue that the left hemisphere works in a much more analytic way, as it processes information sequentially and abstracts out the relevant details, whereas the right hemisphere synthesizes what comes in. The possibility of different forms of cerebral organization is well illustrated by the continuing debate about how speech and language are organized in the brains of lefthanders. Thus some (e.g. Zangwill, 1960), noting the higher incidence of aphasia in unilaterally braininjured lefthanders, have postulated an incomplete functional lateralization of speech in the vast majority of lefthanders, resulting in greater sensitivity to brain lesions.

As the young science of neuropsychology has grown up in different parts of the world, so it has developed its own distinctive emphases and techniques. In the USA, the emphasis has been on quantitative and psychometric techniques. In some cases batteries of tests have been applied to large groups of patients in an attempt to analyse quantitatively the patterns of deficits that emerge between the different braindamaged groups. In the UK, the approach has been more qualitative and less psychometric and has paid more attention to the indepth study of crucial single cases, from which a great deal can be learned and any one of which may, properly studied, call into question an existing neuropsychological hypothesis. The case of H. M. cited earlier is a prime example of work in this tradition, including the work that has been done in Canada. In the USSR also, under the leadership of Luria, qualitative and nonpsychometric techniques have had preeminence. For Luria, the preferred techniques were simple, often using only pencil and paper which could be administered at the bedside and not requiring the full panoply of the experimental psychologist's laboratory. Commenting on Luria's contributions to neuropsychology, Teuber described them as 'monumental', noting that they

spanned a third of a century and, in addition to being concerned with the major syndrome of man's left cerebral hemisphere, encompassed 'a detailed and brilliant analysis of the syndrome of massive frontal lobe involvement'. The publication in 1965 of an English translation of his book, *The Higher Cortical Functions in Man*, made available to the West a wealth of neuropsychological theory and practice.

Each of these distinctive approaches to neuropsychology has contributed significantly to its development and will continue to do so. From time to time, excessive claims have been made for the young discipline, and simplistic accounts have been given of results. In the case of cerebral asymmetries, wide generalizations have been made, speculation going far beyond the relatively limited data and not always helping the development of the subject. One of the major growth areas in recent years has been application of the results of detailed studies of patients to cognitive models of behaviour rather than to the neurophysiological and neuroanatomical substrate of behaviour.

NEUROPSYCHOLOGY OF LANGUAGE. See LANGUAGE: NEUROPSYCHOLOGY.

NEUROSIS is a habit that is either maladaptive in some obvious respect and/or distressing, yet more or less fixed and resistant to modification through the normal processes of learning. Its original meaning was a circumscribed disorder or loss of function of a bodily organ that was attributed, mistakenly, to disorder in the function of peripheral nerves or nervous tissue. It is only diagnosed nowadays when any disease or disorder in the nervous system seems improbable. Examples of neurotic habits are persistent anxiety out of keeping with the immediate circumstances,*phobias, obsessive thoughts, compulsions, and such losses of function as the paralysis of a limb or erectile impotence. (See OBSESSIONS AND COMPULSIONS.)

Therapeutic investigation of a neurosis turns on the mental mechanisms involved, its origins in past experience, and the current circumstances determining its persistence. These tend to lie in the benefits, often hidden, that the habit confers. Thus the essence of the neurosis may be, as Sigmund*Freud argued, the renunciation of a function whose exercise would give rise to anxiety. The neurosis then persists because, keeping away from a situation that would arouse anxiety, the patient is

Page 550

denied opportunities to learn more constructive ways of dealing with the sources of the anxiety.

Compare PSYCHOSIS.

D. R. D.

NEUROTRANSMITTERS AND NEUROMODULATORS. The soft warm living substance of the brain and nervous system stands in stark contrast to the rigid metal and plastic hardware of a modern day computer, but at the fundamental level there are clear similarities between these two apparently

disparate organizational systems and, of course, one is a product of the other. Not only are the nerve cell units (neurones) selfrepairing and selfwiring under the grand design built into our genes, but they can also promote, amplify, block, inhibit, or attenuate the microelectric signals which are passed on to them, and through them, and thereby give rise.

to signalling patterns of myriad complexity between networks of cerebral neurones, and this provides the physical substrate of mind. Such key processes of signalling by one group, or family, of neurones to another is achieved largely by the secretion of tiny quantities of potent chemical substances by neuronal fibre terminals. These neurotransmitters stimulate selected neighbours, with whom they junction, into producing electrical responses which both qualitatively (i.e. by excitation or inhibition) and quantitatively (i.e. by frequency of neurotransmitter release) reflect the patterns of presynaptic stimulation.

In this way, the nerve impulses are passed on from cell to cell. This continuous alternation between electrical and chemical conveyance of signals on their journeys through the pathways of the brain and nervous system, provides a special opportunity for the traffic of electrical impulses to be modulated or blocked as they attempt to jump the gap between one neurone and the next at their junctions, transposed into pulses of chemical substances. This is the point where selected constellations of neurones from the vast array of neuronal populations can effectively interact, one with another, to filter, edit, integrate, and add precise direction to their interplay of communication. Thus, neurotransmitters and their functional partners, the *neuromodulators*, play a cardinal role in controlling the flow of information through the nervous system.

Neurones as Information receivers and transmitters. The extensive web of branching*dendrites which characterizes so many neurones in the brain (see NERVOUS

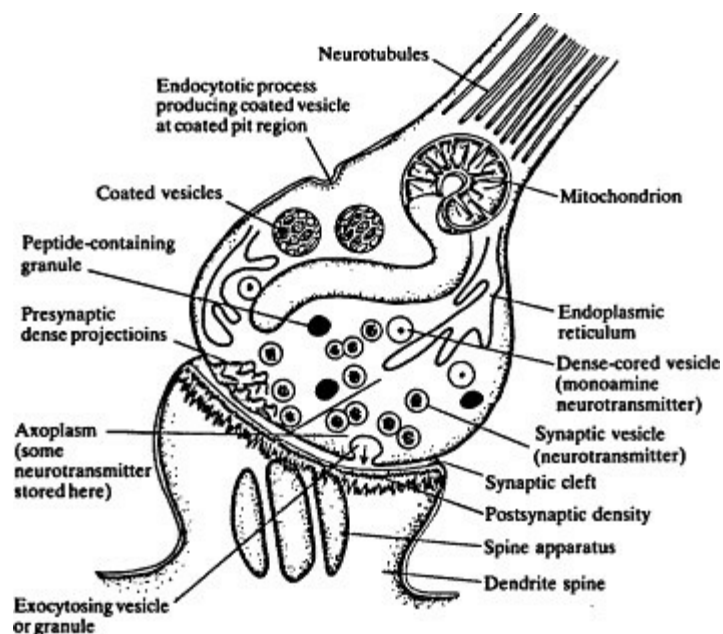

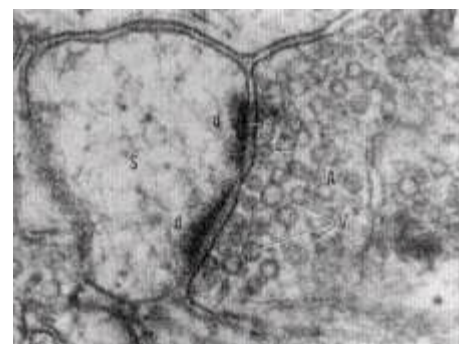

SYSTEM) is primarily an adaptation to provide maximal surface area for receiving inputs from other nerve cells with which they make contact. *Interaction* is very much the principle theme which underlies the shape and cellular anatomy of neurones. Each pyramidal neurone in the vertebrate brain is likely to be receiving up to some 100,000 contacts from the neurones to which they are wired, and the dazzlingly complex and extensive multibranched dendritic tree of the Purkinje cells of the*cerebellum, concerned with learning coordination tasks, probably extends to some 300,000 neuronal contacts. The*axons, the single output line of the neurone, can be rather short (e.g. in socalled *interneurones*) or very long, perhaps 12 metres in cortical pyramidal cells of the giant blue whale, which course from brain to lower spinal cord. At various points along its length, the axon may branch to make contact with local neuronal communities, though most of its contacts are made towards its terminal region. Thus, it is not surprising that the cellbody region of the neurone is Fig. 1.

Golgi preparation from the visual cortex of a human infant, showing the vertical orientation of many neuronal processes.

Dendrites (D) can be identified by the spine processes which

give their surface a rough, granular, appearance. In contrast

axons (A) and cell bodies (CB) are smooth surfaced.

Page 551

estimated to take up only 5 per cent or less of the cellular volume of the brain, the greater part comprising the dense fibrous feltwork of dendrites and axons (Fig. 1).

Sometimes the neuronetoneurone contacts or

Fig. 2.

'tightjunction' variety in rat brain. The presynaptic region

(axon, A) synapses onto the postsynaptic region,

(dendrite spine, S). Note the synaptic cleft (C),

synaptic vesicles (V), and postsynaptic densities (d). The

latter are double because the density forms a 'doughnutlike'

ring and is seen as a cross section through this ring.

This arrangement of the density, is not uncommon.

Note synaptic vesicles exocytosing (*arrow*). Compare with Figure 3.

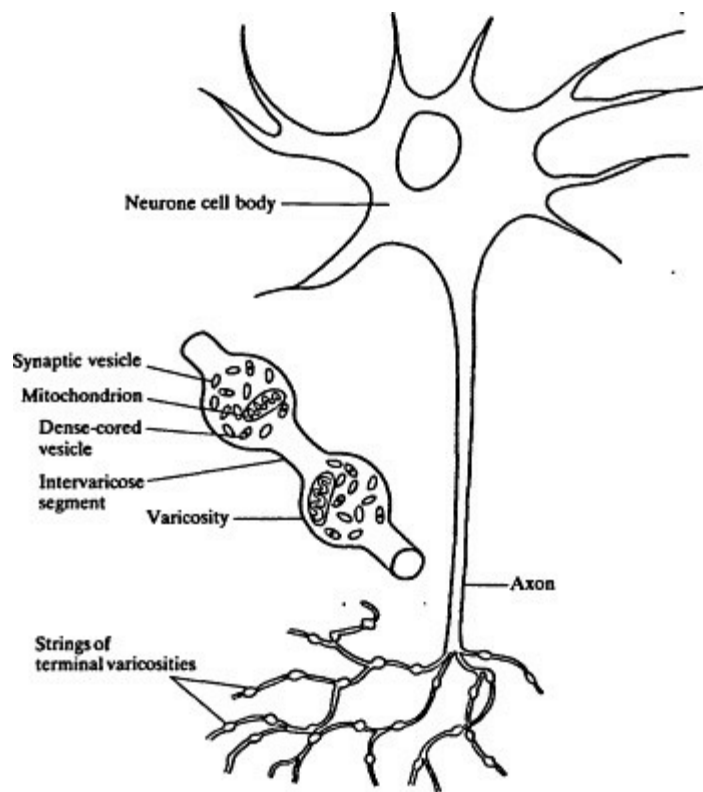

* *synapses*, as they are termed, are highly organized junctions allowing an extremely close approach between the two cells so that they are separated only by a very narrow gap or *cleft* (typically 20 nanometres wide) (Figs. 2 and 3). In this case, neurotransmitters are delivered at a very precise location when their secretion is triggered by the incoming nerve terminal. In other cases, the axon produces long chains of swellings (so-called *varicosities*) towards its terminal branching regions, and these provide multiple sites for neurotransmitter release as the nerve impulse courses through them on its passage towards the distal regions of the neurone (Fig.

4).

These varicosities, whilst containing synaptic vesicles and granules of the type characteristic of the 'tight junction' synapses described above, do not exist in highly organized apposition to other neurones, and the highly structured synaptic cleft (gap between neurones) or postsynaptic thickenings typical of 'tight junction' synapses are rarely present (compare Figs. 3 and 4). The neurotransmitter is probably released from the whole bulbous surface of the varicosity as a miniature cloud which will diffuse away, diminishing in concentration, until it encounters the appropriate neurotransmitter neuroreceptors at which it can bind and act. These varicose modifications of nerve axons were first discovered in the peripheral nervous system, but in the past decade they have become established as a common feature Fig. 3.

Diagrammatic version of an axon terminal forming a synapse on a spine apparatus of a dendrite.

The structures shown are not to scale. Endocytosis produces complex vesicles consisting of a hexagonal basketwork of fibres (cytonet), which form part of the inner surface of the nerve terminal membrane at regions called 'coated pits'. In this diagram, vesicles containing monoamines, neuropeptides, and other neurotransmitters are shown. A vesicle is shown expelling neurotransmitter into the synaptic cleft by exocytosis.

Page 552

Fig. 4.

of the synaptic organization of the brain itself, and provide a semilocalized form of neurotransmitter release called *paracrine* neurosecretion.

How many neurotransmitters are there? The search for chemical agents which could transmit the activity of peripheral nerves onto their target organs began early in the twentieth century. In the 1920s and early 1930s, after a long trail of research* *acetylcholine* was unequivocally demonstrated to be mediating the inhibitory influence of the vagus nerve on the heart, as well as the excitatory action of motor nerve terminals on voluntary muscle. At that point, acetylcholine became the first chemically identified neurotransmitter substance.* *Adrenaline*, too, was an early candidate as neurotransmitter in the peripheral nervous system at ganglionic sites, but after long accumulation of evidence its unmethylated derivative, *noradrenaline*, was finally shown in the mid 1940s to be the actual agent responsible.* *Dopamine*, a closely related amine (monoamines), followed a similar history, with doubt and then certainty following its progress to acceptance as a neurotransmitter in the 1950s (see CATECHOLAMINES). In the 1940s another neuroactive monoamine, *serotonin*, first isolated from blood was accepted as a neurotransmitter in the brain and peripheral nervous system.

Thus, in the 1950s only four compounds, together with a few other unlikely candidates, including a peptide (*substance P*), were the full armoury of agents known to be acting as neurotransmitters. They were found to be localized to the neurones from which they were released. These substances seemed to be specialized for their task as neurotransmitters and were not involved in other biochemical activities. At that time, it seemed likely that, together, they provided the principal means of chemical

neurotransmission throughout the nervous system. However, it was also in the 1950s and later in the 1960s that four amino acids (*glutamate*, *aspartate* as excitatory agents, and *GABA* and *glycine* as inhibitory agents), also amines (but carrying an acidic group as well), were being considered as new and important contenders as neurotransmitters in the brain and spinal cord. They were most unlikely candidates, being found ubiquitously in all cells and organs in high concentrations, and being involved in a wide range of metabolic pathways and biosyntheses in the general biochemical economy of the cell.

The first members of yet another entirely different biochemical category of neurotransmitters became serious contenders in the 1970s, namely the* *neuropeptides* (2 to 50 residue oligopeptides). Unlike the amino acids, the neuropeptides are mostly present in extremely small quantities in

Page 553

localized regions of the nervous system. The earliest candidates proved to be already operating in the brain as local *neurohormones* in the hypothalamus and anterior pituitary gland. One example is thyrotropinreleasinghormone (*TRH*, a tripeptide). During the 1970s and 1980s many or most of the peptides known to be serving an endocrine or neurotransmitter role in the gastrointestinal system were found to be also serving as neurotransmitters in the brain. The significance of the dual existence and bioactivity of these peptides is not clear, but specific neuroreceptors for them exist in both brain and gastrointestinal systems, allowing the possibility of braingut interactions at the neurohormone level, and giving rise to the concept of the ' *braingut axis*. '

Some of these neuropeptides seem to evoke rather more complex responses than simple synaptic excitation or inhibition (both of which they also mediate). For example, very small quantities of TRH can induce euphoric states, and it can act as an antidepressant drug for the treatment of affective disorders. Another neuropeptide, *b endorphin*, causes muscular rigidity and immobility (catatonia), whilst *luteinizinghormonereleasinghormone (LHRH)* is reputed to stimulate the libido, and has been used to cure oligospermy. *Cholecystokinin (CCK)* promotes feelings of appetitive satiety and causes cessation of feeding in animals. *Bombesin* dramatically lowers body temperatures, controls many aspects of gastric secretion, and stimulates appetite by actions at sites within the brain. The**endorphins* and *encephalins* not only produce fairly complex and sophisticated behavioural effects, they also induce analgesia, behaving like endogenous 'morphinelike compounds'.

Unfortunately, they (and their active synthetic derivatives) are also addictive when given in quantity

as analgesic drugs. The endorphins seem to serve a neurohumoral role as well as that of neurotransmitter (see PSYCHOPHARMACOLOGY).

Peptiderelasing neurones show certain special features in their organization. Thus, cholinergic (i.e. 'worked' by acetylcholine), monoaminergic, and amino acidergic neurones synthesize neurotransmitter principally in their nerve terminals, by simple enzymatic processes. Peptidergic cells in contrast, synthesize their peptide neurotransmitters as subcomponents of large 'mother' proteins by protein synthesis processes occurring in the cell body. These are then loaded into large granules and transported down the length of the axon to the terminal regions of the neurone. During this journey, the active neuropeptides are 'snipped' off the mother protein by specific enzymes (proteases), and the peptide neurotransmitters are then ready for release on arrival (Fig. 5). Inactivation of the released peptide neurotransmitter is by enzymatic hydrolysis, as for acetylcholine, and unlike most other neurotransmitters—which are rapidly reabsorbed back into the terminals, and into surrounding glial cells.

When one surveys the current (1987) list of neurotransmitters (Table 1), it can be seen that apart from the simple amines and amino acids discovered during the first seventy years of this century, some fifty neuropeptides must be included. The latter serve in hybrid capacities as neurotransmittersneurohormonesneuromodulators, and in this way trigger off complex patterns of behaviour.

In order to be accepted as a neurotransmitter, the substance must satisfy some seven key criteria. Until they satisfy all criteria, they are called *putative* neurotransmitters. Most of the compounds listed in Table 1 have satisfied these criteria and are fully fledged neurotransmitters. Many of the neuropeptides listed are of putative neurotransmitter/neurohormone status.

Fig. 5.

Diagram illustrating the biosynthesis, packaging, and release of peptides and other neurotransmitters in neurones. The peptides are generated from large precursor molecules (preproproteins) produced in the rough endoplasmic reticulum (RER) of the neuronal cell body. These are packaged into secretory granules or vesicles in the Golgi membrane stacks. The granules are then transported out of the cell body (*axonal transport*) to the terminals, where upon stimulation, they release their contents by exocytosis. Other neurotransmitters are produced in the cytosol of the cell body, axon, and principally in the nerve terminal, and they are packaged by uptake into preformed granules or vesicles.

How do neurotransmitters work? These highly potent substances are released from their storage sites in the close apposition synapses, or in terminal varicosities (or dendrites—see below), and diffuse shorter or longer distances until they encounter neurotransmitter receptors with which they are designed to specifically interact.

Once bound to the neurotransmitter in question, the neuroreceptor, which is a large glycoprotein molecule, spanning the membrane thickness (10 nanometres), undergoes conformational or other structural change, and this results in one of two known categories of response. The first of these is called an *ionotropic* response, and results in the appearance of a 'hole' or 'passage' right through the neuroreceptor protein molecule from outside to inside the membrane, through which only a particular charged ion can pass (Na^+ , K^+ , or Cl^-). The specific ion in question proceeds to move through the neuroreceptor molecule either into or out of the cell interior, driven down its concentration gradient, and attracted or repulsed by the

Page 555

prevailing electric field across the membrane, according to the nature of its own net charge (Figs. 6 and 7). Each neuroreceptor channel may be open for only a very brief period (e.g. 1 microsecond) as the neurotransmitter rapidly dissociates and is inactivated, or may remain open for much longer periods (e.g. 1 sec.) depending on the ion channel concerned. As the postsynaptic membrane is densely packed with these structures, the net effect is a substantial movement of charged ions across the membrane. This movement generates excitatory or inhibitory synaptic potentials and, from this pattern of impingement of electrical signals (information) onto its dendrites and cell body (inhibitory inputs), the target neurone will be triggered to fire its own action potential, or remain quiescent, as appropriate according to the intensity of the excitatory and inhibitory signals received. Individual neuroreceptor channel opening and closing events can now be distinguished by Fig. 6.

Threedimensional models of the nicotinic acetylcholine receptor from the electric ray fish

Torpedo californica depicted as membrane proteins in the postsynaptic membrane of

the synapse between the nerve and the electric organ which works essentially like a

neuromuscular junction and employs acetylcholine as neurotransmitter. The subunit

arrangement around the central channel is tentative. The sites on the two α subunits

that bind acetylcholine, and other related substances are shown as dark patches. The proposed shape of the central channel can be seen in the vertical section. Also shown is the

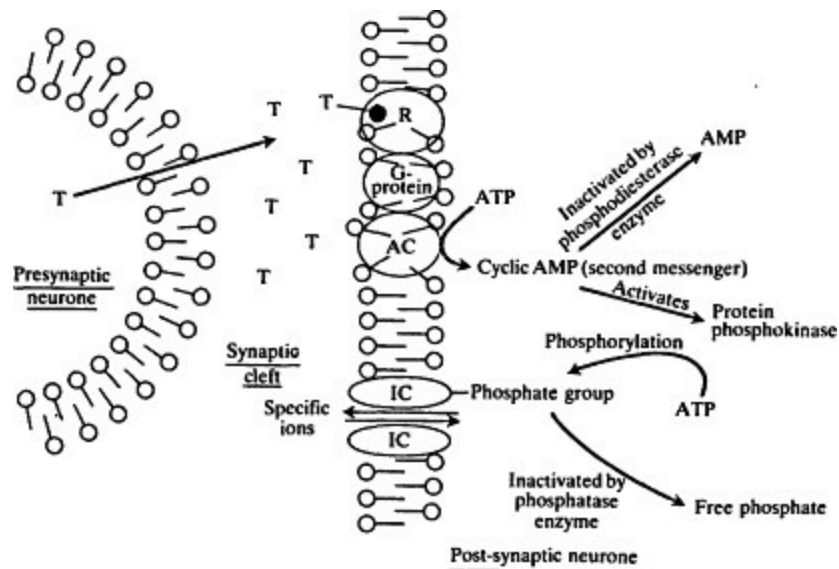

membrane structural protein of mol wt 43,000 often found in association with the receptor in *Torpedo*.

of a cell in the electric organ of *Torpedo*, the electric ray fish. Note the central channel or hole

through the neuroreceptor. This electron micrograph shows the platinum-plated replica of a membrane that has been frozen and etched. The size of the platinum particles limits the resolution to features larger than about 2 nanometres (scale bar equals 100 nanometres).

Page 556

so-called 'single channel recordings' by 'patch clamping' electrophysiological recording techniques where neurotransmitter is perfused onto the postsynaptic membrane and the properties of small patches of membrane are studied.

The second category of neuroreceptor response is known as *metabotropic* because enzymes are involved. These enzymes are buried in the lipid membrane close to, and linked permanently or temporarily (depending on the cellular location) to, the neuroreceptor protein molecule. Following neurotransmitterreceptor activation there are conformational changes in the neuroreceptorenzyme complex, which cause activation of the enzyme. The latter consequently acts upon its substrate, which is situated on the inner surface of the membrane, to produce a soluble product which diffuses into the neuronal cytoplasm and evokes responses which mostly lead on to produce a change in local membrane potential, usually resulting in the generation of a synaptic potential. These soluble enzyme products are called *second messengers*, as they produce actions which are secondary to the primary action of the neurotransmitter. Examples of such metabotropic, secondmessenger, neuroreceptorenzyme systems would be (1) the cyclic nucleotide system and (2) the phosphoinositide system: (1) The key enzyme here is *adenylate cyclase* which produces the soluble product cyclic AMP (adenosine monophosphate). This catalyses a cascade of protein phosphorylations and dephosphorylations resulting in the secondary opening of particular ion channels with accompanying generation of synaptic potentials (Fig. 8). In this system coupling of neuroreceptor to adenylyl cyclase is via a so-called *Gprotein* (because it requires guanylatetraphosphate for its activation) which can convey either a stimulatory (N) or inhibitory (N) influence from the neuroreceptor to adenylyl

cyclase (Fig. 9). There is a parallel system which employs *guanylate cyclase* s

i

linked to neuroreceptors, which is particularly prominent in the cerebellum.

(2) The key enzyme in the phosphoinositide system is a particular molecular subtype of *phospholipase C* (*phosphoinositidase C*) which is buried in the lipid membrane in close association with particular neurotransmitter receptors (Fig. 10). When this enzyme is activated indirectly via a Gprotein following binding of neurotransmitter to neuroreceptor, its substrate, triphosphoinositide (actually, phosphatidylinositol (4,5) diphosphate), is hydrolysed to release watersoluble *inositol triphosphate* (IP₃, Inositol (1,4,5)triphosphate) (Fig. 10). This IP₃ molecule has the ability to release calcium from intracellular stores, and the calcium (which can be 3

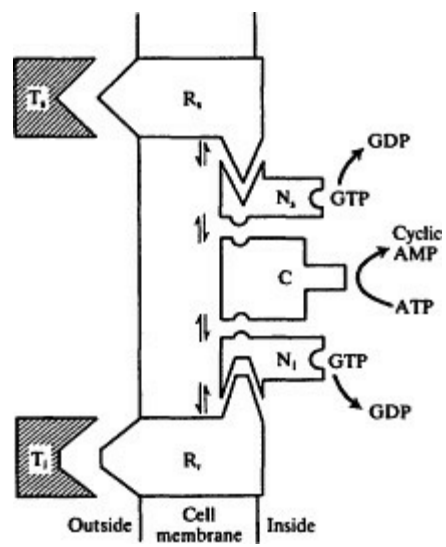

3

regarded as a *third* messen

Fig. 8.

The secondmessenger concept: The adenylate cyclase system. Neurotransmitter receptor (R), buried in the postsynaptic membrane, interacts with neurotransmitter (T) and initiates cyclic nucleotide formation via the adenycyclase enzyme (AC) which is also in the membrane. The cyclic nucleotide (cyclic AMP) is the second messenger. It stimulates phosphorylation of a membrane protein (IC) via a protein phosphokinase enzyme. This protein is an ion conductance channel through the membrane and is opened by being phosphorylated, allowing ions to move in or out of the cell. This leads to a membrane potential change (synaptic potential). The effect is reversed first by a phosphoprotein phosphatase, which dephosphorylates the ion channel, and secondly by a phosphodiesterase which inactivates the cyclic AMP. Coupling between R and CA is known to involve guanylnucleotide binding protein (Gprotein).

See Fig. 9 for details.

Page 557

Fig. 9.

Scheme showing the proposed coupling inside the postsynaptic membrane between neurotransmitters or hormones and adenylyl cyclase via guanine nucleotide binding proteins (Gproteins). Key: T, neurotransmitter or hormone; R, receptor protein; N, guanine nucleotide binding protein (Gprotein); C, catalytic subunit of adenylyl cyclase. Subscript s indicates a stimulatory action; subscript i indicates an inhibitory action. The coupling between the three membrane components is shown as reversible. The binding of GTP by N enhances the interaction, which can result in either stimulation or inhibition of adenylyl cyclase, as shown, depending on the category of N involved. GTP is removed by its hydrolysis. Refer also to Fig. 8.

ger in this case) then initiates a series of other biochemical events, particularly phosphorylations of key proteins in the cell. Such phosphorylations can switch on various ionic movements into the cell through channels (e.g. potassium ions) and thereby cause synaptic potential changes by this delayed and indirect route (Fig. 10).

The other product of phosphoinositidase C hydrolysis is a special neutral fat (diglyceride, containing arachidonic acid, a rather long fatty acid) which, in concert with calcium and a phospholipid, activates another enzyme, *protein kinase C*. This enzyme initiates a series of protein phosphorylations. These can result in the opening of local ion channels, and can therefore generate membrane or synaptic potentials (Fig. 10) on a par with those initiated by adenylyl cyclase activation (see (1) above and Fig. 8).

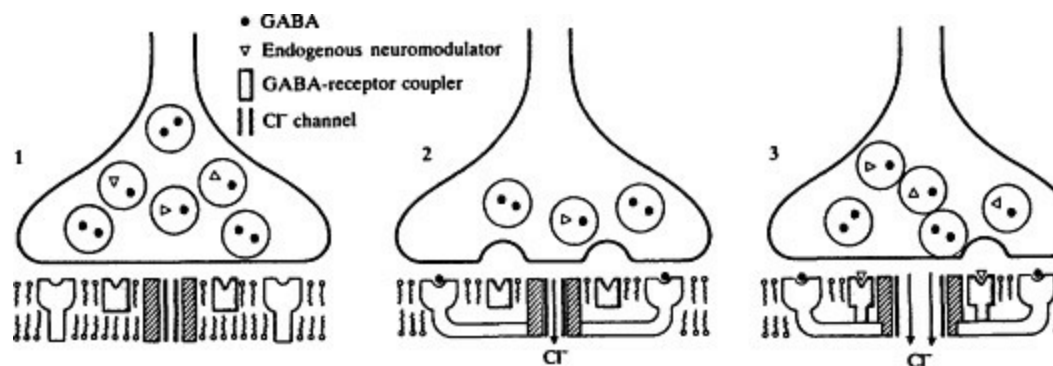

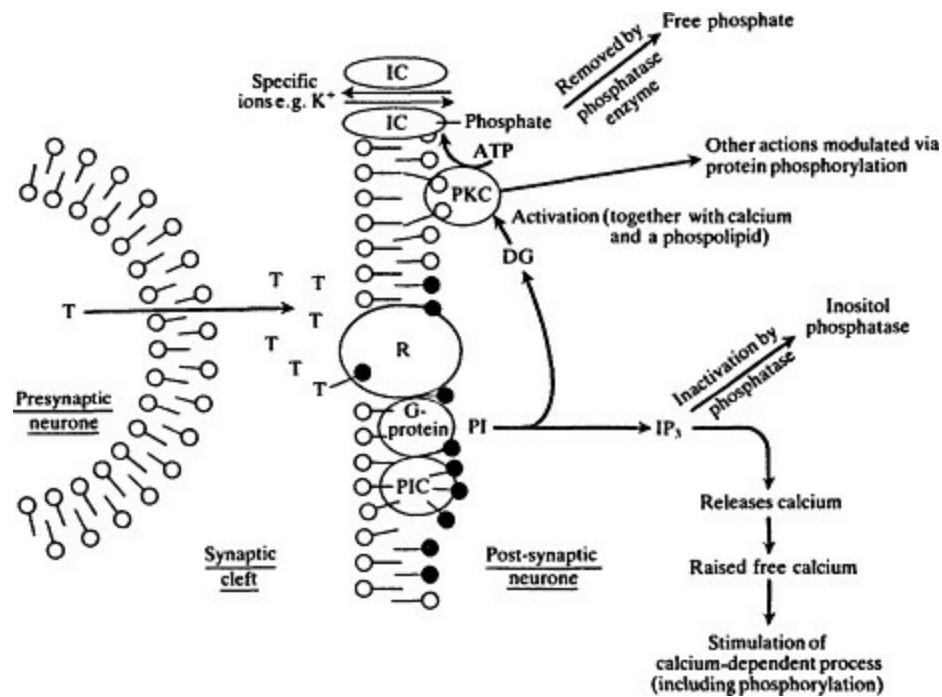

These metabotropic responses to neurotransmitterneuroreceptor activation are necessarily much slower (10 to 30 times) than their ionotropic counterpart, because they involve enzyme activation and subsequent cascades of biochemical responses, which are intrinsically slower than direct 'gating' of ion flow through membrane channels.

Neuromodulators. It is now emerging fairly clearly that the synaptic action of a neurotransmitter may be modulated (i.e. made more or less efficient) by a third party, a *neuromodulator or neuromodulator substance*, thereby amplifying or attenuating the action of the neurotransmitter. This seems to be achieved by more than one mechanism. Thus, the neuromodulator has the capacity to enhance or decrease the extent of release of the neurotransmitter following action potential invasion of the nerve terminal. For example, adenosinetriphosphate (ATP), secreted together with the neurotransmitter, will decrease noradrenaline or acetylcholine release from some adrenergic or cholinergic nerves, respectively. In other cases, the neuromodulator will alter the *efficiency* with which the neurotransmitter interacts with its neuroreceptor and allow the inward or outward flux of more ions per opening period, or a greater activation of neuroreceptorlinked enzymes.

Another, rather curious, neuromodulator substance is of considerable interest because of its links with *benzodiazepine* anxiolytic (anxietyreducing) drugs. In fact, the existence of this naturally occurring neuromodulator has been *inferred* from the potent facilitatory actions of anxiolytic drugs, such as diazepam (Valium), on the most widespread inhibitory neurotransmitter system in the nervous system, namely the GABA (aminobutyric acid) system. These benzodiazepine drugs both increase the affinity of GABA for GABA neuroreceptors located on synaptic membranes, and enhance GABAMediated behavioural responses and synaptic potential generation.

Moreover, there are neuroreceptors present in the brain which very specifically bind to the drugs. The endogenous benzodiazepine receptor protein (or binding site) is thought to form part of the GABA receptor complex. When released from its nerve endings (or coreleased with GABA from GABAergic nerve endings) it is postulated to increase the extent, or period, of opening of GABAoperated chloride ion channels (Fig. 11). Although there are various candidates, as yet no endogenous benzodiazepinelike substance has been isolated which completely mirrors the properties of the endogenous neuromodulator—hence its chemical structure remains a mystery, and it is simply referred to as the '*endogenous benzodiazepine*'.

A precise definition of a neuromodulator is difficult to produce, since the same substance may act as a neurotransmitter in one synapse, and a neuroregulator at another synapse. Therefore, a definition must represent the category of neuroactivity at a particular site, rather than the identity of the substance itself. For instance, ATP, ADP, AMP (adenosine tri, di, and monophosphates), or adenosine itself, may function as a neurotransmitter or as a neuroregulator according to the nature of the neuroreceptors with which it interacts.

Page 558

Fig. 10.

The second messenger concept. The phosphoinositideinositol triphosphate system.

Neurotransmitter receptor (R), buried in the postsynaptic membrane, interacts with neurotransmitter (T) and initiates formation of inositol (1,4,5) triphosphate (IP₃), the

3

second messenger. This is achieved by activation of the enzyme phosphoinositidase

C (PIC, also in the membrane) via Gproteins, with the consequent hydrolysis of a

membrane phospholipid (PI, phosphatidylinositol (4,5) diphosphate) which is located close

to the enzyme and is indicated by the black heads. IP releases calcium from intracellular

3

stores and thereby raises the level of free calcium in the cytoplasm of the neurone. The

second messenger (IP) is inactivated by another enzyme, inositol phosphatase. The

3

other product of PI hydrolysis is diglyceride (DG). This activates another enzyme

inside the cell, protein kinase C (PKC), which begins to phosphorylate proteins. This

phosphorylation activity causes a wide spectrum of responses, including the opening

of specific ion channels (IC) through the membrane, e.g. for potassium ion, thereby generating synaptic and other kinds of electrical membrane potential change. PKC activity can also influence neurotransmitter release rates, as well as produce profound effects on cell growth and

development. Since a large part of the protein kinase C is found in nerve terminals, the

larger proportion of the PKC response is likely to be the result of neurotransmitters

acting at presynaptic receptors located on nerve terminals, rather than in dendrites on cell bodies.

Fig. 11.

Neurotransmitter and neuromodulator action. (1) Model of GABAergic synapse functioning

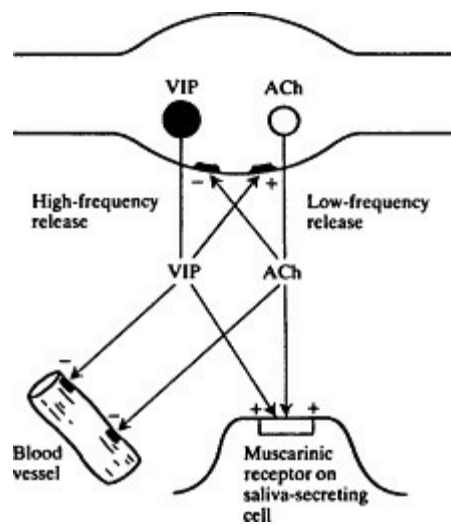

with a double signal generation, i.e. GABA and a neuromodulator whose actions are

mimicked by benzodiazepine drugs. The coupler for the GABA recognition site and chloride

gate is shown as a postsynaptic membrane protein. In (2) the GABA is seen to operate the

chloride ion channel at normal levels. In (3) the released neuromodulator works through

its receptor to increase the passage of chloride ions through the channel by interaction with the GABA receptor.

Page 559

Coexistence and corelease of neurotransmitters. The longheld dictum, enunciated by H. H. Dale and developed by J. C. Eccles, that 'only one and the same neurotransmitter is released by each neurone, at each of its terminals' (Dale's principle), is no longer universally tenable. We now have many examples where the newly discovered neuroactive peptides coexist with longer standing ('classical') neurotransmitters, such as acetylcholine, noradrenaline, serotonin, and GABA. The coexistence of other relatively newly established, neurotransmitters, such as ATP within cholinergic and adrenergic neurones is also now fairly clear and well founded.

For the most part, the different neurotransmitters appear to be contained in different categories of storage vesicle or granule within the nerve terminals concerned, and can be released independently of one another. Thus, *Vasoactive Intestinal Peptide (VIP)* coexists with acetylcholine in parasympathetic nerves supplying the cat salivary gland, each being contained in its own vesicle type. High frequency stimulation of the nerve releases VIP, whilst low frequencies release acetylcholine. Each neurotransmitter can act as a neuromodulator to influence the extent of release or postsynaptic actions of the other (Fig. 12).

Fig. 12.

Proposed scheme for cotransmission at a synapse where a classical neurotransmitter, acetylcholine (ACh), coexists with vasoactive intestinal polypeptide (VIP) in parasympathetic nerve terminals supplying the cat salivary gland. Note that ACh and VIP are stored in separate vesicles, they can be released differentially at different stimulation frequencies to act on acinar cells (producing saliva) and blood vessels supplying the gland. Co operation between the two neurotransmitter systems is achieved by selective release of ACh at low impulse frequencies and of VIP at high impulse frequencies. The two neurotransmitters are also seen acting as neuromodulators mutually influencing their extent of one another's

release and postsynaptic action.

Postsynaptic and presynaptic neuroreceptors. Postsynaptic neuroreceptors represent the longer established category of neuroreceptor, and provide the conventional feedforward of electrical and trophic influences of neurone on neurone. The past decade has seen the discovery of *presynaptic* neuroreceptors which serve a modulatory function in neurotransmission, being primarily concerned with controlling the *extent* of neurotransmitter release. These neuroreceptors respond to the principal neurotransmitter released by the nerve ending concerned (so called *autoregulation*), or to the actions of coreleased, or extraneous, neurotransmitters or neuromodulators of different identity (so called *heteroregulation*), by *reducing* or 'shutting down' the release of that neurotransmitter. This *negative feedback* action is the more common consequence of presynaptic neuroreceptor activation (e.g. noradrenaline release from heart, spleen, vas deferens, and also centrally in the brain). A minor category of presynaptic neuroreceptors actually mediate *enhancement* (positive feedback) of neurotransmitter release. It seems that both negative and positive feedback control can be exercised in the same synapse at a few particular central and peripheral axonal endings, particularly of adrenergic nerves. In this case, integration of their actions is achieved as follows: when low levels of neurotransmitter (e.g. noradrenaline) are present in the synaptic cleft, the facilitatory (usually betatype) neuroreceptors are activated, leading to increased release of neurotransmitters. When higher concentrations are reached in the cleft, the inhibitory (usually alphatype) adrenoreceptors come into play, resulting in a reduction in the level of noradrenaline release. Thus, differential sensitivity to neurotransmitter concentration allows a delicate balance to be maintained between the opposing actions of the two categories of presynaptic neuroreceptor.

How are neurotransmitters released? Calcium ions are the critical factors in triggering neurotransmitter release. Normally these ions are at almost undetectable levels in neuronal cytoplasm (10^{-9} M), but rapidly flood into the terminals from the surrounding fluid through special channels during nerve terminal depolarization caused by the action potential. Equally rapidly, the raised cytosolic levels of calcium are cleared by transport into mitochondria and endoplasmic reticulum within the terminal.

It has been demonstrated that neurotransmitters can also be released from the *dendritic tree* of the neurone as well as from nerve *terminals* as classically conceived.

Indeed, the dendrites show localized accumulations of synaptic vesicles which are characteristic of all neurotransmitter release sites (e.g. synapses, terminal varicosities). Such release has been unequivocally demonstrated to occur in the dopaminergic neurones of the substantia nigra of the brain (see BASAL GANGLIA) and also by the mitral cells and GABAergic axonless

Page 560

granule cells of the olfactory bulb. It may be that neurotransmitters can be released from other regions of the neuronal cell surface, including the unmyelinated regions of axons, and from the cell bodies themselves, though the greater proportion of neurotransmitter is localized to the nerve terminals.

Whether neurotransmitter is actually released from these various sites by a single process remains unclear. Certainly the traditional view envisages an exocytotic process involving the fusion of neurotransmitter-filled synaptic vesicles with the nerve terminal wall, resulting in the expulsion of about 1,000 molecules (one quantum) of neurotransmitter into the synaptic cleft from each vesicle. Many multiples of such quanta are released as the nerve impulse invades the nerve terminal, and this involves fusion and exocytosis by equivalent multiples of vesicles. However, the synaptic vesicles involved must already be in contact with the terminal membrane and ready to release their content as there is less than 200 microseconds between first entry of calcium and first detectable appearance of neurotransmitter in the cleft. It is likely that the vesicles which release neurotransmitters are positioned on, or close to, the calcium channels.

An alternative view is that neurotransmitter is released not from synaptic vesicles, but directly from the cytoplasm through membrane pores or membrane 'shuttle'

devices which require calcium to open or operate. By opening for a predetermined short period (microseconds) a quantum of neurotransmitter could be expelled into the synaptic cleft via these 'vesigates' or 'operators' as they have been called. The dispute is far from resolved, but the balance of evidence is in favour of the vesicular release hypothesis, though this may not be exclusive, and both or either process could be occurring according to the neurotransmitter in question.

Why are there so many neurotransmitters? The answer to this question is far from resolved. Certainly, subgroups of the fifty or so neurotransmitters produce different categories of effect in both qualitative and quantitative respects, and many will coexist in different neuronal populations. First, there is the differential speed of response following receptor activation, with ionotropic being some 10 to 30fold faster than metabotropic responses. Another dimension is provided in the *variety* of secondmessenger activation of *different* cascades of biochemical sequelae, with particular metabotropic neurotransmitter actions being mediated by one or other second messenger system. Further possibilities for adding to the qualitative features of the response could come through the range of distances through which the neuroactive compounds exert their influence once released. This may be 20 nanometres within the synaptic cleft but several millimetres from varicosities or unstructured release points, and of course the concentration of neurotransmitter diminishes rapidly with the distance travelled. Actions ranging over a greater volume of tissue would activate specific neuroreceptors sited on a larger variety of neurone types, producing complex sequences of neuronal triggering, and therefore a greater spectrum of overall responses (socalled *trophic* actions). Continuous (*tonic*) release of neurotransmitter, as opposed to discrete and occasional release, would also provide a basis for variation in the patterns of activation of targeted neurones due to changes in sensitivity, accommodation, and desensitization of neuroreceptors which ensues during continuous neuroreceptor stimulation.

Thus, the large number and the chemical variety of neurotransmitters, together with their tendency to activate anatomically distinct neuronal pathways, often in pairs, and the evidence that they provide many palpable possibilities for variation in response, can be seen to provide a chorus of informational voices, each adding tonal colour or timbre to the final output of the brain and nervous system.

NEUTRAL MONISM. See RUSSELL'S PHILOSOPHY OF MIND: NEUTRAL MONISM.

NEWTON ON MIND. Sir Isaac Newton (1642-1727) was born in the small manor house which still stands in the village of Woolsthorpe, near Grantham, Lincolnshire, where as a boy he made elaborate models (a windmill, a waterclock, and so on). In 1661 he became a student at Trinity College, Cambridge, and in 1665, while back at Woolsthorpe as the University was closed on account of the plague, he formed the outline of the ideas that dominated him for the next thirty years of incomparable achievement. The story that he

Page 561

thought of the moon circling the earth by continual gravitational attraction may indeed have been suggested by the falling of an apple in the Woolsthorpe orchard.

Newton became Lucasian professor of mathematics in 1669, when the first holder of the chair, Isaac Barrow, resigned in his favour. The fact that he did not take holy orders prevented him from becoming the head of a Cambridge college, and partly for this reason he left Cambridge. In 1696 he became warden of the mint in London, and, in 1699, its master. He was elected president of the Royal Society in 1703, and thereafter was reelected annually. In 1705 he was knighted by the Queen for his services at the mint. Twice he was a member of parliament.

Newton's major work, the *Philosophiae Naturalis Principia Mathematica*, usually known simply as the *Principia* (1687), is generally regarded as the greatest scientific triumph of the human mind. He did not accept that space is absolute without the most careful consideration of the alternative, that all motion is relative to surrounding objects with no absolute reference provided by a 'fixed' space. He employed simple experiments, including thought experiments: especially the famous

'bucket argument'. He considered the behaviour of the surface of water in a bucket suspended from the centre of its handle by a rope, and allowed or made to spin.

The water remains level as the bucket spins in relation to the water, when the water is stationary with respect to the room (or to the 'fixed' stars); but as the water speeds to rotate with respect to the room or the stars, but rotates *with* (and so becomes stationary with respect to) the bucket, it becomes concave. So the reference is not arbitrary: it is concave only by rotation with respect to the universe, and not with respect to the bucket. This is the basis of Ernst*Mach's principle, that the average mass of the stars provides an absolute reference for accelerated (including rotational) motion. However this may be, Newton had a reason that seems curious to us for accepting absolute space—he held that space is, and we live in, God's sensorium, or God's mind; we may thus appreciate laws of the universe by thought and mathematics, though the eyes and other senses are needed for transferring facts of the world to our minds.

In the Queries in his *Opticks* (1704) Newton writes (Query 12): 'For because dense Bodies conserve their Heat for the longest, the Vibrations of their parts are of a lasting nature, and therefore may be propagated along solid Fibres of uniform dense Matter a great distance, for conveying into the Brain the impressions made upon all the Organs of Sense.' And in Query 13: 'Do not several sorts of Rays make Vibrations of several bignesses, which according to their bignesses excite Sensations of several Colours, much after the manner that Vibrations of the Air, according to their several bignesses excite Sensations of several Sounds?' Touching upon aesthetics of colours and sounds (Query 14): 'May not the harmony and discord of Colours arise from the proportions of the Vibrations propagated through the Fibres of the optic Nerves into the Brain, as the harmony and discord of Sounds arise from the proportions of the Vibrations of the Air? For some colours, if they be view'd together, are agreeable to one another, as those of Gold and Indigo, and others disagree.' Although Newton held a vibration account of neural conduction he maintained a corpuscular theory of light. He did, however, see that this was not fully adequate (for example, in his long discussion of double refraction by feldspar, in Queries 28 and 29).

Newton sums up his general picture of man's place in the universe at the end of the *Opticks*:

... it seems probable to me, that God in the Beginning form'd Matter in solid, massy, hard, impenetrable, moveable Particles, of such Sizes and Figures, and with such other Properties, and in such Proportion to Space, as most conduced to the End for which he form'd them....

It seems to me farther, that though these Particles have not only *vis inertiae*, accompanied with such passive Laws of Motion as naturally result from that Force, but also they are moved by certain active Principles, such as is that of Gravity, and that which causes Fermentation, and the Cohesion of Bodies. These Principles I consider, not as occult Qualities, supposed to result from the specifick Forms of Things, but as general Laws of Nature, by which the Things themselves are form'd; their Truth appearing to us by Phaenomena, though their Causes be not yet discover'd. For these are manifest Qualities, and their Causes only are occult. And the *Aristotelians* gave the Name of occult qualities, not to manifest Qualities, but to such Qualities only as they supposed to lie hid in Bodies, and to be the unknown Causes of manifest Effects.... To tell us that every Species of Things is endow'd with an occult specifick Quality by which it acts and produces manifest Effects, is to tell us nothing....

Now by the help of these Principles (of Natural Law) all material Things seem to have been composed of the hard and solid Particles abovemention'd, variously associated in the first Creation by the Counsel of an intelligent Agent. For it became him who created them to set them in order. And if he did so, it's unphilosophical to seek any other Origin of the World, or to pretend that it might arise out of a Chaos by the mere Laws of Nature; though being once form'd, it may continue by those Laws for many ages.

Here, surely most curiously, Newton gives up his mechanisms of nature as complete descriptions—first for the astronomical universe, and then for animals. He introduces, at this point, the notion of *choice* into the physics of the stars. This he does while considering eccentric comets: For while Comets move in very excentric Orbs in all manner of Positions, blind Fate could never make all the Planets move one and the same way in Orbs concentrick, some inconsiderable inconsistencies excepted, which may have risen from the mutual Actions of Comets and Planets upon one another, and which will be apt to increase, till this System wants a Reformation. Such a wonderful Uniformity in the Planetary System must be allowed the Effect of Choice.

So, having built the selfperpetuating mechanism of the *Principia* Newton sets limits to its perpetual autonomy—to bring back into the universe the Page 562

mind that his predictable mechanism had banished.

This leads at once to consideration of the forces of living organisms.

And so must the Uniformity in the Bodies of Animals, they having generally a right and a left side shaped alike, and on either side of their Bodies two Legs behind, and either two Arms, or two Legs, or two Wings before upon their shoulders ... and the Instinct of Brutes and Insects, can be the effect of nothing else than the Wisdom and Skill of a powerful everliving Agent, who being in all Places, is more able by his Will to move the Bodies within his boundless uniform Sensorium, and thereby to

form and reform the Parts of the Universe, than we are by our Will to move the Parts of our own Bodies.

A little later Newton writes: 'The Organs of Sense are not for enabling the Soul to perceive the Species of Things in its Sensorium, but only for conveying them thither;

and God has no need of such Organs, he being every where present to the Things themselves.'

Thus we live in the space of God's mind. Newton goes on to say that God might create particles of various sorts, and might change the laws of nature—or even have different laws working in several parts of the universe without contradiction, for the laws are God's ideas.

The startingpoint of Newton's theory of light and colours was Barrow's notes on colour, which Newton edited. According to Barrow (as recorded by Newton's biographer Sir David Brewster):

White is that which discharges a copious light equally clear in every direction— *Black* is that which does not emit light at all, or which does it very sparingly— *Red* is that which emits a light more clear than usual, but interrupted by shady interstices— *Blue* is that which discharges a rarefied light, as in bodies which consist of white and black particles arranged alternatively— *Green* is nearly allied to blue— *Yellow* is a mixture of much white and little red— *and Purple* consists of a great deal of blue mixed with a small portion of red. The blue colour of the sea arises from the whiteness of the salt which it contains, mixed with the blackness of the pure water....

It was Newton's genius to see that all the colours are contained in white light, and that they are separated by refraction of white light. He did not of course discover the spectrum, but he did see its significance; and he showed (probably) how colours can be built up as mixtures by spinning a disc of coloured segments, whose relative areas could be varied to control the mixture. Although the familiar and beautiful series of prism experiments are described in the *Opticks* as a progression of axioms, selfevidently true, it is clear from various notes that they occupied some eighteen months, and that Newton frequently changed his mind, only gradually coming to be sure of his conclusions. Controversy with Robert Hooke was partly responsible for postponing publication of the *Opticks* until 1704, after Hooke's death. Written in English, rather than the Latin of the *Principia*, it is well worth reading today.

Newton's work on colour bordered upon psychological experimentation. He described persistence of vision by noting the luminous path behind a glowing coal whirled around in the dark, which he explained as being like the gradual dying out of ripples on water; and he discusses*afterimages. This was inspired by his staring at the sun, which left an afterimage lasting several days, greatly disturbing him so that he spent some days in bed. He noted that afterimages transfer from one eye to the other eye, and concluded that the origin must be in the brain and not in the stimulated eye. This argument is not, however, sound, for the stimulated eye may continue to send signals to the brain and it is not possible to say which eye is providing signals—although each eye is 'known' to the stereoscopic mechanisms of vision. It is odd that Newton did not think this simple matter out, though he described the universe in terms that met all challengers until Einstein, 250 years later.

For Newton the mathematical laws of nature concern space rather than objects for nonliving objects, such as planets, would otherwise move around of their own accord, without universal law applying (at least in astronomical conditions) to all kinds of objects. He was, however, highly interested in chemistry, which is the study of the matter of objects, and even more interested in alchemy as a key to the design of the universe. Though he spent a great deal of time and wrote a million or more words on chemical and alchemical experiments and theories, he did not publish on these topics.

Why it was that such genius flowered in Newton, whose ancestry and upbringing were not out of the ordinary, has been a matter ever since for somewhat fruitless debate. Psychological reasons for Newton's genius have been most fully discussed by F. E. Manuel (1968; 1980), who offers a Freudian type explanation, based on the effect of his mother, whom Newton adored, leaving him with his grandmother while very young when she went to live in a neighbouring parish with her second husband. (Newton's father had died before he was born.) Newton himself never married. He was a strange, irritable, and jealous man, who explored many paths to knowledge, sought immortality, and found it.

NIETZSCHE, FRIEDRICH WILHELM (1844-1900). Born at Röcken, Saxony, and brought up the son of a Lutheran pastor, he was a brilliant undergraduate at Bonn and Leipzig; and accepted the professorship of classical philology at Basle before graduating. He was a disciple of Schopenhauer; and Schopenhauer's 'will to power' was a

Page 563

basis of his philosophy that only the strong ought to survive, while sympathy perpetuates the unfit. His *magnum opus* is *Also Sprach Zarathustra* (1883/91; Eng.

trans. *Thus Spake Zarathustra*). It develops the idea of the 'superman', which was taken up by George Bernard Shaw in his play *Man and Superman* (1903).

Nietzsche died insane at Weimar.

NITROGEN NARCOSIS is the term used to describe the apparent drunkenness experienced by

deepsea divers. Jacques Cousteau has termed it 'l'ivresse des grands profondeurs' (rapture of the deep), while divers typically use the rather more prosaic term 'the narks'. As its name implies, the primary source of intoxication in air breathed at pressure comes from nitrogen. One might expect therefore that breathing pure oxygen would alleviate the problem. Unfortunately, however, when the partial pressure of oxygen exceeds that obtained at a depth of 912 m it produces oxygen poisoning, resulting in convulsions and loss of consciousness.

Nitrogen narcosis first becomes detectable at a depth of about 30 m, while below a depth of 60 m the effects are sufficiently marked to make working risky even for an experienced diver. The symptoms are not unlike drunkenness: the diver may become euphoric, his ability to reason reduced, and his manual skill impaired, with a tendency to make errors of judgement that can be disastrous at depth. For example, a diver taking part in an opensea experiment at 60 m noticed that he had insufficient air to complete the dive; he reasoned that he had enough air left either to do a decent job and complete the experiment or to get to the surface, but not both. He opted to complete the experiment. Fortunately, being a strong swimmer with a clear head, and having a good lifejacket, he managed to make the surface and was able to collect a fresh supply of air without suffering from 'the bends'—compressed air illness which may occur on return to normal atmospheric pressure, nitrogen dissolved in the bloodstream expanding to form bubbles which lead to pain, and possibly paralysis and death.

Most research on nitrogen narcosis has been carried out in dry pressure chambers, which are safer and allow better control over conditions than opensea studies. Do they, however, provide an adequate simulation of the real thing? An experiment conducted by Baddeley (1966) suggests that they may not. He studied the manual dexterity of divers using a simple brass plate containing 32 holes and 16 nuts and bolts. The diver simply had to transfer the nuts and bolts from the holes at one end of the plate to the other, and was timed as he did so. Subjects performing this task in a dry pressure chamber showed a small but reliable decrement in performance (5

per cent) when they were performing under an air pressure equivalent to pressure at a depth of 30 m of sea water. A parallel experiment tested the performance of subjects at a depth of 3 m, and at a depth of 30 m, in the open sea. The experiment was carried out in the Mediterranean, ensuring good visibility and with no problems of cold. Simply testing a subject under water slowed him down by approximately 28 per cent, while testing him at a depth of 30 m caused a drop of 49 per cent as compared to dryland performance.

Note that the decrement in performance observed at 30 m is greater than would have been predicted by simply adding the effects of water (16 per cent) and pressure (5 per cent). Why should this be? A clue was given by a later experiment which used the same task, and again tested at a depth of 30 m, but on this occasion resulted in a decrement of only 5 per cent. The difference between the two studies was as follows: the first was carried out in the open sea from a ship, the divers being required to go straight down. The second was carried out close inshore, where the diver could swim straight down from the jetty to a site populated by many other divers. It seems reasonable to suppose that the divers in the first experiment were much more anxious than those in the second, and subsequent studies have supported this conclusion. They reveal relatively small decrements when divers are tested in the relatively safe conditions of a 'wet' pressure chamber, and under opensea conditions with

divers who show little evidence of anxiety, while much greater decrements are shown by anxious divers and under relatively threatening opensea conditions.

The nature of the anxiety effect is still far from clear. Performance on a reasoning task does not show the interaction with anxiety, suggesting that the anxiety effect may result from some factor such as muscular tension, impairing motor rather than cognitive skills. The point remains, however, that while initial work is best done in the pressure chamber, generalization to opensea performance must proceed with caution.

How can nitrogen narcosis be prevented? The standard procedure at present is to have the diver breathe a mixture of oxygen and helium (heliox). Using this, dives have been made to as much as 600 m without the diver losing consciousness. For a while it seemed as though there might be no psychological decrement. Although a tendency to tremor and nausea, which was termed HPNS (High Pressure Nervous Syndrome), did occur, it was thought to result from compressing the diver too rapidly so that it could be avoided provided the rise in pressure was gradual. It has, however, subsequently become clear that more general intellectual and performance decrements do occur and are detectable at depths in excess of 300 m. The effect observed is almost certainly different from that obtained with nitrogen, and it is possible that some more complex mix of gases may allow greater depths to be achieved. Heliox has two further disadvantages: it conducts heat very efficiently, making it harder to keep the diver warm, and it distorts the voice. If you take a lungful of helium at Page 564

normal pressure and speak, you sound like Donald Duck, while at pressure the effect is even further exaggerated. A number of helium speech unscramblers have been designed, and do improve communication. However, the existing commercial models still leave a great deal to be desired.

In recent years there has been increasing interest in operating with Trimix, a mixture of oxygen, helium, and nitrogen. Such a mixture has a possible advantage in terms of narcotic potency. However, this is still a controversial issue. At a pharmacological level we still seem to be some distance from understanding the mechanism of inert gas narcosis; theories exist, but it is probably true to say that no theory has yet won broad acceptance.

NOTHINGNESS. Nature abhors a vacuum—and so do we. The idea of a void—of emptiness, nothingness, spacelessness, placelessness, all such 'lessness'—is at once abhorrent and inconceivable; and yet it haunts us in the strangest, most paradoxical way: 'Nothing is more real than nothing.'

For*Descartes there was no such thing as empty space. For Einstein there was no space without field. For*Kant our ideas of space and extension were the forms our

'reason' gives to experience, through the operation of a universal 'synthetic a priori'. The nervous system, intact and active—*Leibniz's stream of 'minute perceptions'—

was envisaged by Kant as a sort of transformer, forming ideality from reality, reality from ideality. Such a notion has the virtue—very rare in metaphysical formulations—that it can instantly be tested in practice; specifically, in neurological and neurophysiological practice.

Let us proceed at once to examples. If one is given a spinal anaesthetic that brings to a halt neural traffic in the lower half of the body, one cannot feel merely that this is paralysed and senseless; one feels that it is wholly, impossibly, 'nonexistent', that one has been cut in half, and that the lower half is absolutely missing—not in the familiar sense of being somewhere, elsewhere, but in the uncanny sense of *notbeing*, or being nowhere. The terms that patients use communicate something of this incommunicable nothing. They may say that part of them is 'missing', 'evacuated', 'gone': that it seems like dead flesh, or sand, or paste; devoid of life, of activity, of

'will'; devoid of the organic, of structure, of coherence—without materiality or imaginable reality; cut off or alienated from the living flesh (with which, none the less, it forms an impossible continuity). One such patient, trying to formulate the unformulable, finally said that his lost limbs were 'nowhere to be found', and that they were

'like nothing on earth'. Hearing such phrases, as one will hear from every patient who finds himself in such a situation—or, more properly, 'situationless'—and from every patient who can articulate this ultimate abhorrence, one is irresistibly reminded of the words of*Hobbes: 'That which is not Body ... is no part of the Universe: and since the Universe is all, that which is not Body ... is Nothing, and Nowhere.'

Spinal anaesthesia is common—perhaps a million women have had it for painless childbirth—but descriptions are most rare, partly because the experience is so abhorrent that it is instantly banished from the memory and mind, and partly because the experience (or nonexperience) is an experience of *nothing*. How can one describe nothingness, notbeing, nonentity, when there is, literally, nothing to describe? This paradox is pungently expressed by*Berkeley, in his denunciations of the nothingness of 'matter': 'It neither acts, nor perceives, nor is perceived ... it is *inert, senseless, unknown* ... a definition entirely made up of negatives.' Spinal anaesthesia provides a striking and dramatic example of a *transient* 'annihilation' (although it does not seem transient, but endless, when it occurs—a part of its peculiar horror).

But there are many simpler examples of annihilation in everyday life: all of us have sometimes slept on an arm, crushing its nerves and briefly extinguishing neural traffic;

the experience, though very brief, is a terrifying one because (it seems to us) our arm is no longer 'our arm', but an inert, senseless nothing which is not part of ourselves.*Wittgenstein (following*Moore)

grounds 'certainty' in the certainty of the body: 'If you can say, *here is one hand*, we'll grant you all the rest.' When you wake up, after nerve-crushing your arm, you cannot say 'This is my hand', or even 'This is a hand', except in a purely formal sense. What has always been taken for granted, or axiomatic, is revealed as radically precarious and contingent; having a body, having *anything*, depends on one's nerves.

Yawning is the abyss of nothing. It is only 'by favour of nature' that there are countless other situations—physiological and pathological, common or uncommon—in which there is brief, or prolonged, or permanent annihilation. Strokes, tumours, injuries, especially to the right half of the brain, tend to cause a partial or total annihilation of the left side—a condition variously known as 'impercception', 'inattention', 'neglect', 'agnosia', 'anosognosia', 'extinction', or 'alienation'. All of these are experiences of nothingness (or, more precisely, privations of the experience of somethingness).

Blockage to the spinal cord or the great limb plexuses can produce an identical situation, even though the brain is intact but deprived of the information from which it might form an image (or a Kantian 'intuition'). Indeed it can be shown by measuring potentials in the brain during spinal or regional blocks that there is a dying away of activity

Page 565

in the corresponding part of the cerebral representation of the 'bodyimage'—the empirical reality required for Kantian ideality. Similar annihilations may be brought out peripherally, either through nerve or muscle damage in a limb, or by simply enclosing the limb in a cast, which by its mixture of immobilization and encasement may temporarily bring neural traffic and impulses to a halt.

To conclude. Nothingness, annihilation, is a reality in this ultimately paradoxical sense. There is, indeed, no space without field; but there are conditions in which the

'field' may be lost—a perceptual ideal 'Kantian' field which is closely analogous to an Einsteinian field. One's sense of *being* is entirely contingent upon, coextensive with, and contained in such a field. And anything which produces 'fieldlessness' (or field defect, or scotoma) is certain to produce a corresponding nothingness.

NULLING. An important technique for precise measurement, by cancelling an unknown against a known standard. When the unknown and the standard cancel, or

'null', then they are equal. The most familiar example is weighing with a balance: when the known mass balances the unknown mass they must be equal, so the unknown mass has been established by a simple hulling technique. A Wheatstone bridge determines electrical resistances with great precision

and over a wide range in a similar way. Nulling methods are particularly useful for instruments as they do not require precise linearity of the apparatus, though the results can be extremely accurate over a wide range.

It has been suggested (Gregory, 1968) that the nervous system may employ nulling for sensory discrimination (especially for weight), by comparing an *expected* against a *sensed* value. This could help to explain how discrimination can be so good over a very wide range, from a few grams to ten or even a hundred kilograms, though neural components are far less stable than the components available for electronic weighing devices, which would probably have to adopt a nulling method to do as well. There is some evidence from the *size-weight illusion* that mass discrimination works by nulling, and this might, possibly, explain the *Weber-Fechner law*.

Page 566

O

OBEDIENCE. Among the more perplexing problems of human nature is this: how is it possible that a decent, kindly person may, in a short time, find himself killing others with ease? Preposterous? No, the transformation occurs routinely in society as young men are inducted into the armed services and are sent to kill the young men of another society. This is not intended as a moralistic statement against war, but as a source of genuine scientific puzzlement. How is such a transformation possible? The answer would seem to lie in an understanding of the psychology of obedience.

For the psychologist, obedience is neither a good nor an evil, but a neutral mechanism whose moral and adaptive aspects depend on the circumstances in which it occurs. Failure to obey the law in order to satisfy selfish interests is the hallmark of criminality; yet an excess of obedience may also present grave moral problems.

To the parents of small children obedience is, no doubt, perceived as a good thing. And indeed, much energy is expended teaching children to do as they are told. This process of socialization is indispensable to producing persons who can function in the everyday world; and humans are born into an overwhelmingly social world, which possesses a structure and order to which they must adapt. Indeed, human society as we know it could not exist unless a capacity for obedience were present in its members.

Obedience is often rational. It makes good sense to follow the doctor's orders, to obey traffic signs, and to clear the building when the police inform us of a bomb threat. But the habit of obedience may be so deeply ingrained that it overrides rationality. Indeed, for the fully socialized adult there is a readiness to defer to authority that is astonishingly powerful.

Obedience is not limited to human beings. Dominance hierarchies are found in many species. But its expression in human beings occurs in a uniquely symbolic field.

We recognize a general category of individuals who, by virtue of status, have a right to direct our behaviour, i.e. we recognize authority. And people respond to abstract, designations of authority such as insignia, rank, and title. Frequently, the transaction with authority benefits the person and the larger society. But this is not always the case.

In recent times, the widespread acceptance by the German people of a system of death camps that destroyed millions of innocent people has raised some profound questions about the way human nature is conditioned by obedience. Most heinous deeds were carried out by people who asserted they were merely obeying orders.

What is the implication for our picture of human nature? Did their behaviour reveal a potential that is present in all of us? An experiment was set up to explore the response of ordinary people to immoral orders.

The experiment was relatively simple: a person comes to the laboratory and, in the context of a learning experiment, he is told to give increasingly severe electric shocks to another person—who, unknown to the subject, is a confederate, and does not actually receive the shocks. This arrangement provided an opportunity to see how far people would go before they refused to follow the experimenter's orders.

A scenario is needed to grasp the flavour of the experiment. Imagine you have answered an advertisement to take part in a study of memory and learning, and are arriving at the university at a time agreed upon. First, you are greeted by a man in a grey technician's coat, and he introduces you to a second volunteer, and says you are both about to take part in a scientific experiment. He says it is to test whether the use of punishment improves the ability to learn. You draw lots to see who is to be the teacher and who the learner. You turn out to be the teacher, the other fellow the learner. Then you see the learner strapped into a chair and electrodes are placed on his wrist (Fig. 1). The experimenter says that when the learner makes a mistake in the lesson his punishment will be an electric shock.

by the experimenter. Learner provides answers

by depressing switches that light up numbers on
an answer box.

Page 567

Fig. 2.

Shock generator used in the experiments.

Fifteen of the thirty switches have already
been depressed.

As teacher you are seated in front of an impressive looking instrument, a shock generator (Fig. 2). Its essential feature is a line of switches that range from 15 volts to 450 volts, and a set of verbal designations that goes from slight shock to moderate shock, strong shock, very strong shock, and so on through XXX—danger, severe shock. Your job, the experimenter explains to you, is to teach the learner a simple wordpair test. You read a list of words to him, such as 'blue day', 'nice girl', 'fat neck', etc., and he has to indicate by means of an answerbox which words were originally paired

together. If he gets a correct answer you move on to the next pair;

but if he makes a mistake, you are instructed to give him an electric shock, starting with 15 volts (Fig. 3). And you are told to increase the shock one step each time he makes an error. In the course of the experiment the 'victim' emits cries of pain and demands to be set free, but the experimenter orders you to continue. The question is: how far will you proceed on the generator before you turn to the experimenter and refuse to go any further?

Before the experiment was carried out, people were asked to predict their own performance. The question was put to several groups: psychiatrists, psychologists, and ordinary workers. They all said virtually the same thing: almost no one would go to the end.

Fig. 3.

Teacher receives sample shock from the generator.

Fig. 4.

Teacher breaks off experiment. On right,

event recorder wired into generator automatically

records switches used by the subject.

But in reality the results were very different. Despite the fact that many subjects experienced stress, despite the fact that many protested to the experimenter, a substantial proportion continued to the last shock on the generator. Many subjects obeyed the experimenter no matter how vehement the pleading of the person being shocked, no matter how painful the shocks seemed to be, and no matter how much the victim pleaded to be let out. This was seen time and again, and has been observed in several universities where the experiment has been repeated.

But there is more to the experiment than this simple demonstration of obedience. Most of the energy went into systematically changing the factors to see which increased obedience, and which led to greater defiance: the effects of the closeness of the victim were studied, as was the importance of the sponsoring institution, and how the sight of other people obeying or defying an authority affected obedience. All of these factors had a powerful effect on whether subjects obeyed or defied the malevolent authority, showing that how a person behaves depends not only on his 'character' but also on the precise situational pressures acting on him.

A person who obeys authority does not see himself as responsible for his own actions, but rather as an agent executing the wishes of another person. In the experiment subjects frequently turned to the experimenter, saying: 'Am I responsible?' And as soon as he said they were not, they could proceed more easily.

Even if the conflict between conscience and duty gives rise to strain, there are psychological

mechanisms that come into play that help to alleviate this strain. For example, some subjects complied only minimally: they touched the switch of the generator very lightly; they had the feeling that this really showed that they were good people, whereas in fact they were obeying. Sometimes they would argue with the experimenter, but argumentation did not necessarily lead to disobedience; rather it served as a psychological mechanism,

Page 568

defining the subject in his own eyes as a person who opposed the experimenter's callous orders, yet reducing tension and allowing the person to obey. Often the person became involved in the minute details of the experimental procedure; becoming engrossed, he would lose all sight of the broader consequences of his action.

When the results of the original experiments were published, opinion about them was sharply divided. On the one hand, the American Association for the Advancement of Science awarded the work its annual sociopsychological prize. At the same time the experiments attracted fierce criticism, centring mainly on the ethical issues of carrying out the research. The experiments that it was hoped would deepen our understanding of how people yield to malevolent authority, themselves became the focus of controversy.

But the problem of authority remains. We cannot have society without some structure of authority, and every society must inculcate a habit of obedience in its citizens.

Yet this research showed that many people do not have the resources to resist authority, even when they are directed to act callously and inhumanely against an innocent victim. The experiments posed an age-old problem anew: what is the correct balance between individual initiative and social authority? They illuminated in a concrete and specific way what happens when obedience is unrestrained by conscience.

OBJECTCONSTANCY. See ILLUSIONS; OBJECT PERCEPTION; PERCEPTION.

OBJECT PERCEPTION. Although, for convenience, physiologists and psychologists tend to study*perception with controlled stimuli presented to the sense organs, man and the higher animals are adapted to recognize and behave in ways generally appropriate to objects of the external world. To understand how objects are perceived it is necessary to appreciate how the sensory inputs of stimuli are 'read' as evidence of objects and where they lie in surrounding space. This ability is in many ways the most remarkable that the higher organisms ever accomplish. The fact that we perceive objects from stimuli without even seeming to try is extremely misleading—for in fact it requires computations by neural mechanisms which at present 'can only be carried out very inadequately by the most powerful available computers.

When objects change in position, or rotate to present a different view, they provide very different stimulus patterns—yet, remarkably, they are still seen as the same object. This is accomplished visually in part by perceptual selection of invariant features, such as corners, whose retinal images do not change much with changes of orientation. It is also a useful technique for computerbased object recognition: internal descriptions of useful identifying features are built up, these descriptions being perceptions.

OBJECTRELATIONS THEORY. See FREUDIANISM: LATER DEVELOPMENTS.

OBSESSIONS AND COMPULSIONS. To say that an individual is obsessed with an idea, a pursuit, or a particular person usually implies, often with more than a hint of disapproval, that he is thus wholly preoccupied. But such obsessions may not necessarily be unhealthy or neurotic, even though, as KräuplTaylor (1979) comments, they have an element of compulsion attached to them. They have to be distinguished from obsessivecompulsive neuroses, or the psychotic's absorption with his delusions. A person may say that because of his beliefs, religious, political, or philosophical, he has to act in a certain manner: he is compelled by convictions which, if ignored, would cause him unease or anxiety. Such a person is not necessarily obsessional. The term obsessional personality is rather applied to one who is conventional, conscientious, reliable, scrupulous, or punctual well beyond average. He may find it necessary to check and recheck his work to assure himself that no errors have been committed; he may adhere rigorously to a routine which, if disrupted, will cause him considerable unease; and he will probably be singularly competent at clerical work, proofreading, typesetting, or other tasks requiring attention to detail. The characteristics of the obsessional personality are not to be despised: they could be essential qualities for anyone engaged in precision work, and much scientific research could not be carded out without them.

In comparison, the individual who suffers from an obsessionalcompulsive neurosis is a sick person. The late Sir Aubrey Lewis (1967) appraised the subject. With some reservations he adopted Cad Schneider's definition of obsession as 'contents of consciousness which, when they occur, are accompanied by the experience of subjective compulsion, and which cannot be got rid of, though on quiet reflection they are recognized as senseless'. Usually 'the contents of consciousness which preoccupy the obsessional neurotic are concerned with ideas of harm, contamination, sex, and sin, although repetitive ruminations about abstract problems and manipulation of words and numbers are

neurosis proper. Fortunately the neurosis is rare, affecting about 0·05 per cent of the general population in Britain and the USA, for example, although obsessional symptoms crop up from time to time in the lives of otherwise perfectly normal individuals. (The symptoms can also complicate other psychiatric disorders, particularly severe depression.) Children, as is well known, engage in repetitive games and rituals such as avoiding treading on the cracks between paving stones; and, as any parent knows when reading a familiar story, an attempt to vary or skip a part of it may be resisted by the child. Many minor compulsions can be discerned in adult superstitions: failure to touch wood or avoid walking under a ladder, for instance; and a sense of mild anxiety may briefly follow the breaking of such rituals. Anxiety is indeed a main driving force in the life of the obsessional neurotic. Resisting a compulsion may arouse acute distress, which can be assuaged only by bowing to the inner need and going back to complete a ritual.

Lewis divides obsessions into primary and secondary. 'An example of the first,' he wrote, 'would be the insistent feeling that one is dirty ... and then there is the impulse to wash—the secondary phenomenon, developed in order to obtain relief from the primary disturbance. The secondary phenomenon can be regarded as defensive and aimed at preventing or relieving tension.'

Standard textbooks of psychiatry give detailed accounts of the many varieties of symptoms which can cripple performance of the everyday activities of the obsessional neurotic. For example, the patient who fears contamination may wash his hands repeatedly only to find himself having to restart the whole process on account of a fear that chance contact with the tap may have again soiled his fingers. Such compulsions can occupy a large part of his waking day, as can the checking of rituals of those who fear that they might inadvertently harm somebody close to them. A sufferer may spend hours checking and rechecking gas taps, electric switches, and the contents of kitchen drawers to ensure that sharp objects such as knives have not been left lying where they could injure another person. Mothers of young children are sometimes tortured with the idea that some carelessness on their part could seriously injure a recently born infant.

There are many examples of wellknown persons who have found it necessary to engage in compulsive rituals. Boswell described such a ritual performed by Samuel Johnson:

He had another particularity, of which none of his friends even ventured to ask an explanation.... This was his anxious care to go out or in at a door or passage, by a certain number of steps from a certain point, or at least so as that either his right or his left foot ... should constantly make the first actual movement when he came close to the door or passage. Thus I conjecture: for I have, upon innumerable occasions, observed him suddenly stop, and then seem to count his steps with a deep earnestness; and when he had neglected or gone wrong in this sort of magical movement, I have seen him go back again, put himself in a proper posture to begin the ceremony, and, having gone through it, break from his abstraction, walk briskly on, and join his companion. (*Life of Johnson*, Aetat. 55.) John Bunyan in *Grace Abounding* gave a good example of an obsessional phobia: 'Sometimes again, when I have been preaching, I have been violently assaulted with thoughts of blasphemy and strongly tempted to speak the words with my mouth before the congregation.' But there is no reason for

thinking that either Johnson or Bunyan suffered from obsessional neuroses, though clearly they did have troublesome symptoms; for fortunately the symptoms did not detract from their competence and genius. Obsessional doubts about religious observance are phenomena well known to confessors and theologians. Such scruples certainly tormented Bunyan as they did Martin Luther.

Successful treatment of patients suffering from obsessional neurosis is far from easy; and this despite the fairly obvious psychopathology—in psychoanalytic terms—of the neurosis. The frequent association of depression with the neurosis implies that appropriate treatment of the affective disorder might well mitigate the full impact of the patient's disabilities. In many cases supportive psychotherapy and behaviour therapy as well as the passage of time seem to ensure that the patients will come to terms with their symptoms sufficiently well to enable them to lead relatively normal lives. In about 60 per cent of the cases of patients who are severely afflicted, one of the modern forms of psychosurgery will bring relief. It may not entirely eliminate the symptoms, but they become less obtrusive and no longer dominate the patient's life.

OEDIPUS COMPLEX. Sigmund*Freud's first mention of the Oedipus complex was in a letter written in 1897, while he was reviewing his relationship with his father, who had died six months before. In *The Interpretation of Dreams*, written at about the same time, he referred to 'being in love with one parent and hating the other'

as being 'among the essential constituents of the stock of psychical impulses' formed in childhood, and as important in determining the symptoms of later neurosis.

These psychical impulses, which he called the Oedipus complex, retain their power to determine neurotic symptoms, he supposed, only when there is fixation at the Oedipal level of development. This happens when rivalry with the parent of the same sex is not resolved through identification with this parent or when sexual feelings for the parent of the opposite sex are not transferred to a sexual partner outside the family. In Jung's theory, the essential process in neurosis is Page 570

not the fixation of the complex, but its revival when a new adaptation is required. Modern theories of neurosis attach more importance to the quality of the relationship between mother and child before Oedipal impulses develop (see ATTACHMENT).

Freud claimed some confirmation of his theory in the universal appeal of the legend of Oedipus Rex in Sophocles' play. The Thebans are told by an oracle that the plague will cease when the murderer of Laius, the former king, has been driven from the land. The play gradually reveals, in the manner of psychoanalysis, Freud remarked, that Oedipus is the murderer, and that he is the son of Laius and Jocasta, whom he married after Laius' death. Freud's formula, which is based, as is usual in

psychoanalysis, on the child's feelings towards his parents, gives a onesided and too simple an account of the complex interactions in a family. The son is the transgressor whereas in the legend the father, feeling threatened because he has been told by the oracle that he will perish at the hands of his son, instructs the mother to destroy him at birth. Instead she abandons him. The father later starts the quarrel which ends in his death. In the story of Hamlet, in Shakespeare's play, which psychoanalysts regard as similar to that of Oedipus, the stepfather, not the son, is the aggressor.

OLDS, JAMES (192276). American psychologist who received his degree in 1947 from Amherst College and his doctorate from the laboratory of social relations at Harvard in 1952, working with Richard Solomon. At Harvard he attempted to combine the neurological views of Donald Hebb with E. C.*Tolman's model of learning.

In 1953 he went to McGill as a postdoctoral Fellow to learn physiological techniques and to work more closely with Hebb. It was during this time that he discovered that electrical stimulation of the septal area, lateral hypothalamus, and some other brain areas could act as a reward, one of the most significant physiological contributions to learning, and one that turned the attention of students of the neural bases of learning from the cortex to the brain as a whole. See also MEMORY: BIOLOGICAL BASIS.

After a further two years' postdoctoral research at the Brain Research Institute of the University of California at Los Angeles, Olds became a member of the psychology department of the University of Michigan, where he continued to explore the anatomy, pharmacology, and behavioural features of brainstimulation reward.

In 1967 he moved to the California Institute of Technology, where he remained until his death in 1976 of a heart attack. Here his main energy was devoted to the study of learning by recording the activity of cells in different areas of the brain during conditioning.

OPERANT CONDITIONING. See CONDITIONING.

OPIUM—the word is derived from the Greek for poppy juice—is obtained by incising the fruit and collecting the exudate from the opium poppy, *Papaver somniferum*. The plant appears to have originated in the lands bordering the eastern Mediterranean, whence it spread both eastwards and westwards. The psychological effects of opium may have been known to the Sumerians, but the first clear reference to poppy juice is found in the writings of Theophrastus in the third century BC, and

Discorides in the first century BC gave the first description of modern opium.

During the subsequent centuries opium appears to have enjoyed both medicinal and recreational uses. Medically it was known to relieve pain and suppress dry coughing, and it was given for a wide variety of other complaints, including epilepsy and colic. Its sleepinducing properties were well known to Greek and Roman writers; the Greeks appear to have taken opium cakes and sweetmeats for relaxation and recreation. Whereas opiumsmoking has been most widespread in the Far East, consumption of the drug in the form of its tincture—laudanum—became fairly commonplace in Western Europe. Its addictive properties were well recognized and described in England at the end of the seventeenth century by John Jones, a physician in Windsor, who, in his book *The Mysteries of Opium Reveal'd* (1700), gave a clear account of the effects of intoxication and sudden withdrawal of the drug in one habituated to it. None the less, regardless of its recreational use, it was as a sovereign remedy for pain that it was most widely prescribed. As Thomas Sydenham wrote, 'Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and efficacious as opium'. In the nineteenth century many patent medicines, freely available to the public both in Britain and the USA, contained opium. Virginia Berridge (1977) has described how easily opium was obtained in the Fenland area of England. Opium pills were sold openly in Cambridge on marketday and many a person bought 'a ha'pennard o'elevation' to last for the week. Although opium was mainly imported in the nineteenth century from Turkey, the medical profession showed a preference for opium from poppies grown in fields near to the village of Winslow in Buckinghamshire.

Opium is a crude preparation containing at least twenty different alkaloids of which the best known are morphine, first isolated by F. W. A. Sertürner in 1803, and codeine, identified by Robiquet in 1832. Heroin is not a naturally occurring alkaloid but is derived from morphine by acetylation (the addition of an acetyl group). It is at least three times as effective as morphine for the control of pain, and when first synthesized in 1898 it was

hoped that it would be less addictive than the parent drug. In fact, as the history of heroin has shown, it has proved to be the most addictive of all the opiates, both natural and synthetic, although none is free from this potential.

In spite of the free availability of opium medicines to the public in the nineteenth century, there is little evidence to show that addiction to the drug was particularly widespread. None the less, the giving of opium to small children as a sedative was a pernicious practice and a not infrequent cause of wasting and premature death.

Although somewhat conflicting opinions were expressed by the medical profession, eventually restrictions were placed on the sale of opium to the public. In the twentieth century these restrictions have been tightened, the main impetus for strict control of the sale of opium and its derivatives coming from the USA, at first through the Harrison Narcotic Act of 1914 and later through the League of Nations and the United Nations Commission on Narcotic Drugs. It was hoped that international control of opium and heroin production would reverse the steady increase in the number of persons addicted to these substances. Unfortunately there is very little evidence that intense legal and law

enforcement activity have made much difference, as the use of these drugs has become more extensive both in the USA and elsewhere.

Addiction. Statements about opium and its derivatives tend to be overshadowed by the problem of addiction to such a degree that concern over this single issue has led to restrictions on their medical use. As a result some doctors avoid their use even for the control of severe*pain in terminal illness, lest the patient become addicted.

Fortunately, however, their medical use is not a common cause of addiction. Even so, if a patient is dying from cancer it is hardly a matter of importance if the drug that ensures freedom from pain also makes him addicted to its continued administration.

Although those who misuse opiates and other types of drugs are generally referred to as addicts, the term 'drug addiction' was replaced by 'drug dependence' by a WHO expert committee report in 1970. Dependence can be both physical and psychological. Opiates, like some other drugs of dependence, can, if taken repeatedly, result in the development of tolerance, so that some drugdependent persons can build up a tolerance which allows them to take massive doses of the drug without immediate harm. De Quincey was well aware of this phenomenon, describing it in his *Confessions of an English OpiumEater*. Sudden withdrawal of the drug will cause an abstinence syndrome: the 'cold turkey' in the slang jargon of the junkie's world. To a high degree of physical dependence will usually be added a compulsion to use the drug on a 'continuous or periodic basis in order to experience its psychic effects' (WHO, 1970).

OTHER MINDS. The classical problem of why we believe that other people (and perhaps at least the higher animals) have sensations, thoughts, and so on, essentially similar to our own. It seems that we draw a widespread analogy from our own behaviour, and related internal affective states, to the internal states of other people (and sometimes animals), especially when their behaviour is similar to ours. Some clinical states, especially coma, are very difficult to interpret or 'read', as behaviour is no longer typical or at all like our own.

Given that computers are developing some abilities until recently thought specifically human, the question of whether computers can have minds is rapidly becoming a significant issue. As Alan*^{Turing} suggested, we may say that a computer is as 'intelligent' as a human if it answers questions as a human does; but would we say that the computer is *conscious*, or *aware*, as we are? It is this doubt that gives*behaviourism its prima facie scientific validity—though behaviourism rejects what we take to be the most important fact of at least *our* minds:*consciousness.

OUTOFTHEBODY EXPERIENCE, or OBE, may be defined as an experience in which a person seems to perceive the world from a location outside his physical body. OBEs have been reported from diverse ages and cultures by old and young, educated and uneducated, and those who have prior beliefs about the experiences and those who know nothing about them.

Some of the most dramatic OBEs have been reported as part of the neardeath experience, for example in those who are resuscitated from cardiac arrest or who survive lifethreatening accidents. However, very similar experiences can occur during resting, meditation, when taking certain drugs, or even during normal everyday activity. A few people claim to be able to induce the experience at will and to control it when it occurs (Muldoon and Carrington 1929; Rogo 1983).

Those who have experienced OBEs claim typically that they seemed to float out of their body and were able to see and move without it. Some seem to possess a duplicate body, or double, but many seem to take on other shapes or seem to be no more than a perceiving point in space. This point, or form, can then move about and observe what appears to be the normal physical world—but often with subtle differences from normal. It may contain odd errors, and objects may be strangely

illuminated on the darkest night. It is possible to see and to travel at will through walls and other objects, though not usually to affect them physically. Sometimes completely different 'worlds' are visited, some merely bizarre, others of mystical quality. In addition there are controversial claims that people have actually influenced objects or acquired information paranormally during their 'travels'.

Whether or not one accepts that something does leave the body, a consistent feature of the experience is that it is described as totally vivid and realistic, and quite unlike a dream or daydream. Very often people who have OBEs feel that the experience affected them deeply and even changed their beliefs and values.

OBEs have been investigated by case collections, surveys, experiments, and personal experience. Case collections show that the experience is very variable, as are the conditions under which it occurs. Muscular relaxation, exhaustion, monotonous sounds, and certain drugs are often implicated. These may all have in common the fact that they tend to disrupt both sensory input and the normal body image (Blackmore, 1982).

Surveys have shown that anywhere between 8 and 34 per cent of respondents report having had an

OBE at some time during their lives, depending on the population sampled. There seem to be no obvious differences between those who have experienced OBEs and others, although recent studies have begun to find differences in imagery skills (Cook and Irwin, 1983).

Experiments have mostly been of three types. First were attempts to detect the double during the OBE, which began early this century. It is probably true to say that the size of any effect detected has decreased with increasing experimental sophistication. Most recent studies have used magnetometers, thermistors, ultraviolet and infrared detectors, and so on, as well as humans and animals. There has been limited success with animals, but no reliable detector has yet been found (Morris et al., 1978).

The second type aims to determine whether a person having an OBE can actually bring back information from a distant location. Many such claims have been made but the experimental evidence is weak. Subjects have been asked to view target letters, numbers or pictures, placed in distant rooms. One subject correctly 'saw' a fivedigit number, but such clear success has never been repeated. Other studies have tried to discover whether subjects seem to be looking from a specific location during OBEs; however, the results have been inconclusive (see Rogo, 1978). Generally these studies provide very mixed results and it is not clear that any paranormal process is involved.

The third type of experiment is studies of the physiological state associated with the OBE. No unique physiological state seems to be necessary. Rather, the experience may occur in a relaxed waking state, or in something resembling stage 1 sleep (Rogo, 1978).

Finally, personal experience should be mentioned as a useful adjunct to the other types of research—for the unique experiential qualities of the OBE demand explanation.

There have been three main types of theory of the OBE. The most popular are those suggesting that we all have a double that can act independently of the physical body. This notion can be traced back to ancient Egypt and to Greek philosophy, and can be found in folklore and mythology; it is an essential part of some religious teachings. A popular modern version is the doctrine of 'astral projection', according to which the astral body is capable of separating from the physical body and travelling without it on the astral plane. In life the astral body is joined to the physical by a 'silver cord'; but at death the cord is broken and the astral body freed, taking consciousness with it. There are numerous problems with this kind of theory. It cannot specify what the astral body consists of, in what sense it is conscious, how it perceives and interacts with the world without any perceptual apparatus and without being detected, or why the world appears so strange. In addition, many surveys have shown that astral bodies are rare and 'cords' even rarer (e.g. Green, 1968). In other words, these theories seem neither to make sense nor to fit with the evidence.

The second type of theory is that the OBE is imagination plus ESP (*extrasensory perception). This can, potentially, avoid the problems of 'other bodies' and separate worlds while allowing for the claims of paranormal abilities in the OBE; but only in the weakest possible way. Since the term 'imagination' is so broad and we know next to nothing about how ESP functions—if indeed it does—it is hard to test this theory.

The final type of theory is that the OBE is a purely psychological phenomenon, involving no other bodies and no paranormal abilities (Blackmore, 1982; Palmer, 1978). There have been comparisons with the experience of birth, and suggestions that the OBE is a way of denying death. Some have suggested that it is no more than a kind of dream, but physiological studies show that the OBE need not take place during sleep, and certainly not in REM (rapid eye movement, or*dreaming) sleep (Rogo, 1978). Also, it does not seem like a dream. Consciousness seems absolutely clear, memory seems normal, and things are seen extremely vividly. If it is like any kind of dream, it is most like a 'lucid dream'—that is, one in which you know *at the time* that it is a dream (Gackenbach and LaBerge, 1985). Some aspects of the OBE resemble certain types of*hallucination. For example, tunnels are frequently rushed through at the start of an OBE or in neardeath experiences, as well as in druginduced hallucinations. The psychological theories attempt to integrate these features of the experience and to explain why it seems so real.

Page 573

One possibility is to view the OBE as an altered state of consciousness in which an imagined model or representation of the world replaces the normal perceptual model. If sensory input is reduced or disrupted, the normal inputbased model of the world may start to become unstable and break down. In this case the cognitive system will try to get back to normal by creating a new model of the world from imagination. If this model is more convincing than the degraded perceptual model, it may take over and seem real. Imagined models are often constructed in bird'seye view, as though from above. So if a model like this takes over then an OBE will have occurred.

The theories obviously differ in their implications for survival after death. Some researchers have seen the OBE as one method of investigating 'survival', and to this end have tried to confirm that there is an objective double which leaves the body and is capable of independent thought and action. But this is in no way implied by the occurrence of the experience itself. Even if it is under stress the physical body is still alive, often quite well, and there is no reason to suppose that it is not responsible for the organized thought and consciousness involved.

All the evidence suggests that, rather than hunt down the elusive 'other body', we shall get closer to understanding the OBE by treating it as a 'psychological response to unusual conditions. What we need is a better understanding of subjective experience—including mystical experience and other altered states of consciousness—

within which the experience of seeming to be outside one's body makes sense.

OWEN, SIR RICHARD (1804-92). British physician and naturalist, born at Lancaster, he studied medicine at Edinburgh and at St Bartholomew's Hospital, London, and became curator in the museum of the Royal College of Surgeons, producing splendid catalogues. In 1856 he became superintendent of the natural history department of the British Museum. He accepted evolution before Darwin but maintained a lengthy dispute, especially with T. H. Huxley, criticizing Darwin's principle of natural selection. They finally made up the quarrel. An important essay is *On Parthenogenesis* (1849). There is a splendid statue of Owen in the British Museum (Natural History), South Kensington, London.

P

PAIN. Pain research and therapy have long been dominated by specificity theory which proposes that pain is a specific sensation subserved by a straightthrough transmission system, and that the intensity of pain is proportional to the extent of tissue damage. Recent evidence, however, shows that pain is not simply a function of the amount of bodily damage alone, but is influenced by attention, anxiety, suggestion, prior experience, and other psychological variables (Melzack and Wall, 1982).

Moreover, the natural outcome of the specificity concept of pain has been the development of neurosurgical techniques to cut the so-called pain pathway, and the results of such operations have been disappointing, particularly for chronic pain syndromes. Not only does the pain tend to return in a substantial proportion of patients, but new pains may appear. The psychological and neurological data, then, force us to reject the concept of a single straightthrough sensory transmission system.

In recent years the evidence on pain has moved in the direction of recognizing the plasticity and modifiability of events in the central nervous system. Pain is a complex perceptual and affective experience determined by the unique past history of the individual, by the meaning to him of the injurious agent or situation, and by his 'state of mind' at the moment, as well as by the sensory nerve patterns evoked by physical stimulation.

In the light of this understanding of pain processes, Melzack and Wall (1965) proposed the gate control theory of pain. Basically, the theory states that neural mechanisms in the dorsal horn of the spinal cord act like a gate which can increase or decrease the flow of nerve impulses from peripheral fibres to the spinal cord cells that project to the brain. Somatic input is therefore subjected to the modulating influence of the gate *before* it evokes pain perception and response. The theory suggests that large fibre inputs (such as gentle rubbing) tend to close the gate while small fibre inputs (such as pinching) generally open it, and that the gate is also profoundly influenced by descending influences from the brain. It further proposes that the sensory input is modulated at successive synapses throughout its projection from the spinal cord to the brain areas responsible for pain experience and response. Pain occurs when the number of nerve impulses that arrives at these areas exceeds a critical level.

Melzack and Wall (1982) have recently assessed the present day status of the gate control theory in the light of new physiological research. It is apparent that the theory is alive and well despite considerable controversy and conflicting evidence. Although some of the physiological details may need revision, the evidence supporting the concept of gating (or input modulation) is stronger than ever.

The subjective experience of pain clearly has sensory qualities, such as are described by the words throbbing, burning, or sharp. In addition, it has distinctly unpleasant, affective qualities which are described by words such as exhausting, wretched and punishing. Pain becomes overwhelming, demands immediate attention, and disrupts ongoing behaviour and thought. It motivates or drives the organism into activity aimed at stopping the pain as quickly as possible. On the basis of these considerations, Melzack and Casey (1968) have proposed that there are three major psychological dimensions of pain experience: sensorydiscriminative, motivational affective, and cognitiveevaluative. Psychophysiological evidence suggests that each is subserved by specialized systems in the brain which interact to produce the multidimensional qualities of pain experience.

Recent recognition of the complexity of pain experience has led to the development of a paperandpencil questionnaire (the 'McGill Pain Questionnaire') to obtain numerical measures of the intensity and qualities of pain (Melzack, 1975). The questionnaire consists of twenty sets of words that people use to describe pain. Ten sets describe sensory qualities, five describe affective qualities and one is an evaluative group. Four sets consist of miscellaneous words. Since each word has a numerical value, patients asked to check those words that best describe their pain provide quantitative measures for each of the major dimensions of pain. The power of the questionnaire has been demonstrated in many quantitative, controlled studies of the effects of different forms of pain therapy (Melzack, 1983). In addition, the questionnaire has been shown to discriminate among different types of pain. Distinctive patterns of words discriminate between migraine and tension headaches, between lowback pain of organic and that of functional origin, and between dysmenorrhoea and pain caused by an intrauterine device.

Drugs, especially*opium and its derivatives, are among the oldest methods for controlling pain. Thomas*Sydenham in 1680 wrote: 'Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and efficacious as opium.' Since then, more

effective derivatives of opium, notably morphine and heroin, have been discovered. The

Page 575

invention of the hypodermic needle and syringe not only stimulated the search for pure, injectable analgesics but also, unfortunately, increased the risk of drug dependence. The quest for preparations free from addictive properties has proved to be fruitless, but withholding such painrelieving drugs from the terminally ill lest they become 'addicted' is as ridiculous as it is inhumane. Other drugs said to have analgesic properties include the antidepressants, but it does not appear that relief of depression is their mode of action. Possibly this may be by blocking the reuptake of serotonin and so potentiating the effect of enkephalins in the brain (see NEUROPEPTIDES).

Many new methods to control pain have been developed in recent years (Melzack and Wall, 1982). Sensory modulation techniques such as transcutaneous electrical nerve stimulation (TENS) and ice massage are widely used in the attempt to activate inhibitory neural mechanisms to suppress pain. These techniques have a long history but were not understood until recently. Acupuncture, for example, is an ancient Chinese medical procedure in which long needles are inserted into specific points at the skin. The traditional Chinese explanation is that the needles bring Yin and Yang (which flow through hypothetical tubules called meridians) into harmony with each other. It has been discovered, however, that the sites of insertion correspond to myofascial 'trigger points' which are well known in Western medicine. It has also been found that acupuncture and electrical stimulation through electrodes placed on the skin (TENS) are equally effective in relieving lowback pain and several other forms of pain, including pains due to peripheral nerve injury. The neural mechanisms which underlie the relief produced by these forms of stimulation are not entirely understood, but evidence suggests that the intense stimulation produced by acupuncture or TENS activates an area in the brain which exerts a powerful inhibitory control over pathways which transmit pain signals.

Psychological techniques that allow patients to achieve some degree of control over their pain have also been developed. These techniques include*biofeedback, hypnosis, distraction, and the use of imagery and other cognitive activities to modulate the transmission of the nerveimpulse patterns that subserve pain. Psychological techniques are being used increasingly and provide relatively simple, safe approaches to pain control. They represent a significant advance over the earlier tendency to treat pain by neurosurgical operations intended to cut the 'pain pathway' and which so frequently ended in failure.

The techniques of sensory modulation and psychological control work well in conjunction with each other. A large body of research demonstrates that several of these procedures employed at the same time—'multiple convergent therapy'—are often highly effective for the control of chronic pain states, particularly those such as lowback pain which have prominent elements of tension, depression, and anxiety.

While great strides have been made in the control of pain, there are still many pain syndromes which are beyond our comprehension and our control. Back pains, especially of the lower back, are the most common kind of pain, and literally millions of sufferers are continually seeking help. Sometimes they

obtain temporary relief, but most continue to suffer.*Migraine and tension headaches similarly plague millions of people. Perhaps the most terrible of all pains are those suffered by some cancer patients in the terminal phases of the disease. In recent years, specialized medical units have been developed to cope with these problems. Their major feature is that physicians and other health professionals from many different disciplines work together in the attempt to alleviate the pain of each individual patient. Pain clinics have been set up in every major Western city to cope with benign chronic pain, and hospices or palliative care units in hospitals have been developed to control pain (and other miseries) of patients who are terminally ill with cancer.

The development of pain clinics and hospices represent a breakthrough of the highest importance in the clinical control of pain. They are radical, new approaches to old problems. Chronic pain and terminal pain are major challenges to the scientist and clinician. But the giant step has been the recognition that they are special problems. The challenges ahead are clear: to conquer pain and suffering in all their forms.

PANPSYCHISM. See ANIMISM.

PARADIGM. 'Paradigm' has become an important technical term in the philosophy of science Page 576

following the publication of *The Structure of Scientific Revolutions* by Thomas Kuhn (1962; 1970). Kuhn's thesis is that 'normal science' operates within a largely unquestioned framework governed by fundamental theoretical models, or 'paradigms'. These ruling paradigms determine the way in which experiments are designed and observational results are interpreted. Once a theory gains the status of a paradigm (an example is Darwin's principle of natural selection by the survival of the fittest) it remains unchallenged until a scientific 'revolution' occurs and it is overthrown in favour of a new paradigm (cf. the switch from Newtonian to Einsteinian physics); when this happens even oldestablished observations and experiments change their significance. This has been likened to a*Gestalt switch in perception of an ambiguous figure. An important part of Kuhn's view is the assertion that different scientific paradigms are 'incommensurable': there is no common body of neutral observation which can be used to decide between two competing theories— a notion which may be thought to cast doubt on the claims of science to objectivity and rationality.

Kuhn's view of paradigms has been criticized in detail by Margaret Masterman (1970), but it has proved of great importance by emphasizing the role of general conceptual models in science and thinking. Psychology may be a somewhat unsatisfactory science because it lacks effective unifying paradigms. Although the great theorists, such as Sigmund*Freud and B. F. Skinner (following the lead of J. B.*Watson), are important partly because they did provide paradigms, found to be useful clinically and by experimenters, these paradigms have never gained the degree of general acceptance achieved by paradigms in the physical sciences.

PARADOX. See ILLUSIONS.

PARALYSIS is loss of motor function. Thought processes and*perception may be subtly modified or impaired. It is an interesting question whether perception (which almost certainly depends primarily on active learning in infancy) and*emotion (which may largely be sensations of bodily changes, for example to perceived danger) can remain normal with extensive paralysis. William*James described the case of a woman paralysed almost from the neck down following a hunting accident, who yet experienced emotions when visited by her family. This has been used as evidence against the JamesLange theory of emotion, which is essentially that emotions are visceral sensations, and should therefore cease with sufficiently general paralysis. It was the observation, in classical times, that head wounds are associated with paralysis on the opposite side of the body, that led to concepts of*localization of brain function, with the left hemisphere controlling the right side of the body, and vice versa.

Paralysis is usually organic, due to brain damage or loss of peripheral 'nerve function, but it can occur as a functional symptom of*hysteria.

PARANOIA. Although paranoia today is a diagnosis used to describe patients who exhibit systematized delusions of grandeur and persecution, its original meaning, as the etymology of the word indicates, was 'being out of one's mind'. Heinroth in 1818 appears to have equated paranoia with *verröcktheit* (madness); Kahlbaum in 1863 was the first psychiatrist to give it its modern meaning, and although he regarded paranoia as a persistent, chronic condition, he believed that paranoid patients suffered from a disorder of intellect. The term survives as the name given to one type of functional*psychosis, viz. that in which the patient holds a coherent, internally consistent, delusional system of beliefs, centring round the conviction that he (or, more rarely, she) is a person of great importance and is on that account being persecuted, despised, and rejected. As Henderson and Gillespie's *Textbook of Psychiatry* (9th edn., 1962) puts it: 'A person so affected believes that he is right, that he is justified in his beliefs, and that anyone who opposes his point of view is behaving maliciously or at least nonunderstandingly towards him.' Such a person does not subscribe to the view that he is ill, does not accept treatment, does not enter hospital voluntarily, and may do great harm to himself and others: to himself by coming into active collision with a world that does not subscribe to his own exalted view of himself, and to others by attacking those he conceives to be persecuting him.

Paranoiacs on occasion commit murders, not infrequently engage in futile litigation, and generally make an infernal nuisance of themselves, quarrelling incessantly with their neighbours and falsely accusing people of trespass or their spouses of infidelity.

True paranoia is, fortunately, rare; it has a bad prognosis and is not amenable to any known treatment. However, despite its rarity, it is for a variety of reasons of considerable interest and importance.

First, incoherent, internally consistent delusions of grandeur and persecution occur in other psychoses, notably in*schizophrenia, where they form part of a clinical picture that includes*hallucinations, emotional withdrawal, and autistic thinking (in which syntax is disrupted). These are three classes of symptom which are conspicuous by their absence in true paranoia. Most but not all textbooks of psychiatry list 'paranoid schizophrenia' as one of three varieties of schizophrenia, the other two being hebephrenic schizophrenia, which is characterized by withdrawal, bizarre mannerisms, and neglect of the person, and catatonic

schizophrenia, characterized by periods of excitement and stupor.

Secondly, many people who are not regarded as mentally ill, and who do not come under the care of psychiatrists, display a cluster of personality traits which can be, and nowadays often are, described as paranoid. These people are opinionated, touchy, and have an idea of their own importance which the rest of the world does not endorse. Such people patently suffer from a disorder of selfesteem, not of intellect—their opinions must be correct because they hold them; their families, their careers, their lives must be especially important because they are *their* families, *their* careers, *their* lives—and the same must presumably be so for true paranoia.

According to classical psychoanalytical theory, paranoia and paranoid traits generally are narcissistic disorders, the implication being that they indicate fixation at some infantile stage of development

during which the self is its own love object; but many contemporary analysts hold that narcissistic selfoverestimation is a compensatory reaction to humiliation in infancy and childhood. Later research (Schatzman, 1973) has shown that Daniel Paul Schreber (1842-1911), the subject of Freud's classic paper 'Psychoanalytical Notes on an Autobiographical Account of Paranoia (Dementia Paranoides)' (1911), was from birth subject to gross mechanical restraints by his father, who was determined to nip in the bud all signs of selfwill and 'innate barbarity' in his infant son. Freud, however, made no enquiries into his subject's childhood, took his expressed devotion to his father at its face value, and interpreted his delusions of being persecuted by God as a reversal and projection of repressed homosexual longings for his father.

Thirdly, paranoid delusions bear a disconcerting, embarrassing resemblance to the beliefs held and propagated by founders of religions, by political leaders, and by some artists. Such people often make claims on behalf of themselves, their religious ideas, their country, their art, which would be regarded as grandiose and delusional if their ideas did not harmonize with the needs of their contemporaries and thereby achieve recognition and endorsement. Nowadays anyone who claimed to be the Messiah, who addressed God as his personal father, and asserted that 'he who is not for me is against me' would be at risk of being referred to a psychiatrist and diagnosed a paranoid. But presumably in the first century AD His Word spoke to many—as indeed it continues to this day to do. Similarly, any politician who asserted the innate superiority of his own race and claimed that his country was the victim of an international conspiracy would today raise doubts as to his sanity, but in Germany in the 1930s Hitler found all too many people prepared to agree with him. There must, it seems, be some as yet unformulated relationship between the psychology of paranoia and that of prophets and leaders.

Fourthly, the adjective 'paranoid' is sometimes used by psychoanalysts to describe anxiety and ideas that are inferred to be projections of the subject's own impulses, so that, for instance, a person who is unaware of his own hostility may suffer 'paranoid anxiety', imagining that everyone else is hostile towards him, or a person who is unaware of his own homosexual tendencies may have the 'paranoid idea' that other men are always about to make a pass at him. This usage derives historically from Freud's idea that the psychology of paranoia hinges on reversal and projection of unconscious homosexual impulses.

Finally, it must be mentioned that the word 'paranoid' has slipped into general use to refer to enhanced suspiciousness, often with the implication that such suspiciousness is evidence of unusual sensitivity and perceptiveness. Hence the catchphrases 'Paranoia is total awareness' and 'The fact that you're paranoid doesn't mean that you aren't being followed'.

Schatzman, M. (1973). *Soul Murder*. London.

PARANORMAL is the adjective used for phenomena lying outside the range of normal scientific investigations. Among other things it includes communication without physical links, telepathy, clairvoyance, movements of objects without known causes, and extrasensory perception (ESP). What these phenomena have in common is not only the lack of accepted explanations but the much stronger claim—essentially difficult to justify—that there never will be acceptable explanations, even for any future science.

It is said of paranormal phenomena (and it is these suggestions that seem to lie outside science) that they demonstrate powers of disembodied minds, are associated with some kind of consciousness, and occur without physical force or material stimulus. They thus have implications for psychology, and for our views of the mind and its relation to the physical world. Many of the claimed phenomena are commonplace events, such as objects falling off shelves, for which no natural cause can be established. If any explicable reason can be supposed, then the claim vanishes, however bizarre the event, for the onus is always to show that the event *is* paranormal.

Although paranormal intervention is nowadays seldom accepted as the reason for any other but very unusual events, except perhaps in astrology, this has not always been so: 'primitive' explanations of everyday events were often in terms of the direct action of mind on matter, or on other minds.

Research on claims of paranormal phenomena has been and still is active in many countries; but the most influential body organizing experiments and examining such claims is the British Society for Psychical Research. After a century of work, by many highly distinguished people, including scientists of the first rank, there is probably less

Page 578

confidence now in the existence of paranormal phenomena than when the society was founded. As experiments designed to test for extrasensory perception, telepathy, telekinesis, 'forkbending', and so on are tightened up, the phenomena tend to disappear or turn out to be clearly fraudulent. Of course one cannot say that every case is mistaken or fraudulent; but it is hardly to be taken lightly that, for example, the conjuror James Randi is able by conjuring methods to duplicate Uri Geller's forkbending and other phenomena which only recently were widely accepted as paranormal. There are, however, a few cases of dramatic demonstrations of claimed paranormal abilities which have never been explained in terms of known or conceivable physics, or as cheating: especially those of Daniel Dunglas Home (1833-86) who, among other inexplicable reported events, was 'seen' by many people at a party in London to levitate—passing out of one window and through another into a different room—and to perform many other dramatic 'paranormal' feats over many years without ever being 'found out'. On the other hand, there have been several accepted conjurors whose methods, though never ascertained, are assumed not to be paranormal abilities. In any case, it has come as a shock to discover how easily even the best observers and experimenters can suffer illusions and be mistaken and misled into errors of observation and reporting. Even if all claims of paranormal phenomena are totally rejected, as they have been by such sceptics as David Hume in his famous 'Essay on Miracles' (1755) and more recently C. E. M. Hansel (1966), it is interesting nevertheless to consider such claims, as they do highlight weaknesses of observation and experiment (for science depends on the

reliability and honesty of its practitioners). They may also highlight some extremely difficult questions concerning the relation of mind to matter, and suggest what kinds of evidence might be useful for settling philosophical questions by scientific means, as discussed for example by S. E. Braude (1978).

The Cambridge philosopher Charlie Dunbar Broad (1887-1971) suggested that we have beliefs which are deeper and more general than scientific theories, and that it is when these 'basic limiting principles', as Broad called them, of acceptable belief are violated that we move into the domain of the paranormal. Broad did not attempt to give an exhaustive list of these limiting principles, beyond which acceptable science cannot go, nor did he say how the limits of scientific acceptance might be determined. No doubt some people do believe that the paranormal is somehow 'beyond' science, and that science is blind to paranormal truths. This may however be difficult to maintain when we consider that many 'paranormal' phenomena are simple and well-known kinds of events—apart from their explanation. So, whether they appear to be within the bounds of science or beyond it depends on showing that they cannot be explained in normal terms in those particular conditions. The difficulty is to establish that some kind of 'trick' conditions are not in operation, such as a child pushing objects off a shelf with a knitting needle poked through the wall from the next room. For example, there is the famous case of the 'telepathic' boys, who communicated with supersonic whistles hidden in their pockets—with air bulbs which they squeezed according to a code. The high-pitched signals were inaudible to the elderly investigators, who assumed that a paranormal explanation was necessary—

until the trick, for trick it was, was found out. But suppose that telepathy can occur by some kind of scientifically acceptable though at present unknown radiation, analogous to radio. (And, after all, radio must seem magical to people with no understanding of its principles—it is amazing enough to those who do!) Telepathy would, then, no longer be regarded as paranormal as it could be explained by science. This brings out the difficulty in defining 'paranormal' as lying outside accepted science—for with new discoveries and theories science often changes dramatically and unpredictably—so what once seemed mysterious or 'paranormal' may become accepted science, as science changes to take account of it. This is so for several past mysteries, which have moved from being regarded as occult or paranormal to being accepted by and even to becoming central in science: such as thunder and lightning being once considered to be the wrath of the Gods, but now understood as the same electricity that we generate and use for wonders of our technology.

While electricity was seen as an occult life fluid—which it appeared to be with its ability to shock and convulse, its frenzied sparks, and its sinuous ethereal glow in discharge tubes responding wonderfully to magnets and to a nearby human hand—both electricity and magnetism were supposed to effect cures, and produce trances and other mental states. Franz Mesmer (1734-1815) convinced many highly intelligent people with his demonstrations of such vital powers of magnetism, seeming to act directly upon mind. As we see it now, Mesmer was demonstrating hypnotism. He worked with histrionic skill, and most effectively. He made wooden pretend magnets, which worked as well as the real steel magnets—provided they *looked* like steel magnets. Mesmer attributed this to some far more general, and indeed all-pervading, spiritual magnetism, acting on mind, though obeying laws of physics (such as being reflected from mirrors). The curious trance states and other phenomena, which Mesmer demonstrated, were gradually distinguished from 'spirit' or 'animal magnetism'—especially

after the clinical demonstrations of the French neurologist Jean Martin*Charcot (1825-93)—when hypnotism was finally seen to be a psychological phenomenon, and it was used as a tool for probing the unconscious mind, by Sigmund*Freud who was a pupil of Charcot's.

However all this may be, we remain uncertain about the powers and limits of mind; so claims of Page 579

paranormal powers can hardly be dismissed out of hand. What seems to underlie accounts of the paranormal is the notion of mind affecting matter, or other minds—

but this is exactly what most of us believe happens whenever we do anything at all, even just wagging a finger. This is part of the deep problem of dualistic accounts of

'mental' mind and 'material' brain (see DUALISM). A way out for psychology is to suppose that minds are not entities which control behaviour, or brains, but are generated by brain activity. Hence the significance of the various kinds of mindbrain identity theories (see THEOLOGY and MINDBRAIN IDENTITY), which deny a causal relationship between mind and brain; it should be recognized, however, that mindbrain identity accounts are controversial and are hard to formulate.

Clearcut paranormal phenomena demonstrating disembodied mind might conceivably show identity theories to be untenable. So paranormal accounts do have empirical consequences, even though—in spite of the immense work of controlled experiments, especially on telepathy, and the collections of accounts of bizarre phenomena by Frederic*Myers (1903) and later writers—we may seriously doubt whether there are any such phenomena.

PARANORMAL PHENOMENA: THE PROBLEM OF PROOF. By the late nineteenth century the spectacular success of science as an explanatory system was drawing attention to a corresponding failure: the inability of science to cope with a wide range of reported phenomena called 'supernatural'. These ranged from*ghosts to*levitation, and included thoughtreading, seanceroom 'materialization', waterdivining, communications with the dead, precognition, hypnosis (arguably), and a long list of others. Did these phenomena really exist, and if they did why did they seem to stay so stubbornly outside the scientific worldview? In 1882 a group of British scholars and scientists founded the Society for Psychical Research with the aim of tackling these questions in a scientific spirit and removing this 'intellectual scandal'. In the ensuing hundred years or so, a steadily growing body of research, of gradually increasing sophistication, has been devoted to the challenge in universities and laboratories all over the world. A century later may be an appropriate time to take stock of the position and to consider how far the aims of these early parapsychologists have been fulfilled.

Perhaps the only noncontroversial statement that can be made about the present position is that the controversy continues. On the one hand we see results continuing to be reported. Several journals more or less regularly publish positive findings from respectable laboratories, written by people with scientific training and (often) higher degrees. On the other hand, with the single exception of hypnosis, not even the existence of one of the phenomena originally classed as supernatural, or later as paranormal, has achieved general acceptance among the scientific community; not one demonstrable, or repeatable, paranormal effect has been discovered; not one characteristic or law has been found which turns up in all those experiments that claim a positive result.

What are we to make of this situation? Should we argue that, since results continue to appear in such a wide range of circumstances in space and over time, there must be at least something there— for there's no smoke without fire? Or is it more reasonable to argue that, if the effects were real, such an intensive search over such a long period would surely have turned up something demonstrable?

If we are to choose between these two interpretations, we need to look rather carefully at the nature of the evidence that is being produced for and against the paranormal, and in particular at the social and psychological setting within which the controversy occurs.

First, it is important to note that paranormal phenomena are not claimed to be repeatable at will. Therefore, in order to claim evidence against the paranormal it is not sufficient to report that an experiment was done and no paranormal effect was obtained, for this proves nothing. In fact the only evidence *against* consists of criticisms of the evidence *in favour*. This situation weights the scales against the sceptic.

It is constructive to consider a case history. The SoalGoldney experiments, with Shackleton as mindreader (or 'percipient'), were carried out in 19413 under S. G.

Soal, a London University lecturer in mathematics. They were widely quoted at the time, and for many years thereafter, as a model of rigorous experimentation, and stood for long as the backbone of the evidence for precognition. So strict were the conditions, with multiple witnessing and numerous changes of personnel and of experimental design, that they were held to be proof against fraud not only on the part of the percipient but by the experimenters themselves. Yet, over the years, the experiments gradually crumbled under the assaults of sceptics.

Page 580

In 1955, G. R. Price showed that several methods of fraud. were possible if collusion were assumed between Soal and two other participants.

In 1960, Hansel showed that only one other participant needed to be in the trick. Some statistical features of the data seemed to lend some support to such a hypothesis, though far from conclusively.

In 1956, pressure from sceptics obliged Soal to reveal that, contrary to the published report, the original records were not available for study because he had lost them. Handwritten copies, however, were still available.

In 1960, further pressure from sceptics obliged him to publish a more serious admission, which had been known to some of them by hearsay. During the experiments one of the participants had reported seeing Soal improperly 'altering the figures'—specifically, changing '1's into '4's and '5's. A full contemporary report had been kept by his collaborator Goldney, but Soal had up to that point refused to allow publication, using the threat of a libel action.

In 1971, Medhurst reported a computerized attempt to identify the sequence of target digits that Soal had used. He was unable to trace the sequences in any relevant sources and concluded that Soal's account of the way in which the targets were prepared must be incorrect.

In 1973 and 1974, Scott and Haskell showed that there was strong statistical evidence in the experimental records supporting the allegation that Soal had 'altered the figures', changing '1's into '4's and '5's among the target digits in such a way as to turn misses into hits. This evidence appeared in three of the forty sittings (including the one in which this manipulation had apparently been observed) and could account for all the abovechance scoring in these three sittings. (There was no sign of such an effect in the remaining sittings.)

The *coup de grâce* came in 1978, when Markwick published the results of an astonishingly tenacious pursuit of the line opened earlier by Medhurst. She first showed that the target digits contained a considerable number of runs of consecutive digits that were repetitions of runs used in earlier sessions, and that this could not have arisen by chance. This in itself was not particularly serious. However, she also showed that in many such cases the repetition was not exact but there were *intrusions*—digits inserted in the sequence—and that these intruded digits were *nearly always hits*. The implication of improper manipulation seems almost inescapable.

The lesson that this story teaches us is not simply that Soal's defenders were wrong and that a

respectable academic can cheat in his own experiments. Equally significant is the time and effort that was required to demonstrate this conclusion. If we confine ourselves to the authors mentioned above, six researchers were involved over a period of thirtyfive years. Yet the SoalShackleton experiments have received more attention from sceptics than any others. Such an effort of destructive criticism is simply not generally available for tackling the mass of less striking experiments that are regularly published. In our society, destructive work is not regarded favourably, and an institution devoted to criticism would have difficulty attracting funds. An experimenter working to demonstrate a new scientific phenomenon may be fired with enough enthusiasm to last him a lifetime; he may see himself as a pioneer on the frontier of knowledge and potentially a figure whose name will go down in history. But where is a sceptic to find his motivation? At the very moment when the researcher begins to lose his belief in the phenomena he begins to lose his interest in the issue.

Once again the scales are weighted against the sceptic.

The SoalShackleton exposure is exceptional in another respect. Very few parapsychology experiments have been so well documented. Detailed records of the procedures are available for study, including copies of the score sheets, and these proved to contain hidden but ultimately damning evidence of manipulation. In far more experiments only minimal records are kept. It is possible that in many cases errors or deceptions were made which left no trace in any subsequent record, so that their detection after the event is literally impossible. Once again, the sceptic's task is rendered more difficult.

For these reasons the argument that there is no smoke without fire—that the continuing flow of positive results proves the reality of the phenomena since the evidence has not been systematically disproved—is scarcely compelling. If the paranormal did not exist the situation could well be very close to that which we observe today.

We have only to assume a small but continuing flow of researchers ready to deceive themselves, or perhaps to deceive others, victims of wishful thinking or conscious frauds. That such people are rare is no doubt true—but so are successful parapsychologists. If the paranormal does not exist then a parapsychology experiment is a selection procedure for finding such people among the overwhelming majority of genuine scientists. On this hypothesis the evidence will continue to flow in, from all countries and perhaps all centuries to come. As for the sceptic, he may expose the more important cases but he can never hope to catch up; the dice are loaded against him.

The characteristic symptom of this situation would be a continuing failure to build up any solid body of accepted knowledge in the area of the paranormal. For the time being this is the position we observe. As long as this situation persists it will be reasonable to regard the case for the paranormal as not proven, though outright disproof is certainly unattainable.

PARANORMAL PHENOMENA AND THE UNCONSCIOUS. In 1972, the Toronto Society for Psychical Research, under the direction of A. R. G. Owen, began an experiment that has already become a classic of parapsychology. What they did was to attempt to *create* a ghost. One member of the group invented the life story of a seventeenth-century nobleman named Philip, including a jealous wife and a gypsy mistress who was falsely accused of witchcraft and burned at the stake.

The group then sat around, meditated, and attempted to 'conjure up' Philip. After long effort they succeeded. The table began to vibrate, then there were raps; using a code of raps, the 'spirit' identified itself as Philip, and told the life story that had been invented for it. On a later occasion the experiment was performed in front of a television audience; the table waltzed up on to the stage and performed its antics before the cameras.

The experiments seem to confirm a theory long held by many parapsychologists: that psychical phenomena originate in the subconscious minds of human beings (although we should also admit the possibility that the group conjured up a real 'disembodied entity' that chose to masquerade as Philip). Ever since the late nineteenth century, psychical researchers have recognized that poltergeist phenomena usually centre round a disturbed child or adolescent: that is to say, the bangs and crashes and unaccountable movements of objects associated with poltergeists seem to be in some way caused by the juvenile 'focus' of the disturbances. Yet in the majority of cases, the 'focus' is unaware of being the cause. Which in turn seems to suggest that the phenomena are 'caused' by the unconscious mind.

This clearly raises more problems than it solves. By what mechanism does the unconscious mind move objects around? Does it, for example, possess invisible pseudopodia? Why should such powers be beyond the reach of the conscious mind? What precisely do we mean by the 'unconscious mind'?

Now, for all practical purposes, the concept of the unconscious was invented by Sigmund*Freud, although it can be traced back as far as*Leibniz. And it is worth considering how Freud came by the idea. In Paris in the early 1880s, J. M.*Charcot was intrigued by the phenomena of hysteria—women whose stomachs swelled up in phantom pregnancies, or whose limbs were frozen by hysterical paralyses. He observed that hysteria was closely related to hypnosis: for example, a hypnotist could sometimes cause a blister by telling the subject that he had been touched by a red-hot poker. It was Freud, who studied with Charcot in 1886, who saw the tremendous implications of these

observations. The *conscious* mind cannot make the stomach swell up, or cause stigmata to appear on the hands of religious

'somnambules'. If the unconscious part of the mind can do this, then clearly its power is in some ways greater than that of the conscious mind. We are all familiar with the simpler manifestations of the unconscious mind—someone talks about itching and we itch; someone talks about coughing and we feel the need to clear our throats.

What Freud recognized was that the unconscious mind can be persuaded to perform astonishing feats by means of suggestion—either of a hypnotist, or of the conscious mind.

Charcot apparently failed to grasp the import of his discovery; so, oddly enough, did Freud. He had, in effect, stumbled upon the mechanism of *neurosis*. My conscious mind scans and assesses the world, and reacts accordingly. If it decides that the tasks confronting it are unutterably tiresome, we experience a kind of inner collapse, a feeling of 'Oh *no*'. What has happened is that the unconscious has responded instantly to a suggestion of futility by a *withdrawal* of vitality. This in turn gives the conscious 'self' a deeper sense of futility, and the continual 'feedback effect'—a kind of vicious circle—produces *neurosis*. Anyone who has seen the old Laurel and Hardy films has observed the same mechanism. Whenever they find themselves in some preposterous situation, Stan looks at Ollie's face to see how he is reacting. If Ollie looks cheerful, Stan grins broadly; if Ollie looks unhappy, Stan is plunged into gloom. He always *overreacts*. The unconscious mind is Stan, and it takes its cues from Ollie. The psychiatrist Viktor Frankl tells a story of how prisoners at Auschwitz were moved by train to Dachau. The journey took three days, during which time they were frozen and halfstarved. At Dachau they had to stand in the freezing rain all night because someone had missed the rollcall; and yet, Frankl said, they were all relaxed and happy, laughing and joking, *because Dachau had no incinerator chimney*. This is an example of the sustaining power of the unconscious. Ollie grins broadly because Dachau has no incinerator, and Stan positively dances with delight. Here we have an immensely powerful 'feedback'

mechanism, capable of explaining all *neurosis*—and perhaps a great deal of physical illness too. The unconscious is nothing less than our *vital support system*. Yet it responds to suggestions from the conscious 'self'. Freud, it seems, failed to recognize this, and went on to create his own essentially sexual theory of *neurosis*.

Now it is fairly easy to accept that the unconscious mind can produce 'psychosomatic' effects, like phantom pregnancies and miracle cures; but it is altogether more difficult to see how

Page 582

it could produce 'psychokinetic' effects, like causing a table to waltz around the room.

The question begins to seem a little less baffling if we clear up certain linguistic confusions. For example, as soon as we ask, 'Why should the unconscious mind possess powers that the conscious mind doesn't possess?', we see that it is not a question of the mind 'possessing' anything. *I* possess

certain powers—for example, I can waggle my toes. In the same sense, I also possess*consciousness; it is an attribute, or power. The term 'unconscious' seems to refer to another area that includes intuitions and buried memories; by the same rules of grammar, one assumes that it is also one of my 'possessions'.

If (for the sake of argument) we assume a central 'I' or self, which is responsible for acts of will, we can also see that these acts can be more or less 'conscious'.

Digestion and breathing seem to involve an unconscious form of will; they certainly take place without my conscious volition. The kind of will involved in urinating seems to be partly conscious, partly unconscious; I apparently control the mechanism, yet if it is inhibited by nervous tension there is very little I can do about it.

The 'unconscious theory' of psychic phenomena suggests, quite simply, that the 'I' possesses powers of psychokinesis: the ability to move physical objects through an unknown form of energy. Recent experiments in psychokinesis involving such 'psychics' as Nina Kulagina and Felicia Parise would seem to indicate that even the conscious will is able to exert a slight degree of psychokinetic force—enough to move very small objects. The implication, apparently, is that, once again, the unconscious will is far more powerful.

There is, of course, no agreement about the nature of the force involved. Professor John Taylor is on record as believing that it could be analogous to radio waves.

Most 'psychics' are inclined to feel that this is too simplistic. One obvious objection is that simple physical models cannot explain other paranormal phenomena such as precognition. *If* it is possible to have precognitive glimpses of the future—for example, in*dreams, as recorded by J. W.*Dunne—then there must be some sense in which the future has already taken place; moreover, there must be some part of the mind—or self—that exists 'outside time', and is capable of 'scanning' these future events. Common sense cannot suggest a 'model' to explain precognition; it can only flatly deny that such a thing is possible. Yet there are as many wellauthenticated cases of precognition as of telepathy, psychokinesis, or second sight. If time is so radically different from our conceptions of it, then the same may apply to space, and Professor Taylor's attempts to provide models for psychokinesis may be, at the very least, irrelevant.

The basic question, clearly, is of the nature of the 'I' to whose common sense we so frequently appeal. This commonsense 'I' is my measure of the possible; if he tells me something is nonsense, it is almost impossible not to be convinced. Yet experiments in brain physiology (see Sperry, 1970) have shown that this confidence may be misplaced. The right and left sides of the brain are virtually two different personalities or selves, the left side controlling language and logical functions, the right side concerned with intuition and insight. When the nerves connecting them are severed, the right side of the brain knows nothing of what the left side is doing. (See SPLIT

BRAIN AND THE MIND.) A patient who is shown an obscene picture in the left half of his visual field (which is seen by the right side of the brain) shows signs of embarrassment. Asked why he is

blushing, he replies truthfully: 'I don't know.' The 'I' who responds is the 'talking I'; yet he considers himself the rightful occupant of the head—in fact, the only occupant. Yet the intuitive half of the brain has just as much reason for regarding itself as the seat of the 'legitimate I'.

All of which raises the obvious speculation that when we speak of the 'unconscious', we are actually speaking of this right side of the brain (or of the 'I' who inhabits it).

But this conveniently simple picture of a 'dual self' is brought into question by the widely observed phenomenon of multiple personality—studied, for example, by Freud's great contemporary Pierre*Janet. (See DISSOCIATION OF THE PERSONALITY.) This seems to suggest that we may all contain dozens of 'I's'. What is so startling about so many of Janet's case histories—and more recent ones like the famous 'three faces of Eve'—is that the same body or brain appears literally to be taken over by distinct personalities, like a car with several drivers. And Janet noted that, in most of these cases, the personalities can be arranged in a hierarchy, with the maturest at the top, the most rudimentary at the bottom. The picture that seems to emerge is of a kind of 'ladder of selves', in which the person we call I is merely the rung of the ladder on which my conscious awareness happens to be resting at any particular moment in time. C. G.*Jung even made the startling suggestion that the person into which we may eventually evolve—if we live long enough—may be already present from birth.

Devising methods to test such theories raises, of course, methodological problems. In science, the basic aim is to *observe* as accurately as possible, then to try to interpret the observations. It is important not to allow 'interpretation' to sneak into the act of observation, for we all know how easy it is to distort conclusions by allowing them to embody expectations. If parapsychological phenomena—or some of them—originate in acts of unconscious will, then it looks as if the mind is already involved before it starts observing.

Here, at least, the answer may be close to hand. There *is* a philosophical method aimed at preventing unconscious prejudices from slipping into the perceptual processes; its creator, Edmund*Husserl, called it transcendental*phenomenology, and its basic recognition is that *all* acts of perception are 'intentional'. (See INTENTIONALITY.) If present

Page 583

trends in parapsychology are anything to go by, the next generation of investigators could do worse than take a course in Husserlian philosophy.

It would, no doubt, be an exaggeration to say that parapsychology is at last entering its 'Newtonian' phase, when masses of disconnected observation can be unified by a single theory. But it is worth bearing in mind that*Newton arrived at his theory by asking the right questions. At least parapsychologists like A. R. G. Owen, who conjured up Philip, seem to have stumbled on some of the right questions.

PARANORMAL PHENOMENA IN ANCIENT GREECE. Modern investigators and practitioners of so-called paranormal phenomena feel themselves to be operating in a dubious but exciting fringe area of human experience. In ancient Greece, many objectively similar phenomena were embedded in the traditional religious structure, and were thus, until that structure came into question, quite differently perceived. A translation intended to convey in Greek the content of the modern term would introduce the notion of the gods, and would therefore exclude the notion of supernormality, the gods being part of normal experience. Greece's most important and respected centralized religious institution, the oracle at Delphi, operated by trance mediumship. The priestess, an uneducated woman, seems to have entered an autosuggestive trance induced by prescribed ritual acts, and in this condition—which was understood as possession by the prophetic god Apollo—to have answered the questions put to her. There followed some degree of editing and interpretation by the temple priests. Two typical features of the finished responses, their verse form and notorious ambiguity, may reflect an occasional (or original) practice of the priestess, but in the majority of cases were probably due to the priests. Trance mediumship was also practised at various other oracles, and by the less respectable marketplace prophets known as 'words in belly'. The normal Greek word for prophet seems to derive from the verb 'to be mad', in reference to ecstatic trance. Unlike the modern medium, the ancient trance prophet sought contact with the gods, not the dead, and his aim was the practical one of securing prophecy or advice.

Other paranormal prophetic states are less important in Greek culture. Divination by mirrorgazing (the mirror functioning like the modern crystal ball) is probably referred to by Aristophanes in the fifth century BC; subsequently, watergazing seems, under Oriental influence, to have become more popular. We may perhaps recognize the widespread phenomenon of glossolalia in two isolated references, one to an oracular priest who answered a foreign enquirer in his own language, the other to priestesses credited with a universal gift of tongues.*Socrates was guided by a divine voice that always dissuaded him from action and never instigated it; like most things about Socrates, this was an exception, an enigma to the Greeks themselves.

Oracular practice was of course founded on the belief that knowledge of the future, or of distant contemporary events, was obtainable; but such knowledge was attributed to divine revelation, not telepathy, clairvoyance, or precognition on the part of humans. Some moderns might wish to reinterpret in these terms certain phenomena that were claimed by the ancients as proof of divine power—prophecies successfully delivered before the enquiry had been voiced (priestess's telepathy), for instance, or the dream revelation of a lost person's location (dreamer's clairvoyance); unfortunately the evidence for the phenomenon will seldom bear much weight.

This is equally true of the relatively few early cases where a man rather than a god is explicitly credited with these powers. We do, however, find interesting theories of paranormal psychic powers in certain accounts of the dream that attempted to preserve its veridical character while excluding divine intervention (see DREAMS IN

ANCIENT GREECE). It was argued either that the dreamer received images or vibrations from the person or object he dreamed of, or that the soul exercised special powers while released from the trammels of the sleeping body. Stoic philosophers add an explicit explanation of precognition (as distinct from clairvoyance): it is the soul's inference from perceptible present causes of future events. Such subtleties are, of course, very far removed from popular religion. In the early period, belief in direct divine revelation was so strong that mortals claimed to have experienced actual epiphanies of the gods, usually in wild country regions.

Popular stories told how those violently killed or improperly buried haunted houses or graveyards. There may be an allusion to a poltergeist in a speech of 400 BC, but the phenomenon is otherwise unattested throughout antiquity. The paranormal physical phenomena that are reported are, in general, cult miracles—the spring that regularly flowed with wine at a festival of Dionysus, doors flying open at the (invisible) approach of a god, and the like. But to collect all the paranormal feats Page 584

attributed to gods would be an endless task, because gods by definition perform with ease tasks impossible for men.

PARAPSYCHOLOGY: A HISTORY OF RESEARCH. The term 'parapsychology' was introduced in the 1930s to refer to the scientific investigation of*paranormal phenomena—in particular the allegedly extrasensory powers of the mind (see EXTRASENSORY PERCEPTION). Previously this interesting but highly questionable area of science had generally been described as 'psychical research'.

Man has always been fascinated by the possibility that his mind may be capable of exercising unusual powers not apparently linked to the physical senses—telepathy, the capacity to see the future, etc.—and it has to be admitted that mythology, religion, and much of art and literature are on his side in this

respect. Furthermore there exists a great body of anecdotal evidence and personal testimony to the effect that such powers exist—almost everyone has had an experience which could be interpreted as having been telepathic, and most people have listened to friends or relations giving superficially convincing accounts of precognitive dreams they have had or of paranormal occurrences that have changed their lives. The history of psychical research or parapsychology in fact reflects the attempts of three or four generations of scientists to convert this intriguing anecdotal material into something more tangible—specifically to trap it in the laboratory. Throughout the course of this history, there has been a continuing shift of emphasis in the focus of research, but for the sake of simplicity it can be conveniently divided into three overlapping phases or periods: spiritualistic research, psychical research, and modern parapsychology.

Spiritualistic research. (See also SPIRITUALISM.) The great achievements of nineteenth-century science seemed to be unfolding a picture of a universe of a depressingly materialistic kind, a vast and rather pointless cosmos made up of tiny billiardballs known as atoms and with no trace of souls or spirits. But most Victorian scientists brought up in the ethos of orthodox Christianity were expected to believe in the reality of an immortal, nonphysical soul. For this reason a substantial body of them became involved in the minority religion of spiritualism, taking the line that if souls or spirits survived the death of the physical body then these spirits must exist *somewhere* in the universe, and should, in principle, be contactable. This remarkable period of science saw some of the outstanding brains of the time—the physicists Sir Oliver Lodge and Sir William Crookes, the Nobel prizewinning biologist Charles Richet, the anthropologist Alfred Russel*Wallace, and numerous others of equivalent calibre—solemnly attempting to induce spirit forms to materialize in their laboratories. No better testimony could be offered of the simple logic and unbounded optimism of Victorian scientists, but their unbridled enthusiasm for their findings led other, more critical and sceptical colleagues to conduct their own experiments. The result was that medium after medium was exposed as fraudulent, the pioneers were shown up to be gullible, incompetent, or both, and this phase of psychical research, which had fleetingly looked as though it might have almost revolutionary importance, came to an inglorious end. Crookes, Lodge, Wallace, and others, having committed themselves to spiritualism, not unnaturally remained steadfastly loyal to it, but by 1900 scientific interest was moving away from seances and was concentrating on 'more plausible' aspects of the paranormal.

Psychical research. Put quite simply, the second phase was the era of the 'ghost hunter', a period when scientists and affluent amateurs turned their attention to such phenomena as manifestations in haunted houses, poltergeist activity, demonic possession, apparitions, premonitions, and other such spectacular and supposedly paranormal events. It also included a large number of casual studies of telepathy and precognitive dreams. The openminded, amateurish, and 'gentleman scientist'

approach of the time is epitomized perhaps by J. W.*Dunne's book *An Experiment with Time*, an influential work, which plotted the author's *ad hoc* investigation into his own dreamlife and its supposedly precognitive content. Almost equally representative were the popularized investigations and writings of Mr Harry Price, who made a decrepit Suffolk rectory worldfamous as 'The Most Haunted House in England'. Price's research findings, and indeed those of all amateur, nonquantifiable psychic investigations, took a heavy blow when he was exposed by members of the Society for Psychical Research for faking phenomena at Borley. Since then (he was exposed in 1955)

it is probably true to say that 'ghost hunting' is no longer considered to be anything much more than crank or fringe science.

Modern parapsychology. The third phase was ushered in by the opening of a special university department devoted to the investigation of ESP at Duke University in North Carolina. The department was headed by a young biologist, Dr Joseph Banks Rhine, who, much influenced by the great British psychologist William McDougall, was convinced that the supposedly paranormal powers of the mind were essentially psychological phenomena, and should thus be investigated with the tools of traditional psychological research. The failure of the pioneers of psychical research to achieve anything concrete he assumed to be not because they were investigating ephemera, but because they had not attempted to quantify the

Page 585

phenomena they were supposed to be studying. Throughout the 1930s, therefore, Rhine and his coworkers embarked on a lengthy series of quantifiable experiments, mainly using decks of specially designed cards (Zener cards) for the ESP tests, and automatically thrown dice for the psychokinesis (PK) tests. The admirable rationale for these studies was that they allowed the experimenter to compare the results achieved with what would have been expected by chance. For example, in a deck of twentyfive cards containing five each of five distinct symbols, one would expect, on average, five to be guessed right 'by chance'; persistent deviations above chance over a long series of trials would suggest that the guesser was receiving some information about the test cards. This in turn would imply that if the experiments had been so rigorously controlled as to exclude all normal or known sensory cues, then the information must be coming via 'extrasensory perception'.

Rhine's early results in fact yielded just such sustained 'abovechance' scores and he swiftly claimed that he had established ESP as a legitimate phenomenon, or set of phenomena. As might be expected, however, his claims were met with considerable opposition from the psychological establishment. Were his subjects physically completely isolated from the experimenter so that information could not be passed over unwittingly—for example, by unconscious whispering or other nondeliberate cues? Were checks on the data and records precise enough to ensure that minor errors were not made, either unconsciously or deliberately, to bias the results in a proESP direction? To do him justice, Rhine tightened up his procedures on both these accounts—separating subject and experimenter in different buildings, for example, and arranging independent verification and analysis of the results. As a consequence, the abovechance results became rarer, but still remained sufficiently common for them to constitute apparently inarguable evidence for ESP. But then came another, and more fundamental, criticism. When psychologists not committed to a belief in ESP attempted to repeat the Duke findings in their own laboratories, they simply failed to come up with any positive results. The Duke team replied with more sets of positive findings, but the critics again failed to replicate them. Aware that this nonrepeatability was a cardinal weakness in their armour, the parapsychologists came up with the ingenious argument that a significant factor in ESP might be the attitude of the experimenter to the phenomena; if he was inclined to be unduly sceptical or dismissive, he might have a 'negative effect' on the results. This is a plausible but also a glib argument which seems to imply that only those who believe in ESP are fitted to investigate it—a point of view which cuts across the main spirit of

scientific research. More recently, however, parapsychology received a severe blow when the director of research at Rhine's laboratory (Rhine had himself retired) was caught flagrantly modifying experimental results to provide proESP

data, thus offering up to the critics of parapsychology evidence for an argument they had frequently advanced in the past—that no researcher, however distinguished, can be exempted from suspicion of fraud, minor or major, in this controversial field. Since this rather cataclysmic exposure, new evidence has appeared which seems to imply that one of the most distinguished British parapsychologists, Dr S. G. Soal, was also guilty of falsifying data in a key experiment. (See PARANORMAL

PHENOMENA: THE PROBLEM OF PROOF.)

At the time of writing, it looks as though the third phase of research in this area is coming to a close without parapsychology having demonstrated ESP to the general satisfaction of science. Indeed there appears to be a swing back to the study of poltergeist phenomena, paranormal healing, and the spectacular claims of Uri Geller and others, almost as though the failure of the strictly experimental approach has been implicitly recognized and agreed upon by all workers in the field. In sum, while it is true that many feel that parapsychology or psychical research is still a legitimate area of study, most scientists who have studied the topic in any depth are inclined to the view that a hundred years of fairly dedicated research has yielded disappointingly little in an area which should have offered great riches.

C. E.

PARAPSYCHOLOGY AND THE MINDBODY PROBLEM. The scientific study of the*paranormal, originally 'psychical research' but nowadays generally known as parapsychology, is, historically speaking, a product of the conflict between science and religion that came to a head in Victorian England. It was then that the belief in an immaterial soul that animated the body when alive and survived its dissolution at death, which had been so central to most of the world religions, had to contend against an increasingly selfconfident scientific materialism. The new psychophysicists and experimental psychologists who followed in the wake of Hermann von*Helmholtz were particularly anxious to explain behaviour in terms that did not require the intervention of any kind of inner occult entity. Moreover, the*Darwinian revolution, which stressed the continuity of living things, seemed to make nonsense of the idea of an immortal soul that was the special prerogative of man, as*Descartes, who is credited with formulating the mindbody problem in its classic form, had taught.

The group of scientists and scholars who came together in 1882 to found the Society for Psychical Research in London, of whom Frederic*Myers was, perhaps, the most important in this connection, were all acutely aware of the materialistic implications of contemporary science and were no less convinced of the futility of trying to counter it with a reaffirmation of the dogmas of revealed

religion. They believed, however, that it might still be possible to defend the autonomy of mind, as distinct from brain, if the objective methodology of science were to be deployed in the study of so-called paranormal phenomena. These phenomena, which defied a conventional scientific explanation, had been part of popular belief down the ages and, later, after the rise of *mesmerism and then *spiritualism, had been reported as occurring under controlled conditions. From the start, two classes of paranormal phenomena were recognized: (i) the parapsychical, which meant, originally, manifestations of physical mediumship such as the levitation of objects and the materialization of human figures, or else the effects observed in the course of poltergeist disturbances, and (ii) the paracognitive, which meant the awareness of external events otherwise than via the known sensory channels, i.e. telepathy, clairvoyance, precognition, etc. Later, when, under the influence of J. B. Rhine, statistical type tests became the standard method of studying the phenomena, the former class came to be subsumed under the heading of PK (psychokinesis) and the latter under the heading of ESP (*extrasensory perception), the two together being technically referred to by the generic term 'psi'.

Of particular importance to the pioneers of psychical research, and especially to Myers, was the search for proofs of survival, usually by examining ostensible communications from the deceased received through a medium. Had such proofs been forthcoming, nothing could well have afforded a more absolute vindication of a full-blown dualist solution of the mind-body problem, but this was not to be. At most it could be claimed that the simplest interpretation of the evidence demanded the survivalist hypothesis—yet, paradoxically, the greater the success of the psychical researchers in adducing evidence for the various paranormal powers of mind, the more alternative possibilities they opened up for reinterpreting the survival evidence. At all events, at the present time, the problem of survival is a peripheral rather than a mainstream concern of parapsychologists.

From the standpoint of the mind-body problem, perhaps the two salient features of the 'psi process' are, first, that it does not appear to be governed by constraints of space, time, or material screening such as delimit normal physical communication and, secondly, that it appears to achieve its results with an immediacy that suggests some kind of teleological rather than mechanistic causation. According to one current theory, proposed by Thouless and Wiesner (1947), psi is to be understood as an extension, directed on to an external target-system, of a power which, normally, we use to control our own brain when engaged in ordinary perception or in voluntary movement.

It should not be thought, however, that all parapsychologists are necessarily committed to a dualist interpretation of the mind-brain relationship. At the present time especially, many exponents prefer to think of psi as essentially a function of the brain, or of some special brain-mechanism or process. The importance of parapsychology, as they see it, lies not in the vindication of a dualist metaphysic, but in the extended scope of physics which it suggests, so that, eventually, what we now refer to as paranormal will be understood as no less lawful or physical than any other natural phenomenon. Recently a number of physicists who have been attracted to the field have been attempting to build a theoretical bridge between psi phenomena and one possible interpretation of quantum theory. Whether or not their efforts will prove fruitful, it could be a mistake to suppose that parapsychology as such, any more than any other body of empirical knowledge, could ever settle the philosophical issues raised by the mind-body problem.

Nevertheless, just as certain facts inevitably strengthen the plausibility of a materialist interpretation, so other facts, if accepted, would tend only to enhance the plausibility of a mentalist interpretation. The position which could, probably most fairly, be described as the current orthodoxy in philosophical circles of the Englishspeaking world is to accept some variant of the 'mindbrain identity thesis', the view that mental events and processes are no more than a particular aspect of brain events and processes. This view draws its empirical support partly from the achievements of the brain sciences, especially with regard to the detailed effects of brain lesions on mental functioning (see NEUROPSYCHOLOGY), and partly from the new sciences of*cybernetics and*artificial intelligence which seek to demonstrate rational and purposeful behaviour in machines. Indeed, the computer analogy which now dominates cognitive psychology has created a conception of man as an informationprocessing system which has become the mainstay of the modern materialist view of mind. On the other side, parapsychology alone can provide empirical support for the transcendent view of mind. So long, however, as the parapsychological evidence is open to question, the contest is bound 'to be an uneven one. It is an astounding fact that, a century after the founding of the Society for Psychical Research, there is still a total lack of consensus regarding the actuality of any parapsychological phenomenon. (See PARANORMAL PHENOMENA: THE PROBLEM OF PROOF.)

PARIETAL CORTEX. The region of cerebrum between the frontal and occipital lobes, and above the temporal lobe. Associated with stored information, mechanisms mediating language, and learning and memory, it is a key region for human intelligence. See NERVOUS SYSTEM.

PARKINSONISM is the name given to a syndrome, or characteristic set of symptoms, shown by patients with lesions to certain subcortical areas of the brain. From the patient's point of view the main complaints are of involuntary tremor in the limbs together with a difficulty in initiating and controlling voluntary movements, and some general changes in posture, mood, and level of activity. There is no pain, little loss of sensation or awareness, and the mental state often remains well preserved.

From the scientific point of view Parkinsonism is of interest because of the insight it gives into the processes involved in translating thoughts and intentions into the appropriate actions for their overt expression. It produces a number of behavioural changes stemming from a disruption of the brain mechanisms that mediate these processes.

Originally called the 'shaking palsy', the syndrome was first described by the surgeon James Parkinson in 1817. Nowadays it is termed 'idiopathic paralysis agitans' in recognition of its status as a naturally occurring degenerative disease of the nervous system of late middle or old age, and of its main features of impaired voluntary movement and a noticeable, continuous, induced shaking of the limbs at rest. The disease has an insidious onset, and there is a tendency for the patient's condition to deteriorate slowly, but it may remain stable for long periods. This is Parkinson's disease proper, for which no cause is yet definitely known—it is almost certainly not hereditary, but no definite link has been established with any slow virus, dietary deficiency, chemical toxin, or other suggested environmental cause.

The characteristic features, however, may occur as 'symptomatic Parkinsonism' in adults of any age as a result of a wide range of damage to the brain, including metal poisoning, anoxia (oxygen deficiency), strokes, certain drug overdoses, and infections. One special instance of the last category was the epidemic viral disease of the 1920s called 'encephalitis lethargica', which is often held to be the cause of a certain kind of Parkinsonism in that generation. Recently a dramatic series of cases occurred in California in young heroin addicts who injected themselves with a designer drug containing the toxic sideproduct MTPT, which destroys the same cells in the brain as are affected in idiopathic Parkinsonism.

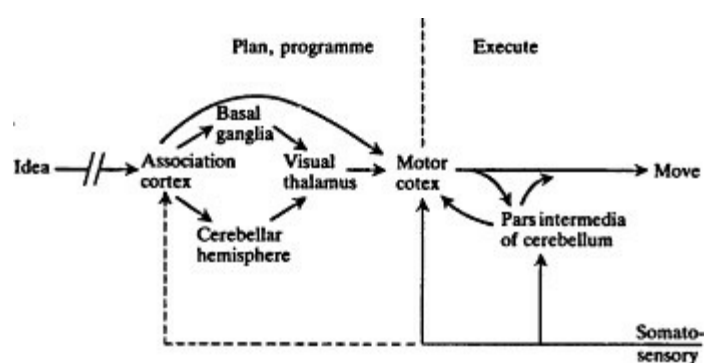

The main defining features of Parkinsonism involve the motor system, and comprise *tremor* of the limbs at rest, a relatively slow repetitive oscillation which disappears during sleep or deliberate movement; *increased rigidity* of the limbs to passive movement; and *akinesia*, an impairment of the

voluntary control of movement. Other symptoms which may be associated with these include difficulties in maintaining or adjusting posture; difficulties in walking steadily or with normal size steps; an immobile facial expression; loss of strength in and modulation of the voice; eye movement abnormalities; and an inability to get up out of a bed or low chair without help. The disease in fact affects all the forms of action, communication, and expression by which we interact with the environment and with each other.

In all Parkinsonian disorders the parts of the brain affected are groups of cells lying in the centre and at the base of the forebrain—the *basal ganglia*. These nuclei have extensive and complex connections, and form part of several circuits through different levels of the brain. Neural activity in these circuits involves the neurotransmitter dopamine, whose progressive depletion underlies the disease, at first disrupting, and ultimately blocking, transmission through the pathways. A number of drug therapies are now available to patients to help them regain biochemical balance in the system and restore normal movement.

Pathways through the basal ganglia include some to and from the *autonomic nervous system* (which controls bodily functions), the cortex, and the limbic system. So it is not surprising that other symptoms often associated with the disease include autonomic changes such as excessive sweating or trouble with digestion; cognitive changes, with impaired memory and thinking ability; and personality changes, most notably depression and lethargy or increased irritability. Although the latter may be a reflection of the patients' reaction to their impaired movement or embarrassing tremor, some observers think that they stem directly from the effects of the disease on the working of those circuits in the brain concerned with an individual's cognitive and emotional state. On this view Parkinsonism has a widespread effect on behaviour, and may be seen as a neuropsychological and neuropsychiatric disease.

Motor symptoms: the role of the basal ganglia in movement. While tremor is obvious and

Page 588

embarrassing, the impairment of voluntary movement is the disabling symptom of Parkinsonism. In its extreme form, untreated, it results in an immobile 'frozen' state where the patient remains fixed in a catatonic, typically crouching, posture. Even mild cases sometimes experience 'freezing' when walking or shifting posture.

More often, however, the mild form results in a subtle disturbance of movement, involving both a

retardation in initiating movements (akinesia) and slowness and clumsiness in carrying them out (bradykinesia). There is an obvious lack of control, with patients complaining that their hands and fingers 'won't do what I tell them to'.

Movements are slow and appear uncoordinated, as if the patient has lost the art of automatically performing familiar skills and has to think about and monitor his actions all the time as he carries them out. But the limbs are not numb, nor paralysed, although the grip may be weak and writing become small and spidery. When doing things slowly movements may be reasonably accurate, and visual control is still precise enough to allow fine adjustments of the fingers—patients who continue (on a good day) to mend watches or carve wood have been known. Moreover the muscles themselves, and their immediate control from the motor cortex (see Fig. 1) are still intact, because they respond normally to direct stimulation.

Thus the components of movement appear to be intact in Parkinsonism, but patients have difficulty in coordinating them so as to produce effective actions. There is a dissociation of some kind between thought and action, suggesting that the basal ganglia play a crucial role in the neurological systems that underlie perceptual motor coordination. Parkinsonism disrupts the process at the very centre where the orders for movement are formulated; the patient's difficulty stems from faulty instructions being sent to the motor system, rather than from the motor system responding inaccurately.

Recently, anatomical studies have shown that the basal ganglia provide a connecting link between those areas of the brain mediating thought and those directly initiating movement. They receive inputs from the association cortex of the forebrain (frontal and parietal areas especially) and send their main outputs to the motor cortex and the red nucleus which innervate spinal motor neurones. In this respect they are similar to the cerebellum, another structure known to be concerned with the control of movement. The two subcortical areas are in fact connected in parallel between association and motor cortex (Fig. 1).

On this model it may be postulated that the idea or initial plan for a movement takes place in the cortex, that this is passed on to the basal ganglia and cerebellum where some kind of 'programming' of orders for the contraction of muscles takes place, and that these are then passed on to the motor cortex for transmission to the muscles. The subcortical structures may thus be a kind of 'general staff' of the motor system, organizing the force, duration, timing and coordination of various kinds of movement.

This physiological model reinforces the notion of the basal ganglia and cerebellum as interface mechanisms between cognitive and motor systems of the brain, providing the means by which general intentions and ideas for action are translated into specific programmes of movement for their fulfilment. If either is damaged, therefore, connections through one pathway will be impaired, but those through the other will still be intact. So patients will not be paralysed, but will lose some aspect of control according to the function disrupted by the lesion. Exactly how the two structures divide control is not known, but there are several possibilities. Some workers have suggested that each is concerned with a different kind of movement (the cerebellum generating visually controlled and the basal ganglia proprioceptively controlled movements); others that each controls a different parameter of movement (for example, the basal ganglia determining the strength to be put into a

muscle contraction while the cerebellum regulates its spatial position or timing). These, and other, possibilities are open to experimental test—showing that the disturbed nervous system may be a good proving ground for theories of how the normal system works.

Experimental investigations of Parkinsonian movement, by the author and others, have found

Fig. 1.

The pathways concerned in the planning,
execution, and control of voluntary movement.

Page 589

that Parkinsonian patients asked to hit a visual target with hand or arm movements from a stationary startingpoint have difficulty executing quick, largeamplitude aiming movements which are preprogrammed and executed as discrete units (ballistic movements). They can, however, perform small or slow movements under continuous visual correction reasonably well. Patients with cerebellar action tremor show just the reverse. Parkinsonian subjects tend not to increase the amount of force they put into largeamplitude ballistic movements appropriately, so that their movements undershoot the target point (hypokinesia) and are more erratic. Similar dissociable effects between 'ballistic' and visually guided movements have been found in monkeys who, in an experiment, track a target while output from either the basal ganglia or cerebellum is temporarily inactivated by cooling. These features may underlie the slowness and clumsiness in executing movements which characterize bradykinesia in Parkinson's disease.

If bradykinesia reflects a difficulty in programming individual muscle actions appropriately to achieve an intended movement, akinesia reflects a difficulty in the accurate selection and initiation of responses, that is, in the formation and implementation of 'motor plans'. This is the point at which a general decision or intention is specified as a particular set of actions to achieve item computer terms an 'algorithm' for movement. Often it involves switching in a repertoire of welllearned sequences of movement (as in playing scales or chords on a piano) but it may involve assembling new patterns and sequences for the immediate task in hand. It also involves timing (when to start and stop movements) and whether to control movements through vision, touch, or proprioception—or without*feedback—in short, what strategy to adopt to achieve the goal originally set.

There is some evidence that Parkinsonian patients lose their facility in such higherlevel aspects of a motor plan. They are slow in initiating movements of any kind, even when not aiming at a target but just responding to a signal as quickly as possible. They take longer to switch from one movement or movement sequence to another, even when using different limbs where there is no overlap of musculature involved. They have difficulty doing two things at once, and in running off rapid sequences where they cannot monitor each movement separately. They sometimes 'freeze' while walking or getting up out of a chair, as if unable to coordinate and synchronize an action involving several groups of muscles. They have difficulty tracking a continuously moving target on a screen if

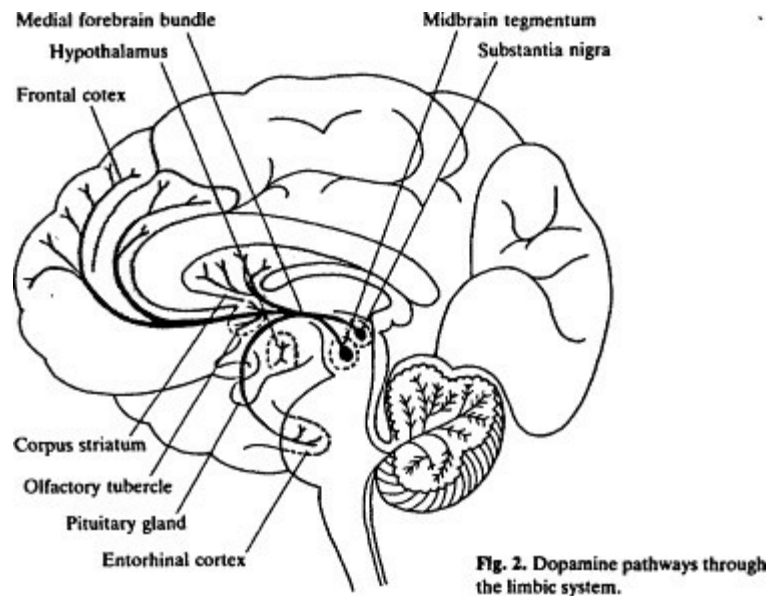

the target disappears for even short periods, as if they need continual visual information to initiate successive actions. (Tremor patients carry on through such gaps in visual data quite well.) And they tend not to make use of any available advance information about impending movements to reduce their reaction time or events, as normals do, as if the initiation of movements has to be done from an external trigger signal, Parkinson subjects being unable to begin them spontaneously.

Such rather curious Parkinsonian characteristics suggest that the basal ganglia are especially involved in the assembly, selection, and triggering off of sequences of action, which explains why Parkinsonian subjects may tire quickly with repeated movement, be unable to do two things at once, or find difficulty in switching from one action to another. The functions disrupted are at the transition point between cognition and action, and are central to the control of behaviour. It is not surprising, therefore, that Parkinson's disease affects other aspects of behaviour as well, both mental and social.

Cognitive and personality changes: the role of the basal ganglia in general behaviour. In his original definition of the disease, Parkinson specifically excluded mental changes, declaring 'the senses and intellect being uninjured'. Since then, many observers have disagreed with him, and associated Parkinsonism with dementia or other psychological disturbances. In this they possibly mistake the outward appearance of the untreated advanced stage, with its profound motor immobility and unresponsiveness, for an inner mental deterioration. Nowadays it is generally agreed that Parkinsonian patients may show impairments on a range of cognitive activities, and personality changes too. But their nature is not certain, nor what are the crucial underlying changes in the brain.

Some studies emphasize certain subtle perceptualmotor difficulties in Parkinsonism. The only sensory deficit reported is a slight blurring of vision, possibly due to a retinal dopamine deficiency; otherwise there seems to be little disturbance of the ability to register and identify sensory information. But patients are reported as showing perceptual difficulties in the ability to use sensory information to guide their actions, especially where this involves orientation in space. Thus they have been reported as showing deficits in locating parts of the body correctly from diagrams; in following a given route round a room from a map; in setting a tilted rod to the vertical with the body itself tilted; and in correctly copying or making up gestures with the arms. In all these cases, the difficulty appears to lie in keeping track of one's own movements so as to maintain one's orientation in space, and results from a loss of the reafferent information that one gets from one's own movements. But perceptual judgements of external objects and space are still intact.

Thus the Parkinsonian difficulty is not a cognitive deficit *per se*, but rather a deficit in the use of knowledge for action. It raises the intriguing possibility that motor and behavioural systems use a different sensory input from that, through the cortex, which underlies our conscious perception, so that one's actions may be initiated by signals and controlled by systems not directly amenable to

Page 590

Fig. 2.

Dopamine pathways through the limbic system.

awareness, which is a dissociation commonly found in motorskills learning and performance.

On standardized tests of intellectual function, Parkinsonian patients often do badly, but this is probably at least partly due to motor difficulties on timed tasks which require manipulation of materials. On many tasks of perception, memory, and reasoning, Parkinsonian patients show little deficit. Or they may have lower scores than normal without showing any qualitative differences typical of dementia, indicating rather a slowness in thinking (bradyphrenia). Where there is often a specific impairment is in what is termed mental 'set' (that is, the ability to choose one behavioural or mental strategy when several alternatives are available, and then either to maintain it or to switch to another strategy, as appropriate). This deficit in mental control parallels some of the motor difficulties described above, implying that the mental and motor effects of Parkinsonism are similar.

Some years ago, attention was drawn to the existence of ascending dopamine pathways through the basal ganglia from cell bodies in the reticular core of the brain to forebrain areas, especially the prefrontal cortex and the limbic system of the temporal lobes (Fig. 2). Disturbance of these diffuse projections might well interfere with the activity of the innervated structures, producing cognitive impairments, or emotional changes respectively. There are several theories of this kind.

(i) *Parkinsonism and dementia as diseases of a common core.* According to this theory, a loss of neurones in the reticular core of the brain will at first produce symptoms appropriate to whichever structure first loses its input. As neuronal losses increase, symptoms typical of other diseases of old age (dementia, depression, and Parkinsonism) will appear as all three systems are affected. This theory is supported by a number of anatomical and biochemical studies showing similar neuronal changes in Parkinsonism and dementia, and clinically there is often overlap of symptoms too. But not all advanced Parkinsonian patients show signs of dementia, so the overlap may be coincidental.

(ii) *Loss of arousal*. On this theory, ascending projections through the basal ganglia are necessary to activate or initiate cortical activity. Loss of this facility means that patients show lethargic thinking and behaviour because they lack arousal, resulting in inefficient mental activity, although the mechanisms of thought, memory, and thinking are themselves still intact. Undoubtedly lethargy and a lack of spontaneous activity are often observed in Parkinsonism, particularly in the advanced stages, and increasing motivation can improve performance (although it does not always do so).

In the past, advanced cases deteriorated into a 'frozen' state of rigid immobility and unresponsiveness to external stimuli. The discovery in the 1960s of drugs which rectified the biochemical deficiency of Parkinsonism led to dramatic increases in the level of spontaneous activity, even in longstanding catatonic cases. The effect has been appropriately described as 'awakening' by Oliver Sacks (1973) in a vivid and moving account.

(iii) *Frontal syndrome*. This theory proposes that Parkinsonian patients show behavioural effects similar to those of frontal cortical damage, that is, personality and behavioural symptoms rather than loss of intellectual capacity and awareness. The mental set effects described above would fit this description, as would other observations of such frontal signs as perseveration—being unable to

Page 591

change an adopted strategy or sequence of behaviour if conditions change during a task, as for example, in perceptual adaptation or on tasks where the requirements or rules change on different trials. The theory emphasizes the close mutual interconnections of parts of the basal ganglia with prefrontal cortical areas, and it is likely that cortical and subcortical areas of the brain work together as an integrated unit, such that disruption at any point in the circuit impairs the function of the whole.

An extension of this theory attributes the personality changes often found in the disease (notably depression and irritability), as well as the autonomic changes, to basal ganglia connections with the*limbic system. The limbic system is a complex circuit of pathways connecting up structures on the inside borders of the cortex with central structures in the brainstem and cerebrum, and is often described as the cerebral mechanism of emotional behaviour. Parts of the frontal lobes form an important link in this circuit, so frontal symptoms might well be accompanied by disturbances of mood and personality. Some authorities, therefore, describe Parkinsonian behavioural changes as frontallimbic dementia, or subcortical dementia, to distinguish them from senile dementia (Alzheimer's disease) with its global deterioration in memory, thought, and language.

Of particular interest is the finding that while a deficiency of dopamine is associated with Parkinsonism, overactivity in the dopamine system produces schizophrenialike behavioural effects (see DOPAMINE NEURONES IN THE BRAIN). This opens up the possibility that it is the biochemical status of the nervous system that underlies psychological and psychiatric changes in Parkinsonian patients and schizophrenics. It also holds out hope for the continued development of effective treatment, but as with studies of the biochemical basis of*schizophrenia, the exact relation

of the mechanisms of the nervous system to the characteristics of the mind remains elusive. Progress in this problem may well depend as much on advances in our understanding of the latter as of the former.

PASCAL, BLAISE (162362). French mathematician and philosopher. Brought up in Paris by his father to be a mathematician, he worked out for himself when 11

years old the first twentythree propositions of*Euclid, and at 16 published a paper on solid geometry that*Descartes refused to believe had been written by one so young. With his father he confirmed Torricelli's theory that nature does not abhor a vacuum—by carrying mercury barometers up a mountain and showing that the column of mercury varied in length. This finally disposed of Greek notions of air, pneuma, and the void. In 1642 he built the first metaltoothwheeled calculating machine, later to be developed by*Leibniz.

Pascal was also an influential Christian thinker. He contested the view of Descartes that human reason reigns supreme, arguing that it is unable to deal with ultimate*metaphysical problems. 'The heart has its reasons of which reason knows not.' His religious writings were published after his death as *Pensées* (1670; Eng.

trans. A. Krailsheimer, 1966).

PATTERN RECOGNITION has become the name of a technology that includes automatic

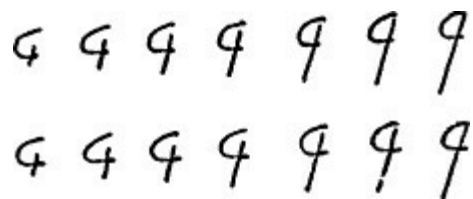

recognition and analysis of patterns by machines, and usually excludes the study of*perception in animals. (For pattern recognition by humans, see GESTALT THEORY; VISION: THE EARLY WARNING SYSTEM.) One of the uses of pattern recognition is in readingmachines; and since the 1920s many such machines have been patented. Although there is still no complete and definitive solution to the problem of making machines recognize characters, readingmachines with worthwhile though limited capabilities are commercially available and widely used. Their practical value arises mainly from their high speed of reading, which is typically in the range 200 to 1,000 characters per second.

Each of the 2s in Fig. 1 would be regarded technically as a somewhat different pattern. To 'recognize' a given numeral, a machine has to determine whether this numeral belongs to the class of patterns that are called '2' or to the class of patterns that are called '3', and so on. In this context, 'recognition' means 'classification'.

Clinically normal electrocardiograms are not always exactly the same, but instead are somewhat different waveforms, that is, different patterns. 'Recognizing' an electrocardiogram as 'normal' means assigning it to the class of patterns that are

Fig. 1.

Copies of 2s and 3s written by different people.

Page 592

considered normal. This general idea holds in many applications: for instance, a bloodpressure wave should be recognized as normal if it belongs to the class of normal waves. Fingerprints from the same finger may have somewhat different patterns due, for instance, to different pressures on the skin, yet these patterns should all be classified as belonging to the same finger.

In nuclear physics laboratories, machines that assist humans in the visual processing of events in bubbleandspark chamber photographs are required to do more than classify configurations of linelike tracks. Relevant configurations have to be picked out from a morass of irrelevant detail, and then not only classified but also measured. In metallurgy there are established applications in which a machine is required to find, count, and measure the area of many objects in a picture, but not to classify their shapes. Machines that check optically for cracks in glass, or fractures of bones in radiographs, or defects in printed circuits are attempting to recognize defects whose shape is not known in advance.

Machines which became commercially available in about 1976 for recognizing and counting the different types of white blood cell actually take account of colour and texture, as well as shape. Colour and texture are also often important in the automatic interpretation of satellite photography and

other remotely sensed imagery, and various techniques for recognizing (i.e. classifying) colour and texture have been devised.

The automatic analysis of television pictures of natural scenes and other three-dimensional compositions is known as computer vision. Computer vision may have as its source of data a single static monocular image, or a stereo pair of images, or a sequence of images of moving objects. Typical practical objectives are to determine three-dimensional disposition of surfaces, and possibly also parameters of motion. In computer vision, recognition—that is, the automatic assignment of names to objects—often appears less important than 'reconstructing' the scene from one or more visual images. It is not yet clear to what extent a scene can be reconstructed, particularly from a single image, without some kind of recognition of known objects.

The classical approach to the recognition of separate isolated objects has two stages. The first consists of detecting various attributes or features of patterns. For instance, the number of closed loops, the number of line-ends pointing roughly leftwards, and the number of junctions of lines might be chosen as features of written characters. The square of the perimeter divided by the area, and the diameter of the largest inscribed circle, might be among the chosen (orientation-independent) attributes of a blood cell. The ratio of light flux through a red filter to total light flux might be chosen as one attribute of colour; and variance of grey-level is a simple example of an attribute of texture.

If the attributes or features found in the first stage of recognition have numerical values, then the list of attributes can be treated as a vector. For instance, such vectors might be obtained from, say, 1,000 specimens of '2' and averaged. If the attribute vector obtained from a given character is sufficiently close to this average in multidimensional space, then the given character can be classified as '2' in the second and final stage of recognition. Many more sophisticated techniques of vector classification are explained in pattern-recognition textbooks.

Instead of detecting, in the first stage of recognition, a fixed number of attributes or features constituting a vector, *linguistic* systems detect variable numbers of features or primitives that constitute strings. The final stage of recognition now consists of classifying strings by the syntactic methods of Chomskyan linguistics (see LANGUAGE: CHOMSKY'S THEORY). There might, for instance, be at least one separate grammar for '2', one for '3', and so on; and a pattern would be classified as '2' if it were syntactically accepted as '2'.

In the progressions illustrated in Fig. 2, the distinction between '4' and '9' depends upon the proportions of lines that constitute a character. It has been usual to deal with proportions, in the first stage of recognition, by attempting to choose features that will remain almost invariant when a pattern is subjected to limited deformation.

Indeed the first stage of recognition ideally eliminates all unwanted variations of patterns (such as noise), but preserves distinctions between different classes. Careful design of the first stage has proved to be essential in the most successful of the vector-classification and linguistic-recognition systems.

Fig. 2.

Transition from 4 to 9 caused by lengthening the central upright stroke. In the lower row the transition may appear to occur further to the right because the horizontal stroke protrudes further rightwards.

The large literature reports cases where automatically selected features or attributes have proved more useful than randomly selected ones. Best of all, however, are features carefully chosen and worked out by humans using an intuitive trialanderror process.

In Fig. 1 there are many pairs of 2s such that one 2 looks like a distorted or deformed version of the other. Similarly, one clinically normal electrocardiograrn might look like a somewhat distorted version of another. Such limited distortions preserve positional relationships within some sort of tolerance. Relational matching techniques,

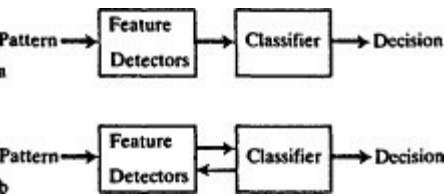

Fig. 3.

- a. Classical block diagram for pattern recognition.
- b. Block diagram in which there is a twoway exchange of information between the blocks.

which depend upon consistency of contextual constraints instead of relying only on judicious choice of features to deal with distortion, have a structure more like Fig.

3b than the classical structure shown in Fig. 3a. In Fig. 3b there is essentially an iterative interplay between the processes of classification and feature detection, these being best regarded as a single integrated monolithic process. Various systems that use context in recognition also have the Fig. 3b structure, and the recurrence of this structure is important because it shows the danger of presupposing, as many workers did unquestioningly in the 1960s, the optimality of the Fig. 3a structure.

In Fig. 1 there are some 2s and 3s that have almost the same top curve. Similarly, one can think of many pairs of words that contain the same letter, many pairs of sentences that contain the same word,

and so on. In general, processes of analysis and recognition may be facilitated by subdividing patterns hierarchically into parts, just as a map may be subdivided into countries subdivided into counties subdivided into parishes. In principle the recognition of parts may be easier than recognition of wholes, particularly if the parts are features that remain almost invariant when a pattern is subjected to limited deformation, as mentioned previously. In practice, segmentation, which is the business of dividing up a pattern into hopefully relevant parts, may be difficult or impossible to achieve reliably until *after* a pattern has been recognized as a whole.

When a pattern has been successfully segmented into parts, for instance when an aerial photograph has been partitioned into fields, lakes, forest, etc., the parts may have interdependences that cannot be overlooked. For instance, the angle of the sun may be similar for neighbouring parts of an aerial photograph. The dialect or accent may be similar for different parts of one spoken utterance; and characters written by one person tend to have similar graphology. Machines may not be able to compete with humans in pattern recognition without taking account of such dependences.

A more firmly established use of context in pattern recognition is in precluding combinations of objects that are known to be impossible (or very unlikely). For instance, if a machine reading English words classifies a fourletter word as QOIT, which is absent from the dictionary, then the machine should make a second attempt at classifying the individual characters, particularly the second. But some of the contextual techniques described in the massive literature do not yield enough practical improvement to justify their cost.

It is worth remarking that contextual knowledge can be useful in segmentation. If a pattern is segmented into parts that are subsequently classified, and if the combination of classifications of parts is known contextually to be impossible, then the pattern can be segmented differently, and the process repeated until contextually acceptable segmentation is achieved. Instead of relying on contrast to segment a pattern into parts as a preliminary step that precedes recognition, segmentation can be integrated with recognition by using knowledge of contextual relationships between segments. This can be regarded as an iterative process, more like Fig. 3b than Fig.

3a. Processes of this type have been developed for the analysis of pictures of outdoor scenes, using, for instance, contextual knowledge that sky should be above a mountain, not below it. In several speechrecognition systems (see SPEECH RECOGNITION BY MACHINE), lexical, syntactic, and semantic contextual knowledge is used in choosing between alternative possibilities in segmentation and in the early stages of classification. In these sophisticated systems, pattern recognition tends to fuse with*artificial intelligence. The design of these systems in which segmentation increases contextual knowledge, which improves segmentation, and so on iteratively, is mainly *ad hoc*.

There is a tantalizing possibility of using practical pattern recognition to clarify various philosophical problems. For instance, how can a machine recognize all triangles as a triangle without having a 'general idea' of a triangle that is 'neither oblique, nor rectangle, neither equilateral, equicrural, nor scalene, but all and none of these at once'? The problem of recognizing the 2s in Fig. 1 is like this, and one can seek in clear practical systems for some useful abstraction corresponding to a 'general idea'.

PAVLOV, IVAN PETROVICH (1849-1936), Russian physiologist. His importance for the study of animal behaviour is mainly due to his work on conditional reflexes; this work provided the basis for much of the subsequent research on learning. Pavlov also conducted significant research on the physiology of digestion and on neurosis.

Brief life. Pavlov was born in Ryazan, Russia, and attended the religious school and seminary there, where he studied natural science. He did not complete his studies, but entered St Petersburg University in 1870, where he continued to study natural science, and decided to make his career as a physiologist. After graduation in 1875, he went to the Military Medical Academy to pursue his research. He completed his doctorate there in 1883, and then went to Germany (1884-6), where he studied in Leipzig with Carl Ludwig, and in Breslau. In 1890 he was appointed professor in the department of pharmacology in the Military Medical Academy, and in 1895 he moved to the department of physiology. In 1904 he received the Nobel prize for his work on the physiology of digestion. He remained professor of physiology until 1925, when he resigned in protest against the expulsion of sons of priests from the Academy (he himself was the son of a priest, but would not have been expelled).

Initially Pavlov was outspokenly opposed to the Bolsheviks, even though they supported his research. In 1922 he asked Lenin's permission to transfer his research abroad, but was refused: Lenin wanted prestigious scientists. However, during the last few years before his death (in Leningrad) Pavlov increasingly accepted and approved of the Bolsheviks. From 1925 to 1936 he worked mainly in three laboratories: the institute of physiology of the Soviet Academy of Sciences (which is now named after him), the institute of experimental medicine, and the biological laboratory at Koltushy (now Pavlovo), near Leningrad.

Physiology of circulation and digestion. Pavlov held that physiologists should study 'the actual course of particular physiological processes in a whole and normal organism'. He also held that the main problems for experimental research were the mutual interactions of organs within the body, and the relation of the organism to its environment. The method of working on the whole, healthy body of an animal contrasted with the mainstream of physiology in the latter half of the nineteenth century; most investigations then were on isolated organs and prepared specimens.

Pavlov's work on the physiology of circulation (c. 1874-88) was mainly concerned with the mechanisms that regulate bloodpressure. His experimental animal for this, and for most subsequent research, was the dog. He was mainly interested in nervous mechanisms. He discovered, for instance, that the vagus nerve controls bloodpressure, and that there are four nerves controlling the heartbeat, which can vary the heartbeat's rhythm and intensity (work on the nervous control of the heart had formed his doctorate).

Pavlov's work on the physiology of digestion began in about 1879, and culminated in his book *The Work of the Digestive Glands* (1902, a translation of *Lektsii o rabotie glavnykh pishchevaritel'nykh zhelez*, 1897). He investigated the nervous mechanisms controlling the secretions of the various digestive glands, and how these nervous mechanisms were stimulated by food. He had to expose the

structures of interest surgically, and work on them in a healthy animal, so it was crucial to his success that he was also a brilliant surgeon. (Similar experiments had been attempted in the laboratory in Breslau that he visited in the mid 1880s, but had failed because the experimenters lacked Pavlov's surgical skill.) Once he had exposed part of the gut, Pavlov could directly insert food or chemicals, and observe the effects on the activity of the digestive glands. The method of sham feeding was a related development. A slit is made in the animal's throat so that food entering through the mouth falls out through the neck before reaching the stomach. The animal can be fed through a second opening made into the stomach. By sham feeding, Pavlov could observe the effect of food in the mouth on the secretion of digestive juices elsewhere in the gut; he found that the taste of food in the mouth causes the release of gastric juices in the stomach. A smaller quantity of juice is released if food is put directly into the stomach. Sham feeding has been used and developed extensively by later workers.

Pavlov's own theory for the control of digestive secretions postulated control exclusively by nervous mechanisms. Subsequent research has shown this theory to be incomplete: control by hormones also occurs. He made many other important discoveries while working on digestion. Two of the most important were the enzyme *enterokinase*, which controls the activity of another digestive enzyme, and the connection between the properties of the saliva and the type of food being eaten (the Pavlovian curves of salivary secretion).

Page 595

N. P. Shepevalnikov and Pavlov were codiscoverers of enterokinase.

Pavlov's work on the physiology of digestion is important for understanding his work on animal behaviour, for his explanations of animal behaviour are similar to those of the control of digestion. In addition, his methods were similar in all his studies.

Conditional reflexes. While at the seminary in Ryazan, Pavlov had read I. M. Sechenov's *Refleksy golovnago mozga* (Reflexes of the Brain), which argued that mental events were reflexes. Then, while working on the physiology of digestion, he had noticed 'psychic' salivation: when the dog was confronted by a stimulus that customarily preceded feeding, it salivated even before being fed. This psychic salivation could be induced, for example, by the animal's food container, or by the presence of the attendant who normally fed the animal, or even by the sound of the attendant's approach. Armed with these incidental observations and with the reflexology of Sechenov, and stimulated by Charles Darwin's evolutionary arguments about animal behaviour (which encouraged materialistic analyses of mental events), Pavlov set out to investigate the psychic salivation of dogs. This was a simple extension of his earlier studies on the control of digestive secretions, and once again it was the nervous reflex that he looked to for his explanation. He worked on conditional reflexes from about 1902 until his death.

A typical Pavlovian experiment on psychic salivation would be as follows. On several occasions a bell is rung just before the dog is fed, and the dog salivates on receiving its food. Then the bell is rung without presentation of food. It is observed that the dog salivates in response to the bell's ringing. Pavlov termed the food the *unconditional stimulus*, the sound of the bell the *conditional stimulus*,

the salivation to the food the *unconditional reflex*, and the salivation to the bell alone the *conditional reflex*. ('Conditional' is what Pavlov actually wrote, but the early mistranslation of 'conditioned' is now widespread in the psychological literature.) Many of the fine details of the conditional reflex were studied by Parlor and his collaborators. First, there is the temporal sequence of stimuli. Parlor found that it is much easier to form a conditional reflex if the unconditional stimulus (food) follows the conditional one (bell) than if they are simultaneous, or if the conditional stimulus follows the unconditional. Second, there is the time delay between stimuli. Here he found that a discrete conditional stimulus is more effective in forming a conditional reflex if it occurs near in time to the food than if it occurs a long time before. However, if the conditional stimulus starts a long time before, but continues right up to when the unconditional stimulus is presented, then it is as effective as a conditional stimulus which starts just before the food is given. Third, there is the intensity of the stimuli. A dog salivates more if it is trained on bigger pieces of food; and similarly, it salivates more to a louder bell. Fourth, Pavlov studied generalization of the conditional stimulus. If the animal has been trained on a stimulus of one pitch, it can then be tested for a response to a stimulus of another pitch. This leads to a method of investigating the animal's powers of sensory discrimination, which again was originated and developed by Pavlov.

Pavlov was not only interested in how conditional reflexes were gained; he also studied how they were lost. He classified factors causing loss of a conditional reflex into cases of either *external inhibition* or *internal inhibition*. If an animal, conditioned in one way, is moved into a new environment, or is exposed to new stimuli before being fed, it loses its original conditional reflex; this is called external inhibition. There are several forms of internal inhibition. The most straightforward is the gradual loss of the conditional reflex if the food is withheld after the conditional stimulus; the conditional reflex requires regular reinforcement (to use Pavlov's term) by the unconditional stimulus.

Pavlov thought of the conditional reflex as similar to any other kind of reflex. The flow of digestive juices is stimulated by the mechanical and chemical properties of food, through the mediation of a nervous (unconditional) reflex. Similarly, salivation could be induced by some environmental indicator of food, again by a nervous (conditional, in this case) reflex. The conditional reflex, however, is easily modifiable by the environment, according to whatever the local indicators of food happen to be. So, Pavlov regarded the formation of conditional reflexes as an adaptation whereby the animal could survive better in a changing environment.

Pavlov also speculated on the fine details of the formation of a conditional reflex. He suggested that the cells of the central nervous system must change structurally and chemically when a conditional reflex is formed: 'the locking in, the formation of new connections, we attribute to the functioning of the separating membrane, should it exist, or simply to the branching between neurones'. This idea has subsequently been confirmed.

Although nearly all his research was on dogs, Pavlov also showed that conditional reflexes can be formed in mice and monkeys, and he was in no doubt that they occur in man, and in all other animals. He wrote: 'A temporary nervous connection is a universal physiological phenomenon in the animal world and exists in us ourselves.' He also showed that more or less any environmental factor can act

as a conditional stimulus (though this conclusion has been slightly modified by later research). Pavlov was aiming at truly universal laws of learning, and that is why his discoveries are so fundamental to modern theories of associative learning. One branch of psychology—*behaviourism—

Page 596

went so far as to attribute all human behaviour to*conditioning and reinforcement. Pavlov, however, made no such extravagant claims for the conditional reflex, and ridiculed the claims of behaviourism to scientific status. The most famous expression in English of Pavlov's work on conditioning is his book *Conditioned Reflexes* (1927). In psychiatry, conditioning is used in*behaviour therapy.

Experimental neurosis and personality. In a famous experiment (1921) by ShengerKrestovnika a circle was used as a conditional stimulus before feeding, and the dog was also trained to associate an ellipse with not being fed. By small steps the ellipse was then made more and more like a circle. When the ellipse was almost round, initially the dog could usually distinguish it from a circle. But after a few weeks the dog became neurotic: it ceased to be able to recognize obvious ellipses and circles, became very excited, and was no longer calm during experiments. Parlor termed the animal's abnormal condition experimental*neurosis, and he attributed it to a disturbance of the balance between excitatory and inhibitory processes in the*nervous system. This explanation of experimental neurosis is grounded in Pavlov's theory of personality. He explained personality by variation in the excitation of the nervous system. He did not, however, attribute neurosis solely to external factors, such as contradictory stimuli. His experiments on experimental neuroses showed that dogs with different 'personalities' were differentially susceptible to the treatment: the same treatment on different' dogs could produce quite different neuroses. In the 1930s Pavlov decided to work on the*genetics of behaviour, and his government built him the biological station at Koltushy for this research.

There is an underlying unity to all Pavlov's work. In his earliest work on blood circulation he established his method (intervention in unanaesthetized, whole dogs) and his paradigm explanation: nervous control. The same procedure was used in his work on the control of digestive secretion, and he started research on conditional reflexes as just another kind of nervous control of digestion. Late in his life, he saw how conditioning could be used to analyse personality and neurosis, and once again he was able to carry over his theoretical framework into a new field.

PEIRCE, CHARLES SANDERS (18391914). Considered by many to be the most original of American philosophers, Peirce is remembered principally for his teleological account of truth, for founding*pragmatism, for contributions to formal logic, and for pioneering work in the theory of signs

(semiotics). His early published work attacked the idea, dominant in the nominalist tradition from William of Occam onward, that a proposition is true if it corresponds to a reality which is the efficient cause of our sensations. In place of this Peirce gave (1871) an account based on the idea of 'a final conclusion, to which the opinion of every man is constantly gravitating'. Peirce, however, understood this gravitational attraction strictly in terms of the operation of rigorous scientific method, and as a practising experimental scientist he was impressed by the way a scientific concept is made precise by being tied to observable consequences of concrete operations. It was along these lines that he formulated (1878) a general maxim for achieving clear ideas, which he later came to identify as the core of his pragmatism. From the outset the centre of Peirce's philosophic concerns was logic, and he made important contributions to the logic of relations and devised, a few years after, but independently of, Gottlob Frege, the theory of quantification. Both his pragmatism and his work on logic were embedded in a theory of signs based on the idea that the meaning of a sign is its power to determine observers of it to interpret it in a determinate fashion.

Peirce had mixed feelings when in 1898 William James drew attention to him as the founder of pragmatism but at the same time advanced under this label a doctrine of truth (seen by many as the crude idea that truth is what works or what is useful) to which Peirce was quite antipathetic. As a result Peirce tried (in vain) to change the name of his approach to 'pragmaticism'.

Peirce's father, a professor at Harvard, was the leading American mathematician of his generation, but the son, largely through an inability to get on with people, failed to secure a permanent academic appointment. Apart from five years teaching at Johns Hopkins University, Peirce was employed as a scientist by the US Coast Survey. He published voluminously (estimated total of twentyfour volumes) on science, mathematics, and philosophy but never succeeded in giving his logical and philosophical ideas a systematic treatment in book form.

One extensive selection of Peirce's work is *Collected Papers* (vols. 1-6 edited by C. Hartshorn and P. Weiss, and vols. 7 and 8 by A. W. Burks), Cambridge, Massachusetts, 1931-58. Another selection, *Writings of Charles S. Peirce: a chronological edition* (edited by M. H. Fisch, et al.), Bloomington, Indiana, began to appear in 1982. Two one-volume selections are available: *Charles S. Peirce: selected writings* (edited by P. P. Wiener), New York, 1966, and *Philosophical Writings of Peirce* (edited by J. Buchler), New York, 1955. Two useful introductions to his thought are *Peirce and Pragmatism* by W. B. Gallie, Harmondsworth, 1952, and *Peirce* by C. Hookway, London, 1985.

J. E. T.

PENFIELD, WILDER GRAVES (1891-1976). American neurosurgeon, born in Spokane, Washington, and educated at Princeton and Page 597

Oxford, where he held a Rhodes scholarship. At Oxford, he came to know C. S. Sherrington and returned to work with him for two years after qualifying in medicine at Johns Hopkins University, Baltimore. He also made contact with Gordon Holmes and other neurologists at the National Hospital for Nervous Diseases in London, where David Ferrier had pioneered brain surgery. On his return to America, Penfield specialized in neurosurgery and worked in both New York and Baltimore

before moving to Montreal, where he was largely responsible for setting up the Montreal Neurological Institute, erected with the support of the Rockefeller Foundation and of which he became the first director. It has since led the world in the field of neurosurgery.

Penfield was remarkable not only for his high surgical accomplishment but also for his belief that neurosurgery made possible important advances in our scientific understanding of the functions of the brain. This, in its turn, made possible important progress in surgical treatment and rehabilitation. He made extensive use of advances in neurophysiology, in particular electroencephalography, and later of techniques in experimental neuropsychology, in ascertaining the localization and extent of brain lesions. He also undertook important work on the surgical treatment of focal*epilepsy.

Penfield was elected a Fellow of the Royal Society in 1943. He was a man of varied accomplishments, who wrote several novels in addition to an informative autobiography, *No Man Alone: a neurosurgeon's life* (1977). Of particular interest is his book with Theodore Rasmussen on *The Cerebral Cortex of Man* (1950).

O. L. Z.

PENROSE, LIONEL SHARPLES (18981972). British physician, born in London. Penrose's father was a portrait painter and both his parents were members of the Society of Friends. After serving in the Friends' Ambulance train of the British Red Cross during the First World War, he went in 1919 to St John's College, Cambridge, where he wanted to study mathematical logic with Bertrand*Russell. He obtained his degree in 1921, and then studied with F. C.*Bartlett and at the University of Vienna, where he did work on*memory and*perception in E. Buhler's laboratory and met Sigmund*Freud. At this time, Penrose was very interested in the problems of abnormal psychology and mental disorder and realized that he would be advised to qualify in medicine in order to pursue this interest. He therefore went to Cambridge in 1925 and subsequently to St Thomas's Hospital in London. He presented his MD thesis on the subject of*schizophrenia in 1930 and the following year applied for, and ultimately obtained, an appointment as research medical officer at the Royal Eastern Counties Institution at Colchester.

From this time on, the chief interest of his life, namely the study of mental deficiency, began to dominate his work, and when he left Colchester in 1939 to go to Canada, as director of psychiatric research for Ontario, he had already produced his classic *A Clinical and Genetic Study of 1,280 Cases of Mental Defect* (1938). This work alone would have established him as a leader in the subject, and at the time it advanced the study of mental deficiency very considerably. In addition, before leaving for Ontario he had developed a test which he believed might aid the diagnosis of schizophrenia, and had been instrumental, according to his own statement, in proposing the idea and outline of the test that subsequently became generally known as the Raven's Progressive Matrices (1936).

In 1945 Penrose was appointed to the Galton professorship of eugenics at University College London. He retired in 1965 but continued to work at the Kennedy

Gallion Centre, which he set up at Harperbury Hospital, St Albans. He remained a leader in the field of subnormality and genetics, especially in relation to Down's syndrome (mongolism). He was elected a fellow of the Royal Society in 1953 and received many other awards. Other details of his career are given by Harris (1973).

Penrose's great contribution to the study of subnormality was to lift the subject from the realms of speculation and myth and give it a respectable place in the field of psychiatry, biochemistry, and genetics where it properly belongs. He achieved this by his two major investigations, the first into the 1,280 cases which he studied from Colchester and secondly through his application of measurement to the study of Down's syndrome. In the first study Penrose was able to investigate not only the 1,280 patients in the Royal Eastern Counties Institution but also their numerous sibs and relatives. The patients were graded on the basis of Stanford-Binet and Porteus Maze tests and classified according to intellectual grade. They were also classified according to diagnostic categories, and their family histories were investigated. An immense amount of data was collected by very limited staff. Over all, the survey indicated the continuity of subnormality with normal intelligence and the very considerable heterogeneity of mental defect and the multiplicity of its causes. The figures concerning incidence also reliably contributed to knowledge concerning mental defect. Finally the survey demonstrated that mental defect was more common among parents and relatives of patients of IQ 50 and above than in the parents of more severely handicapped patients. Arising from this work, Penrose was able to make observations concerning the genetics of epiloia (or tuberous sclerosis) and also Down's syndrome. In all this and subsequent work, he developed the mathematical theory of genetics applied to human populations, and always showed himself ready to collaborate with leaders in the field of statistics, such as R. A. Fisher. At the same time, because of his considerable ability in mathematics, he was able to demonstrate a maturity of judgement not only in

Page 598

the field of human genetics concerning specific disorders, such as epiloia, but also in relation to the much more confused field of the inheritance of intelligence. In the latter area, he was one of the very few people who made the correct prediction concerning changes in intelligence in Scottish schoolchildren, in his Godfrey Thomson lecture in 1959. In this respect he differed from Cyril Burt and most other psychometricians.

Penrose had been interested in Down's syndrome from his first days at Colchester, and in his work from the Galton laboratories he was able to pursue this interest. In the work at Colchester he showed great ingenuity in assessing the relative contributions of maternal and paternal age as causative factors in the birth of Down's children, controlling for such questions as birth order in sibs. He was thus able to demonstrate ultimately the significance of maternal age and the relative unimportance of paternal age. He also interested himself in the familial incidence of Down's syndrome, though without providing a satisfactory explanation, but at the same time through these studies developed the concept of palmar dermatoglyphics in relation to Down's syndrome, by extensive studies involving 235 sufferers and 698 of their relatives as well as over 2,000 controls. Later, during his time in Canada and during his occupation of the Galton professorship, he was able to take advantage of the discovery

of chromosomal anomalies in Down's syndrome, and as a result of this work, combined with his observation of dermatoglyphic deviations among the relatives of Down's children, he was able to note that although maternal age might account for one group of Down's syndrome births, the births which occurred to mothers of a comparatively young age might show particular chromosomal anomalies.

It is impossible in such a short account to give a comprehensive view of all Penrose's many achievements. His interests in abnormal and subnormal psychiatry notwithstanding, he displayed at different times initiative and inventiveness in the areas of models of inherited intelligence, topological illogicalities, chess problems, mechanical models of genetic succession, mathematics, epistemology, art, the genetics of dermal ridges in association with sex chromosomes, and in many other things.

His character appealed strongly to many colleagues and also to young children. The view of one of these latter, committed to an essay included at the end of Harris's survey, presents him as a genial professor with a generous, warm attitude to encouraging cognitive skills in everyone he met, both young and old. He was never the sharp and contentious intellectual with an incisive and startling clarity of ideas, but more the gentle but widely and acutely aware observer.

PEPPER'S GHOST. A simple optical effect which is used for stage ghosts and in optical instruments, such as the *camera lucida* for drawing from the microscope, and the tachistoscope, which presents pictures for controlled duration in visual experiments. A partreflecting mirror superimposes one picture (or object) which is *reflected*, by another seen *through* the glass. By brightening one while dimming the other, one is seen to appear as the other disappears—and when roughly equally illuminated both are seen, superimposed, as transparent ghosts. The effect often occurs in window panes, especially at night, though curiously it is seldom noticed unless attention is drawn to reflected lampshades, etc., floating outside. This effect may produce 'flying saucers'.

PERCEPTION. Our senses probe the external world. They also tell us about ourselves, as they monitor positions of the limbs and the balance of our bodies, and through pain they signal injury and illness. More subtly, there are innumerable internal signals monitoring physiological activities, and conveying and maintaining our wellbeing; though little of this enters our*consciousness. It may

surprise the nonscientist just how little of the daybyday, secondbysecond perception that allows us to survive in a threatening world is conscious. But although the processes are generally unconscious, through investigating them experimentally we can discover a great deal about the physiological basis of perception and how, as babies and later, we discover the world of objects and come to read meanings in pictures and symbols. In perception, as Sir Ernst Gombrich (1950) realized to such good effect, art and science meet.

Just how we know things through sensory experience is a question that was discussed by the Greek philosophers and has been ever since. But, perhaps curiously, planned experiments in the spirit of the physical sciences were hardly attempted much earlier than the midnineteenth century. Since then, the experimental study of perception has yielded fundamental knowledge for physiology and psychology, especially from the outstanding work of Hermann von*Helmholtz (1867). It has revealed many surprises in the form of processes of which we are unaware, though they can often be demonstrated simply and dramatically. The study of perception, especially of vision and hearing, has allowed psychology to grow from its philosophical roots into an experimental science; yet deeply puzzling philosophical questions remain—especially over the role of consciousness. It is puzzling, both that we are aware of so *little* of perception—and that we have *any* awareness!

Page 599

There is a longstanding tradition in philosophy that perception, especially touch and vision, gives undeniably true knowledge. Philosophers have generally sought certainty and have often claimed it, whereas scientists, who are used to their theories being modified and upset by new data, generally settle for today's best bet.

Philosophers have a heavy investment in perception. They stake their all on the certainty of knowledge from the senses because they need secure premisses for their arguments from experience. Scientists, on the other hand, who are used to errors in measurement and observation by instruments, and have consequently found it necessary to check and compare and repeat experiments, do not so readily expect reliability from the senses. Indeed, many scientific instruments have been developed precisely because of the limitations of the senses and the unreliability of perception: for it is, after all, easy to produce and demonstrate all manner of dramatic*illusions which could hardly occur if perception constituted direct reliable knowledge. Yet although illusions of object perception have been discussed by philosophers from*Aristotle to*Berkeley (1709), and more recently as well, philosophy generally has paid more attention to errors of logic and ambiguities of expression than to the fallibilities of perception.

Philosophers are particularly impressed by the undeniability of the 'raw experience' of*sensations, such as colours and tickles and*pain. The sensation of toothache may be undeniable—but are perceptions similarly as infallible? One will necessarily think so if one believes that perceptions are simply sensations; but we now regard perception as giving us knowledge, albeit surprisingly indirectly, of the causes or *sources* of sensations—such as the states of our bodies and objects in the environment—rather than of the sensations themselves. It is now clear that there are vast and still largely mysterious jumps—intelligent leaps of the mind, which may land on error—between the

sensation and the perception of an object. One can indeed be wrong about the cause of toothache!

It is worth asking why we have both *perceptions* and *conceptions* of the world. Why is perception somehow separate, and in several ways different, from our conceptual understanding? Very likely it is because perception, in order to be useful, must work very quickly, whereas we may take years forming concepts, since knowledge and ideas are in a sense timeless. It would probably be impossible for perception to draw upon all of our knowledge, as it has to work so fast. Rather, it employs a rapid *but* not deep intelligence with a small knowledge base.

Perception is not traditionally thought of as an intelligent activity, even though the power, especially of vision, to probe distance gains the time needed for intelligent reactions to ongoing events. It can be argued (Gregory, 1970) that the development of distance perception freed organisms from the tyranny of reflexes, and was the necessary precursor of all intelligence. The special intelligence of perception has more recently been discussed by the psychologist Irvin Rock (1984). However, an earlier account portrayed sensory perception very differently as a passive undistorting window through which the mind accepts sensations which were considered to be 'sensedata' of perception, selected and assembled somewhat like the pieces of a jigsaw puzzle. On this kind of account sensedata may be selected according to need or *attention; for vision, the brain (or mind) has little to do except select and 'pick up' features of the 'ambient array' of light (Gibson, 1950, 1966).

But are sensations, such as colours and shapes and sounds, *picked up* by the senses, or are they *created* internally by the perceiver? This question about the passiveness or activeness of perception is a longstanding one which is still debated and has significant implications; for if sensations are created by the brain—a notion that receives strong support from recent physiology (Zeki, 1977, 1980)—they can hardly be data for perceiving the object world, whereas if they are in the world, to be 'picked up', they must exist apart from us.

This raises the question: what is 'objective' and what 'subjective'? The philosopher John*Locke (1690), who was well aware of the new science of his time, suggested that there are two kinds of characteristics: *primary* characteristics, such as hardness, mass, and extension of objects in space and time—being in the world before life, and quite apart from mind—and *secondary* characteristics, which are created by mind. Thus colours are not in the world, but are created within us, though they are related in complex ways to light and the surfaces of objects.

It is generally accepted that Locke's 'primary' characteristics are present independently of mind; and it is clear that his 'secondary' characteristics are affected by states of the sensing organism—for colours change as we look through haze, or wine, and everything appears tinged with yellow if we have jaundice. It is such considerations that bring to mind the distinction between appearance and reality; even so, it is important to note that sensations do have a kind of reality, although they are created by and within us. Thus Isaac*Newton, writing on sensations of colour in *Opticks* (1704), agreed with his friend Locke, saying that red light is not itself red, but is 'redmaking'. Spelling this out, he said of light rays: '... there is nothing else than a certain power and disposition to stir up the sensation of this or that colour. For as sound in a bell or musical string ... is nothing but a trembling motion.' Then (in Query 23) he specifies something of the neural mechanism of vision that leads to the mysterious seat

of sensation: 'Is not vision perform'd chiefly by the Vibrations of this (Eatherial) Medium, excited in the bottom of the eye by Rays of Light, and propagated through the solid, pellucid and uniform Capillamenta of the

Page 600

optic Nerves in the place (the "Sensorium") of Sensation?'

The empiricist school, of which in their different ways Locke and Newton were founders, rejected the notion that had been the basis of much philosophy, that minds can receive knowledge by direct intuition, quite apart from sensory experience. Mind was now regarded as essentially isolated from the physical world: linked only by tenuous threads of nerve. At the same time there were attempts to discover 'laws' of mind, corresponding in some ways to the laws of physics though seldom, if ever, seen as being in quite the same category. Newton did however write (in a letter to Henry Oldenburg, secretary of the Royal Society): 'I suppose the *Science of colours will be granted Mathematicall* and as certain as any part of Optiques.' Laws of colour mixture were developed later, especially following the work of Thomas*Young, who made the important discovery in 1801 that all the spectral colours can be produced by mixture of various intensities of only three coloured lights.

This took the sensations of colour somewhat outside the realm of physics, and yet they were seen as bound by certain laws. So evidently there could be a lawful science of sensation, and so of mind. Newton fully appreciated that colour sensations are not always given by light, as he said (*Opticks*, Query 16): 'When a Man in the dark presses either comer of his Eye with his finger, he will see a *Circle of Colours* like those of a Peacock's Tail.' At the same time, much like Pythagoras linking music with the physics of vibrating strings, Newton tried to describe aesthetics according to physical principles (Query 14): May not the harmony and disacord of Colours arise from the proportions of the Vibrations propagated through the Fibres of the optick Nerves into the Brain, as the harmony and discord of Sounds arise from the proportions of the Vibrations of the Air? For some Colours, if they are view'd together, are agreeable to one another, as those of Gold and Indigo, and others disagree.

So we find attempts to explain perceptual experience, from sensation to aesthetics, by physical principles of the natural sciences. But though, for example, colour mixture is linked to the physics of light, it is not derivable from optical principles. As the direct realism of immediate experience of the object world has been (almost universally) abandoned, we are left with having to devise bridging theories of perception, to relate mind to matter.

It is now generally accepted that perception depends on active physiologically based processes, but this notion is nonintuitive, for we know nothing of such processes or mechanisms by introspection. Moreover, perceiving objects around us seems so simple and easy! It happens so fast and so effortlessly it is hard to conceive the complexity of the processes that we now know must be involved. The notion takes us, however, to concepts familiar to engineers. It is not misleading to describe the organs of the senses—the eyes, ears,*touch receptors, and so on—as 'transducers' that accept and signal patterns of energy from the external world as coded messages, which are read by the brain to infer the stateofplay of the world and of the body's own states. (For detailed information

on sensory mechanisms and processes, see Barlow and Mollon, 1982.) Another useful engineering concept is that of 'channels'. The various senses—touch, vision, hearing, and so on—are each subdivided into channels which can be discovered only by experiment. Thus, for example, although this was not at all realized before Young's (1801) colour mixture experiment, colour vision works with just three channels responding to red, green, and blue light, respectively. All the hundreds of colours we see are neurally mixtures from these three colour channels. Then there are channels representing the orientation of lines and edges, and channels for movement, as shown by direct physiological recording from the visual cortex, and demonstrated dramatically by Hubel and Wiesel (1962). By less physiologically direct methods, such as selective adaptation, it has been found that there are more or less independent channels for spatial frequency and many other visual characteristics. The ear has many frequency channels, and there is a score of channels for touch, various kinds of pain, tickle, and for monitoring the positions of the limbs and setting muscle tensions for moving them appropriately. Somehow the outputs from the many channels are combined to give consistent perceptions. Small discrepancies—such as the delay in sound between seeing a ball hit a bat and hearing the impact—are rejected, or pulled into place, to maintain a consistent world.

For signalling by the senses, as from instruments, it is important to appreciate the range of likely or possible objects that may be present. The eye receives all sorts of irrelevant stimuli which are mainly disregarded, just as unwanted data and random disturbances are rejected whenever possible by scientific instruments and in computer signal processing. Sometimes, though, what is rejected turns out to be just what is needed! The immense difficulties encountered in current attempts to program computers to recognize objects from signals provided by television cameras indicate the incredible complexity and subtlety of animal and human perception.

David Marr (1980) suggested that object shapes are derived from images via three essential stages: (i) the 'primal sketch'(es), describing intensity changes, locations of critical features such as terminal points, and local geometrical relations; (ii) the '2 1/2D sketch', giving a preliminary analysis of depth, surface discontinuities, and so on, in a frame that is centred on the viewer; (iii) the '3D model representation', in an objectcentred coordinate system, so that we see objects much as they are in 3

D space though they are presented from just one viewpoint. Marr supposed that this last stage is aided by restraints on the range of

likely solutions to the problem of what is 'out there', the information processing restraints being set by assuming typical object shapes—for example that many objects, such as human beings, are modified cylinders. Interestingly, the painter Paul Cézanne came close to this notion in 1904: 'Treat nature by the cylinder, the sphere, the cone, everything in proper perspective so that each side of an object or a plane is directed towards a central point ... nature for us men is more depth than surface....'

The limited variety of typical objects may set restraints that are useful, both for the artist representing objects and for the artificial intelligence endeavour to program computers to see; but although it can be difficult to represent or see some atypical objects (or even familiar objects from atypical viewpoints) perhaps it is not clear that these difficulties reflect accepted restraints based on cylinders, spheres, and cones—for many other very different shapes can be depicted and seen without

special difficulty.

Looking 'inwards' by introspection, we *seem* to know that perceptions are made of sensations, although from physiological and psychological experiments—as well as from this essentially engineering approach—it has to be denied that sensations are the data of perception. The data are neural *signals* from the transducer senses, analysed by many parallel channels to generate immediately useful predictive hypotheses, which are our perceptual reality of the object world.

It has usually been thought that perception *occurs passively* from inputs from the senses. It is now, however, fairly generally accepted that stored knowledge and assumptions *actively* affect even the simplest perceptions. The relative importance of what are called (especially in artificial intelligence) passive 'bottomup' processes to active 'topdown' processes is a central controversy. Some evidence bearing on this is presented in the entry*illusions. The changes of shape of wire cubes which reverse spontaneously in depth (Fig. 5 in ILLUSIONS) is clear evidence of subtle 'topdown' processes affecting what used to be regarded as simple characteristics such as size and brightness. But these must be knowledgebased, 'topdown' effects because there are no changes of input from the eyes with depthreversals of ambiguous figures. These are examples of how illusory phenomena can reveal processes of the perception we depend upon for our knowledge of the world and ourselves.

PERCEPTION: CULTURAL DIFFERENCES. Crosscultural studies in perception arose from speculations on whether different patterns of behaviour and linguistic usage indicated differences in perception. For example, the difficulty of translating colour terms suggested that the ancient Greeks perceived colours differently from presentday observers, and reports from travellers and missionaries suggested that there might be differences in perception between Western and non

Western populations.

The growth of anthropology as an empirical discipline, and the development of psychological techniques modelled on those of physics (sometimes by scientists whose interests spanned both disciplines, such as G. T.*Fechner and E.*Mach), encouraged systematic research and led to several research projects, of which the Torres Straits expedition (1899) is probably the most significant. The object of this expedition was in part to assess the perceptual characteristics of remote groups. The scope of its investigations included acuity of vision, colour vision, visual illusions, and visual perception in general, which were studied by W. H. R.*Rivers; cutaneous sensation and discrimination of weight, studied by W.*McDougall, and hearing, smell, taste, and reaction times, studied by C. S.*Myers.

Although such studies as these, where hypotheses are selected by a worker from an alien culture, have been criticized for restricting the choice of hypotheses and introducing a bias, they are by far the most common and have provided some interesting results.

The effects that have been investigated subsume forms of social usage (for example, the economic structure of a group, childrearing practices, and nutritional habits), purely environmental influences such as the topology of the terrain, the effect of cultural artefacts such as architectural

style, and even genetic factors. Such is the plethora of factors which may influence perception that an entirely convincing isolation of one of them and a demonstration of its effects is not generally achieved. The results to hand strongly suggest, however, that although isolation of causes of the observed crosscultural differences may be difficult or even impossible, such differences probably do exist.

Visual perception. The differences seem to be most pronounced in the visual modality (although this observation may be a result of the experimental bias described above). For example, an extensive study of simple*illusions conducted by Segall, Campbell, and Herskovits showed that certain illusion figures, such as the*Müller

Lyer and the Sander parallelogram, did not evoke such strong effects in the cultures where rectangular

objects and arrangements of objects were rare as in those more

'carpentered' cultures where such phenomena abounded. The more carpentered the culture in which the observers lived, the higher was their susceptibility to these illusions. Another influence was found to affect the magnitude of the horizontal-vertical illusion. Observers living in open vistas, such as savannah, experienced the illusion more strongly than those living in more visually confined environments, such as tropical rain forests.

Crosscultural differences have also been noted in the ability to perceive shape and the orientation of simple geometrical patterns and in the magnitude of shape constancy scores. The latter issue is thought by some to be related to the characteristics of art styles, since these differ in the manner in which they employ constancies.

Similarly the ability to *interpret* pictorial material is found to differ with culture. This finding is of some practical consequence, since such materials are used as primary means of communication in illiterate cultures. Specifically it was found that pictures which to a Westerner appear unambiguous are often misunderstood in nonpictorial cultures. However, detailed, but unfortunately sparse, followup investigations offer no evidence to sustain the claim that single clearly depicted objects are likely to be consistently misperceived in these cultures. Even in a culture entirely devoid of graphic art, when large drawings of familiar objects printed on cloth were displayed, these were recognized, albeit with difficulty and rather slowly. There is, on the other hand, sufficient evidence to show that *relationships* between various items in the same picture are likely to be misperceived. Thus an observer may maintain that an elephant is nearer to a man than an antelope simply because the elephant is drawn nearer to the man (by perspective) in the plane of the picture, notwithstanding the fact that the elephant is drawn smaller than the antelope and hence, if the implied depth cue is taken into account, should be seen as being further away.

Such failures in correct interpretation of pictorial depth cues were first investigated systematically by W. Hudson, whose work has proved seminal to a large number of studies which confirm the existence of crosscultural differences. The likelihood of such a misinterpretation varies both with the characteristics of the observer and the nature of the picture. Neither a correct interpretation nor a misinterpretation of any particular picture can therefore be regarded as an index of the observer's ability to perceive pictorial depth.

Considerations of such basic phenomena as the implicit shape constancy in abstract figures show that the differences observed are not confined to depictions of lifelike scenes. A drawing of a square on a face of a drawn cube, both of which are, in a strictly geometrical sense, diamonds, leads to an impression of a figure whose

'squareness' appears to vary with culture, being greater, for example, in Scottish than in African observers.

Consistent with the above observations, the extent to which pictures can be regarded as object substitutes varies with culture. For example, the ability to categorize objects does not predicate an

ability to categorize pictures of these objects equally well.

Perception of colour has traditionally formed a testing ground for linguistic hypotheses, such as the Sapir-Whorf hypothesis which argues that any grouping of colours is entirely determined by linguistic labels extant in any given culture. However, studies of grouping of colours by people drawn from a variety of linguistic communities have put such an interpretation in question. It seems that the same colours are regarded as *focal* (or archetypal) whether a language has a very rudimentary or a sophisticated colour vocabulary. Yet the linguistic cause cannot be said to be entirely routed, for language may exercise influence within the valleys between such focal peaks.

Another issue which has been studied is the perceptual outcome of binocular rivalry, when two different stimuli are presented separately to the two eyes. When the stimuli used were derived from two different cultures, it was observed that the subjects tended to describe the stimuli derived from their culture and ignore the alien stimuli. Ambitious but unfortunately inconclusive studies of eidetic imagery have also been carried out.

Other perceptual modalities. Perceptual modalities other than the visual one have received but scanty and unsystematic attention in crosscultural studies. Of the more complex issues, perception of time has been studied; but here, too, the effects observed can be more readily attributed to the social values that are attached to activities occupying time rather than to time itself.

Theoretical approaches. Two theoretical frameworks, deriving from the work of Piaget and from that of H. A. Witkin, dominate the research. The former is concerned with the stages through which

Page 603

a child passes as it gradually acquires cognitive concepts needed for the effective handling of perceptual information. Such stages as defined by Piaget have also been reported in other cultures and are said to occur in similar sequence. The age ranges within which they occur are, however, said to differ between cultures. Witkin links the style of childrearing and therefore of general social structure and ecological conditions with the extent to which members of a culture show field dependence. The effects of dependence are apparent not only in perception of social relationships but also in perception in general. Subjects with higher dependence find it more difficult to perceive parts of the perceptual field as discrete from the field as a whole, than do subjects with lower dependence. This distinction in ability affects greatly performance on such tasks as reproduction of simple geometric designs (block design test), detection of a figure embedded in a matrix of irrelevant lines (embedded figure test), or adjustment to the true vertical of a luminous rod presented within a tilted luminous frame in a darkened room. In addition, there are a number of more *ad hoc* hypotheses attempting to interpret the way in which various factors combine to affect perception. One group of these, whose popularity owes more to their appeal to the sense of charity or justice than to empirical evidence, are the 'compensatory hypotheses'. These suggest that rather poor performance by a cultural group in one perceptual modality (such as vision) is likely to be compensated by (generally as the result of ecological or cultural adaptation) a relatively superior performance in another modality (such as hearing or touch).

Problems. Although crosscultural comparisons provide an excellent ground for testing the universality of postulated theories or of observed phenomena, they also present the experimenter with greater than usual methodological obstacles. The main problems are the difficulty of 'distinguishing differences of perception from failures of communication' (D. T. Campbell), and the lack of adequate control groups, since generally populations not only differ in culture but also live in different ecological conditions and are of different genetic stock. Indeed so intertwined are these three variables that many of the studies which are now classified as crosscultural would, in the notso distant past, have been seen as studies of differences in racial characteristics.

PERCEPTION: EARLY GREEK THEORIES. The*PreSocratic philosophers attempted to

explain the phenomena of perception, and to show how sensory interactions with the external world differ from nonsensory interactions. Of the several theories they produced, that of Empedocles may stand as typical. Empedocles' views are summarized for us by*Plato in his dialogue the *Meno*:
SOCRATES. Do you agree with Empedocles that existing things give off a sort of effluence?

MENO. Certainly.

SOC. And that they have pores into which and through which the effluences travel?

MENO. Yes.

SOC. And of the effluences, some fit some of the pores, while others are too small or too big?

MENO. That's fight. soc. And there's something you call sight?

MENO. There is.

SOC. From this, then, 'grasp what I say to you', as Pindar puts it: colour is an effluence from things which is fitted to sight and perceptible.

The book in front of you is constantly emitting 'effluences' (streams of minute particles) differing one from another in kind; as they strike your body, some fit snugly into various of its 'pores' or openings, others do not; one kind of effluence (call it 'colour') fits precisely into the pores of your eyes— and thus you see the book. To see the book is simply for your eyes to receive coloureffluences sent out by

the book. Similarly with the other senses; so that, in general, to perceive an object is to receive from it effluences of a kind to fit the organs of perception.

This theory is thoroughly 'materialistic': it makes no mention of nonphysical objects of perception (immaterial 'sensedata'), and it does not invoke a peculiarly 'mental'

relation of 'experiencing' or 'being aware of' an object; rather, one physical object reacts with another. The theory was criticized for just this reason: Theophrastus observes that 'one might wonder ... how inanimate objects differ from the rest with regard to perception; for things fit into the pores of inanimate objects too'.

Empedocles himself used the mechanics of pores and effluences to explain various nonperceptual phenomena (reflection, magnetism, deciduousness): how, then, can his theory distinguish between perception and other, nonsensory, poreandeffluence interactions with the world? (Suppose a modern psychologist were to say that perception was a discriminatory capacity, nothing more; then we might ask him how he proposed to distinguish genuinely perceptual activity from, say, the performance of a potatosorting machine which discriminates among potatoes according to their size.) Theophrastus remarks that, in Empedocles' view, perception comes about 'by likes'; and a surviving fragment from Empedocles' own pen confirms the point: For by earth we see earth, by water water,

by air bright air, and by fire brilliant fire.

Thus for perception to take place, the effluence

Page 604

must not only 'fit' the appropriate pore: it must also be 'like' or homogeneous with (some parts of the walls of) the pore. I see red when a red effluence slots neatly into a rededged pore in my eye. Perceptual interactions differ from nonperceptual interactions just because they require homogeneity, as well as a good fit between effluence and pores.

There are two points to note about this suggestion. First, it is pretty crude: as a physical theory of perception, it will not do; and Theophrastus tells us that Empedocles himself, in his detailed accounts of the modes of perception, did not in fact assign much work to the notion of 'likeness' or homogeneity. But secondly, and more importantly, the notion of homogeneity is thoroughly materialistic: in order to distinguish perceiving from other, nonperceptual, activities, Empedocles does not leave the hard land of matter. He does not appeal to some soft 'mental' or 'experiential' aspect of perceivers to mark them off as beings of a unique kind; rather, he supposes that the crucial difference between perceiving and nonperceptual activity can be characterized in physical terms: biology and physiology (we might now add: neurophysiology) will suffice to give a complete account of the phenomena of perception.

J. BA.

PERCEPTION OF MOTION PICTURES. The explanatory power of perceptual theories and the

generality of perceptual research findings are both strongly challenged by the sensory phenomena on which motion pictures and television are based, and by the perceptual devices that they employ.

Motion pictures are possible because we perceive continuous movement in response to a rapid succession of static views. The phenomenon is often called *apparent movement* (or stroboscopic movement). Writers about cinema routinely appeal to 'visual persistence' to explain this fundamental phenomenon. Such persistence, however, although real enough (see AFTERIMAGES) simply cannot explain apparent movement. At best, it names the fact that we do not detect the brief periods (*c.* 1/80 sec.) during which the motion picture screen is dark. At worst, persistence would result in the superposition of the successive views. In fact, we have only begun to explore the sensory mechanisms (including direct motion detectors, retrograde masking, and fast and slow neural channels) that must contribute to the phenomenon of apparent movement by eliminating the superposition of successive disparate views that mere visual persistence would provide, and to consider the cognitive processes that fit compelling perceptual meaning to those views (Hochberg and Brooks, 1978).

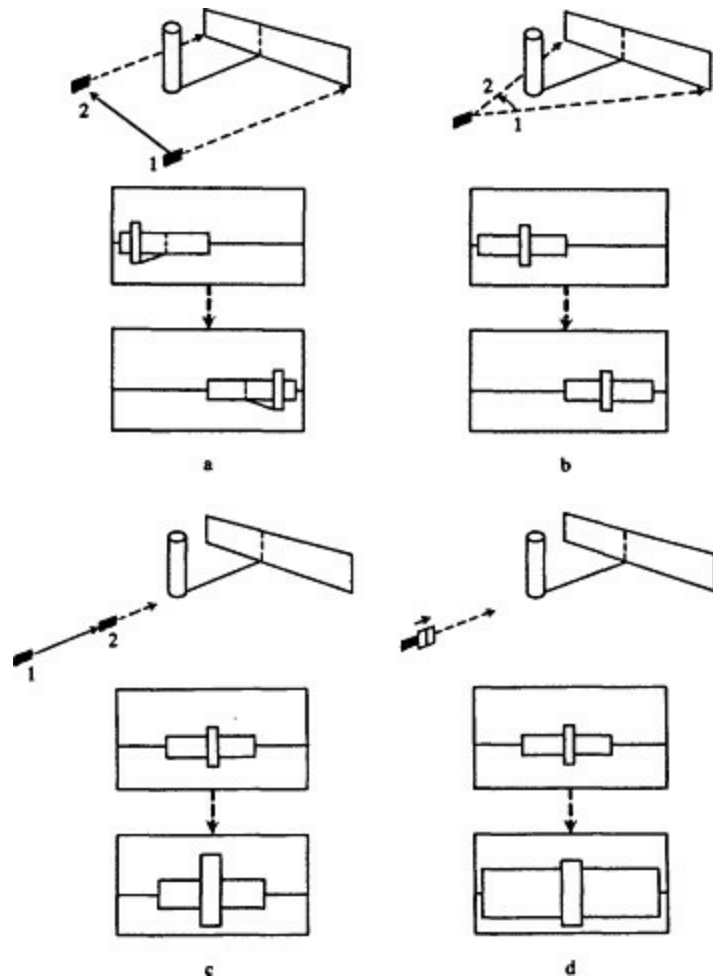

Some of these mechanisms and processes must also be engaged when we build up a continuous percept of our physical environment by taking successive discrete and discontinuous glances at it. Motion pictures and television differ in significant ways, however, from the information provided by glances taken at the real world. When the viewer looks over his environment, his knowledge of where in space his eye is directed during each successive glance is at least potentially informative about how the separate glimpses fit together into a single coherent object or scene. Considerable thought and research have been devoted to this matter of 'taking eye direction into account', but motion picture and television usage assures us that more elaborate integrative processes are available to the viewer than have been the subject of such research. When different camera shots of an object or scene are projected successively on the screen, the viewer's knowledge of where his eye is directed could not possibly tell him how the successive views are to be put together. At best, by taking his eye direction into account, the viewer could learn only that all of the partial views of the scene have been presented at the same place in space, i.e. on the viewing screen.

Changes in camera viewpoint are made for many purposes, and in several distinct ways. Such view changes serve to direct the flow of thought, emphasizing specific objects or events; to provide visual rhythms analogous to those of poetry and music; to recapture visual attention once a view's content has been identified and the viewer's visual interest wanes; and to provide narrative economy by 'skimming' lengthy events and presenting only the essential features. Most importantly, by changing camera viewpoints, the filmmaker can present a scene that is vastly larger than each view on the screen, and can present scenes that do not really exist in any one place, or that are too large to display all at once on the screen in sufficient detail.

View changes can be continuous or discontinuous. That is, the camera may move continuously, as shown by the solid arrow in Fig. 1, from one station (1) to another (2), moving perpendicular to the line of sight (as in the *tracking shot*, Fig. 1a), or moving in the direction of the line of sight (as in the *dolly shot*, Fig. 1c). These movements, or their combinations, usually offer visual information about the depth relationships within the scene (for example, *motion parallax*; note the different displacements of near and far objects between the first and last shots as shown in Figs. 1a and 1c).

Keeping the camera stationary, but changing the direction in which it is pointed from 1 to 2 in the *pan* shot of Fig. 1b, or changing its focal length in a *zoom* which merely imposes a uniform magnification on the field of view (Fig. 1d), achieves changes in view that are superficially similar to the track and dolly shots respectively, but provide no motion parallax and therefore no depth information.

Theoretically, because they lack depth information, pans and zooms should look very different from dolly and track shots, but for reasons of convenience and economy filmmakers often use the former instead of the latter, with results that appear to be acceptable to the viewer. Although our ability to detect motion parallax in the

Page 605

Fig. 1.

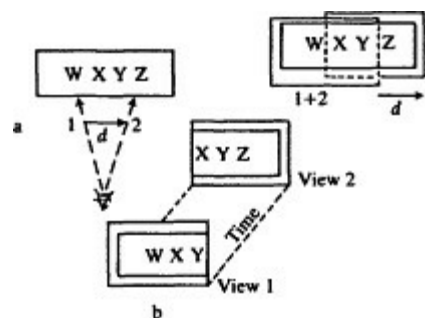

Continuous transitions. a. Tracking shot: at top, the camera (black rectangle) moves from station I to station 2 (solid arrow); the dotted arrows show the camera's line of sight at beginning and end of section. Below: view from point 1 over view from point 2. Note effects of parallax.

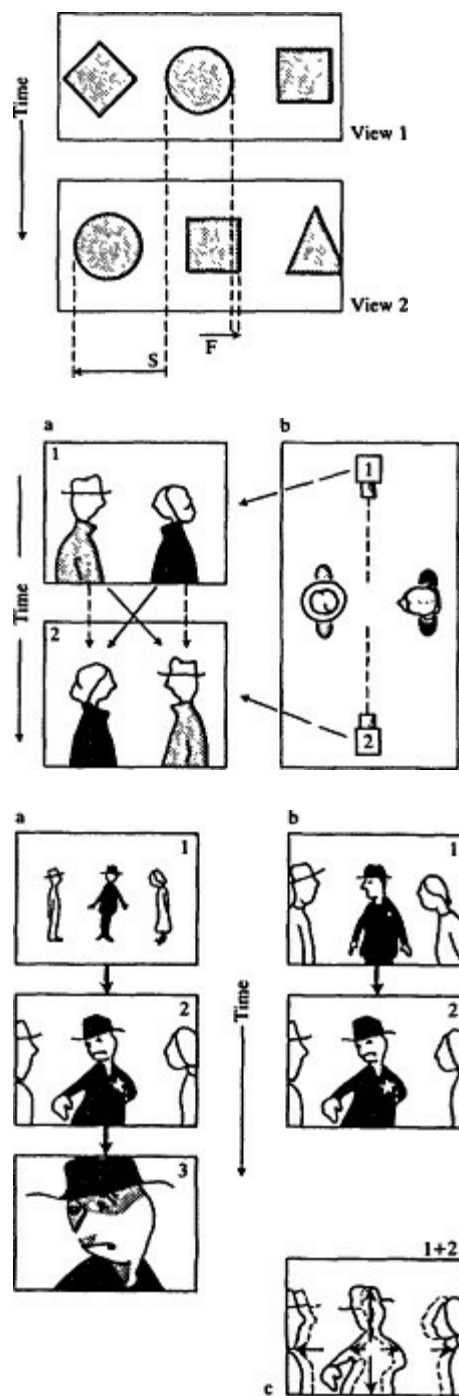

b. Pan shot: camera rotates (solid arrow) around stationary point. Note absence of parallax in resulting views. c. Dolly shot: camera approaches from station 1 to 2. Note parallax (i.e. change in relative size of nearer and further objects). d. Zoom shot: camera remains stationary, but focal length is increased. Note that magnification, but no parallax, is obtained.

laboratory is astonishingly good, how much we actually use it in motion pictures or in real life is an unexplored question of some importance to filmmakers and of considerable theoretical interest to psychologists.

Part of its theoretical interest rests on the following issue: in recent years, several perceptual theorists have proposed that our visual systems are *directly* sensitive to the spatial information that is provided by transformations over time within the light that reaches the eye of a viewer who is in motion relative to a scene. In the case of track and dolly shots, this includes the three-dimensional relationships within the scene; in all of the transformations, the overlap between successive views provides information about the loci of objects in the scene and the order in which the successive views were obtained. This is true of *discontinuous* sequences of overlapping views, as well: the sequence in Fig. 2 specifies that W is to the left of Z even though the two are never shown at the same time.

It is proposed that both in normal saccadic glances (rapid changes of regard between which the eye remains static for about 200 milliseconds), and in motion picture transitions, we respond directly to the visual information about spatial layout that the view sequences contain. At least in the case of discontinuous motion picture cuts, however, the perceptual process appears to be

Page 606

Fig. 2.

Overlapping view sequence specifies the relative loci of parts of the scene (W, Z) that are not on the screen at the same time, and also specifies the direction of change in view (d) of eye or camera. a. Scene. b. Successive views. c. Information theoretically available in the view sequence at b.

Fig. 3.

Bad cut, 1.

neither as automatic, direct, nor veridical as the preceding analysis implies. The relationship between successive views may be grossly misperceived, even though those views overlap substantially. In Fig. 3, for example, although successive views 1 and 2 are in fact displaced leftward (vector S), rightward movement (F) is perceived (except at very slow presentation rates) because objects in one view have been incorrectly 'identified' by the viewer's perceptual system as being quite different objects in the preceding view. There is a great deal of laboratory work showing that apparent motion occurs, in this way, even between unlike but contiguous shapes or parts of shapes (Hochberg and Brooks, 1978; Kolers, 1972; Orlansky, 1940). And these are not merely laboratory phenomena: filmmakers distinguish good and bad cuts, and most examples of the latter result from an unwanted apparent movement that may be completely independent of the actual displacement between views (Vorkapich, 1972), or indeed result from an apparent absence of displacement where a large displacement in fact exists. For example, when the camera direction changes by approximately 180° ('crossing the camera axis', as in Fig. 4), there is a brief but upsetting impression that the people remain on the same places on the screen, but change their shape (as signified by the dotted arrows in that figure). Similarly changes in focal length in the traditional sequence of Fig. 5a should be large ones, for if they are small, as in Fig. 5b, the apparent movement between contours in successive views is perceived as a rapid expansion or approach, rather than as the changes in the field of attention that we discuss below.

Successive views of different objects or people

are often aligned deliberately in order to avoid the apparent 'jump' that occurs between successive nonaligned contours, and thereby to achieve a cut that is smooth and unaccented. Such cuts probably take longer to comprehend, however, because no adequate signal has been given to the eye that the view has been changed.

The factor of apparent movement between unrelated but contiguous successive shapes is of practical importance in that its various cinematic manifestations are evidently used by filmmakers (through rules of thumb, and by trial and error in film editing) to achieve comprehensibility, and to control the accents in the cutting rhythm (or montage). It is theoretically important in showing that the overall relationship between discontinuous overlapping views is not directly and automatically perceived. Where the local factors do not change to provide apparent movement that conveys the intended spatial relationship, the filmmaker must allow the viewer sufficient time to construct the spatial relationship using other sources of information. Those responses (i.e. 'readings' of any sequence) that depend on factors that are relatively local, but undetailed, like the phenomena in Fig. 3, seem to be rapid, effortless, and transient, and tend therefore to determine how sequences of brief views are perceived. Responses that depend on more detailed identification, or on more involved 'visual inferences', as discussed below, are slower, and perhaps more sustained. The same sequence of views may therefore be differently comprehended at different cutting rates. For instance, Fig. 3 appears to move rightward at rapid rates (less than a second per view) and leftward at slow rates (such as three seconds per view).

Why don't these local factors cause noticeable confusions in the course of normal saccadic glances as they do in cinematic view sequences? Several factors may account for this difference. In saccades, the entire field of view (well over 100°) is translated as a whole, as compared to the relatively small regions ($\approx 45^\circ$) within which translation occurs on the motion picture or television screen; a brief but significant period of partial visual suppression accompanies each saccade, and this may prevent the local apparent movements that afflict cinematic cuts, and may perhaps thereby permit invariant information in overlapping saccadic glimpses to be correctly used. Furthermore, we know that the viewer can take some account of the direction in which his or her eye has been ordered to move. Perhaps most important of all, in the case of saccadic glances, the viewer has asked the visual question that motivated the eye movement, and to which the resulting glimpse comes as an answer.

Such perceptual questionasking or 'hypothesis testing' (a central feature in current perceptual theories:

see Gregory, 1974; Hochberg, 1979) cannot readily be studied in the course of normal saccades, nor even with motion picture cuts that overlap substantially (e.g. Fig. 2), because of the purely visual information such events contain, and the possibility of the direct use of such information. But the fact is that *many or even most motion picture cuts occur between views that do not overlap at all*. It is these that allow the filmmaker to construct scenes and events that never existed. No purely sensory information within such transformations could provide the basis for their combination in the mind's eye of the viewer, nor make the view sequence comprehensible. The filmmaker connects such nonoverlapping shots either by leading the viewer to ask the visual question, to which the next view is an answer, or by providing a context that identifies the relative locations of subsequently presented views. Fig. 6a is an example of the former: an actor looking leftward in one view naturally leads the viewer to expect that the next shot shows the object of the actor's regard, i.e. to the viewer's left. Fig. 6b is an example of the latter: in the sequence of a long shot followed by a medium shot and closeups (views 14, respectively), the long shot acts as an *establishing shot* within which the nonoverlapping closeups take their appropriate places. (Note that the factor at work in Fig. 6a would reverse the relative locations of views 3 and 4, were the latter presented without the first *two* shots in their sequence.) After a sequence of nonoverlapping closeups has gone on for a while, or after a *cutaway shot* has shown Fig. 6,

Typical devices for providing meaning to successive views.

Page 608

parallel action going on elsewhere, *reestablishing shots* (like view 1) may again be needed.

Some of the filmmakers' devices are clearly mere conventions (for instance: dissolves, indicating parallel action; calendar leaves, indicating elapsed time); some are simply logical inferences that follow from the viewer's legitimate assumption that the film sequence was created with a coherent narrative or expository purpose (recent attempts to analyse the maxims of spoken discourse, notably by Grice, 1968, and Searle, 1969, may suggest ways to study such inferences). Some methods probably tap more general cognitive processes: for example, in the sequence from long shot to closeups in Figs. 5 and 6, the viewer's attention is directed first to a general survey of the scene and then constrained to smaller regions and details that take their meaning from the preceding context.

Research in this area has barely begun. The cognitive skills by which the information from successive glances is integrated—skills that are of the utmost importance to any perceptual theory that aspires to apply beyond the momentary glance—are open to study through the medium of motion picture cutting. Since*Leonardo da Vinci, perceptual research and theory have been primarily concerned with the still picture. For both practical and theoretical reasons, we should turn our attention to motion pictures.

PERCEPTION AS HYPOTHESES. Philosophers have generally considered *visual* perceptions to be closely related to, or even to be samples of, surfaces of surrounding objects. Thus, vision was thought to be rather like *smell, and as direct and immediate as *touch. However, with the invention of the camera obscura, and the related discovery that the object world is imaged optically in the eyes, it became clear that patterns of light in the eyes (retinal images) are transmitted to the brain by coded electrical signals (action potentials), which are then, somehow, read as objects having very different and far richer properties than the optical pictures in the eyes. It became clear, at least to physiologists, that there must be a great deal going on in the brain in order to produce perceptions from sensory signals: that our perceptions are created in us, and that they may be very different from the corresponding objects of the external world, as described by physicists.

Physical accounts of objects have changed greatly over the centuries, but without, in general, corresponding change in the appearance of the objects in question.

Objects *look* much the same whether they are believed to be made of billiardball atoms, or probability distributions of wave functions; so there must be discrepancies between the appearance and the scientific description— even though science depends on observation. Furthermore, there are *illusions, of many kinds, which are hard to reconcile with a 'direct' or 'immediate knowledge' account of *perception.

The notion that perceptions are *hypotheses*— perhaps much like the predictive hypotheses of science—derives from the account of perception given by Hermann von *Helmholtz (1821-94), who suggested

that perceptions are *conclusions of unconscious inductive inferences*. Introducing this idea, he compared visual perception with language, and how we learn language (see LANGUAGE: LEARNING WORD MEANINGS). Thus, Helmholtz (1866) points out that, as with meanings of words, 'the concept of the normal meaning of frequently repeated perceptions can come about with immutable certainty, lightning speed and without the slightest meditation.' Helmholtz continues:

The example of language is instructive in another respect, for it affords an explanation for the problem of how such a certain and conventional understanding of a system of signs may be obtained, considering that these signs can have only a quite arbitrarily selected effect upon the individual observer ... The child hears the usual name of an object pronounced again and again when it is shown or given to him, with the same word. Thus the word becomes attached to the thing in his memory more firmly the more frequently it is repeated.... The same name may become attached to a class of objects similar to each other, or to a class of similar processes. ...

I conclude from these observations that by frequent repetition of similar experiences we can attain the production and continual strengthening of a continually recurring connection between two very different perceptions, or ideas, e.g. between the sound of a word and visible and tactual perceptual images, which originally need not have had any natural connection; and that when this has happened we are no longer able to report in detail how we have arrived at this knowledge and on what individual observations it is based.'

Helmholtz stresses that the association of word with meaning, and of sensation with meaning in perception, comes from regular experiences of the Page 609

connection with no (or few) exceptions. In this way, meanings are built up *inductively* (from many instances to a conclusion that is not logically necessary), both for language and for perceptions. These associations are, presumably, built up largely by interaction with objects—so that, for example, the patterns of the grain of wood become associated with a hard substance which can be dropped without breaking, and which can be cut with a saw; and the transparency of glass becomes associated with potentially dangerous brittleness; in consequence, we behave very differently with wooden as opposed to glass objects. Helmholtz suggested that we come to our ideas of the physical form of objects inductively, by combining visual experiences from many viewpoints, following the rules of perspective. Comparing these 'inductive conclusions' with the scientific method, Helmholtz says: 'Inductive conclusions are never so reliable as welltested conclusions of conscious thought. ...

False inductions in the interpretation of our perceptions we tend to label as illusions.' Of these he says (1894) 'Obviously, in these cases there is nothing wrong with the activity of the organ of sense and its corresponding nervous mechanism which produces the illusion ... It is, rather, simply an illusion of the judgement of the material presented to the senses, resulting in a false idea of it.' He goes on to say, 'These unconscious conclusions derived from sensation are equivalent ... to [his italics]

conclusions from analogy'. He attaches a lot of weight to active structuring of perception, which is especially evident in conditions of dim illumination, or when complex crystals or other structures are

viewed stereoscopically:

a visual impression may be misunderstood at first, by not knowing how to attribute the correct depth dimensions; as when a distant light, for example, is taken to be a near one, or *vice versa*. Suddenly it dawns on us what it is, and immediately, under the influence of the correct comprehension, the correct perceptual image also is developed in its full intensity.... Similar experiences have happened to everybody, proving that the elements in sense perceptions that are derived from experience are just as powerful as those that are derived from present sensations.

In this connection, phenomena of *ambiguity* (which occur especially with vision and hearing) are clearly very important: 'Without any change of the retinal images, the same observer may see in front of him various perceptual images in succession, in which case the variation is easy to recognize.' For these and other reasons, Helmholtz thinks of perception as given by learning, and as *empirical*. It is not passive acceptance of stimulus patterns, but rather *projection* (though not merely geometrical projection) from internally organized knowledge of objects and processes. In current terminology, this may be termed use of stored knowledge 'topdown', for interpreting or reading sensory signals, as originating from particular objects. Similarly, we project our meanings of words on what we describe. The emphasis on processes searching for the best reading, or interpretation, on the available evidence, we call 'active'; in comparison with 'passive' accounts, such as that of J. J. Gibson.

It seems a natural development, to extend Helmholtz's account, by calling perceptions (which, not altogether happily, he called 'perceptual images'), rather, *perceptual hypotheses* (Gregory 1970, 1981). This suggests useful analogy with hypotheses in science, and the ways in which they are developed, used, and tested. That is not to say that perceptual hypotheses and scientific hypotheses are formed, or used, or tested identically; but they do seem to share strikingly significant similarities. Since the methods of science are open to inspection, they may provide a basis for considering processes of perception, which (as Helmholtz realized) are exceedingly hard to discover by direct methods, because they are hidden in brain processes that are only beginning to be understood; and also because they are unconscious.

It is generally accepted that science starts with inductively discovered associations and regularities, which may be conditional (glass breaks if it is dropped). These generalizations are used for *prediction* (the glass will break if it is dropped; it will rain when the temperature falls), and so for anticipating and planning—allowing intelligent behaviour. Only primitive behaviour is reflex from stimuli (see REFLEX ACTION); behaviour that follows the identification of objects is appropriate to their characteristics and potentialities—and these are generally not able to be sensed at the time. For example, the fact that glass is brittle has been established (at some cost) by experience in the past—and this fact is available now as knowledge, allowing appropriate perception of, and behaviour towards, it. It follows that a soap film or a perspex sheet, mistaken for glass, may be treated and seen inappropriately. Powers to predict are vitally important uses of hypotheses, both in science and in perception. In each case, prediction involves the application of analogies topdown from stored knowledge. In each case, also, it allows behaviour to continue with only partial, or even *no*, available sensed information, such as when we cross a familiar room in the dark. And the predictive

'look ahead' registers the speed needed, for example, to return a fast moving tennis ball, so that behaviour is not generally delayed by the physiological*reaction time (which Helmholtz was the first to measure).

The present is read from the past, to enable prediction and planning for the future. But, for perception, this applies only to the immediate future, generally less than one second ahead in time. Perception is remarkably fast, and needs to be, because unexpected events do happen, and they can be dangerous. In this respect, perception differs from science—and differs from our conceptual understanding. Indeed, it may be said that we have perceptual hypotheses and conceptual hypotheses of the world (and of ourselves), which

Page 610

are different, and which work on different timescales. The factor of differing timescales provides a clue to why perceptual and conceptual hypotheses differ, and why they may conflict. For it would be impossible to access the entire corpus of our knowledge for each perception, occurring in a fraction of a second. (This principle of small computers with restricted knowledge bases, without access to the main database, for rapid if tentative and approximate decisions, is now of necessity used in large computer systems.)

Perhaps the most dramatic separation between perceptual and conceptual hypotheses occurs in conjuring (Gregory, 1986)—a subject which, though extremely interesting, is not well studied by psychologists. During a successful conjuring trick, which may unfold quite slowly, the spectator sees events occurring which are either divorced from his understanding or are linked to some false understanding which generates predictions that fail to materialize.

We relate perception to conception by perceptually guided activities requiring understanding, such as making and mending things. Thus, the new development of hands-on science centres (such as the Exploratorium in San Francisco, the Toronto Science Centre, the Launch Pad gallery of the Science Museum in London, the Exploratory in Bristol, and others in France and in India) may help to enrich the perception of participants, by developing their understanding so that they appreciate in depth what they see, and so that they see more fully because they understand what they are handling and looking at. This has exciting implications for*education.

Hypotheses in the sciences are not only selected according to data: they also affect how data are selected and interpreted. This is true, also, for perception. Thus, the eyes are directed to what may be needed next, and to checking current perceptions, especially by checking predictions. But more subtly, as was shown by Ernst*Mach, apparently raw sensory data may be affected by the prevailing perception, with no change of stimulation involved—as in depthambiguous figures, or objects, such as Mach's card. This may be seen by folding a piece of card to form a corner, standing it on a table, and viewing it from a few feet away. It should be placed so that an inside surface is in shadow. The card will 'flip' in depth. When depthreversed, the shadow will appear as a mark or stain, and considerably darker.

This is because it is unlikely that an *outside* surface (as the inside shadowed surface now appears to be) would be in shadow. It is more likely that it is truly darker (has lower albedo) and this is how it appears when depthreversed as shadows are minimized by the perceptual system. So a basic, relatively simple sensation such as brightness, is affected topdown by the prevailing perception—or hypothesis—of the objects before the eyes. Topdown knowledge of specific classes of objects also has clear perceptual effects. For example, a hollow mask of a face, seen from a few feet away, and viewed with both eyes in normal lighting, does not *look* hollow, but appears instead as a normal nose sticking out face. Here, evidently the stored knowledge about faces is forcing rejection of the many and powerful

'bottomup' depth information cues (from stereoscopy, texture, shadows, and so on) signalling that the mask is hollow, in order to maintain what is usually a correct (though in this case incorrect) perception of a face. This happens only with very familiar objects which are virtually never reversed in depth, so this is a specific effect of 'topdown' knowledge. The same tends to happen in science when data contradict a well established hypothesis—for it may be more likely that the data are incorrect than that the hypothesis is wrong. This is one reason why it is (rightly) very difficult to refute firmly held hypotheses—and why prejudices can be useful.

Helmholtz wrote of the importance in perception of rules (such as the laws of perspective, for seeing distance and form), and rules and laws are of course central in scientific hypotheses. Rules of perception are emphasized in much of the recent work in computer vision (Marr, 1982), as algorithms for handling data. Such rules can produce even clearly impossible perceptions when they are applied from misleading data, or false assumptions. A simple example is the Impossible Triangle picture (Penrose and Penrose, 1958) and the corresponding three dimensional object (Gregory, 1970). (See ILLUSIONS, Fig. 8.) There are also many examples in Maurits Escher's pictures. These paradoxes are produced by the (false) assumption that features, which from a given viewpoint are seen as touching, are lying at the same distance or in the same plane, though in fact they are not. It may be noted that when similar juxtapositions in depth occur with separate objects (as in William Hogarth's engraving, the *Fisherman*, (1754), in which the woman leaning out of the window with a candle is apparently lighting the pipe of a distant walker on the hill, behind the house), this is not seen as a visual paradox—but rather an explicable joke. (See ART AND VISUAL ABSTRACTION.) It seems that such visual paradoxes from false assumptions only occur *within* objects and not *between* objects. Similarly, paradoxes from false assumptions in science probably only occur within a single descriptive system.

On this essentially Helmholtzian account, mind is seen as consisting of hypotheses of perception and understanding: hypotheses (as perceptual illusions) may be ambiguous, distorted, paradoxical, or fictional, and perhaps never close to truth; nevertheless the private hypotheses of perception and the shared hypotheses of conceptions make up our reality.

PERSONAL EQUATION. Several important characteristics of the human observer have been discovered by astronomers. Most celebrated is the 'personal equation': corrections applied to individual differences in response time in observing stars crossing graticule lines in transit telescopes. This was extremely important as clocks were set by these measures; in 1799 the Astronomer Royal at Greenwich, Nevil Maskelyne, dismissed his assistant, D. Kinnebrook, because Kinnebrook recorded stellar transit time almost a second later than Maskelyne did. The method used was James Bradley's (16931762) 'eye and ear' method. The observer looked at the clock, noting the time to the nearest second, and then counted seconds as he heard the beats of a pendulum while watching the star cross the telescope field. As it crossed the field, he noted the position of the star in relation to each of a series of parallel threads in the eyepiece. This task involved coordination between eye and ear, and judgement of the position of each thread. The method was supposed to be accurate to one or at least to twotenths of a second—so Kinnebrook's difference of eighttenths of a second appeared as such a gross error that Maskelyne concluded he had fallen into 'some irregular and confused method of his own'.

However, the German astronomer Friedrich Bessel (17841846) at Königsberg eventually heard of the incident and realized that there may be large personal differences. In 1820 Bessel compared himself with a colleague, Walbeck at Königsberg, by taking observations of ten stars on alternate nights, for five nights. Bessel observed them earlier than Walbeck, there being an average difference of 1.041 seconds between them. This difference was so large that there may have been an error of method—but nevertheless it stimulated research. When the chronograph was invented in 1859 absolute response times could be made; and observations were corrected accordingly.

It seems clear that, in this complicated task at least, there is a major element of*anticipation in response to a stimulus. If the importance of anticipation had been generally realized, the history of experimental psychology would have been very different—for the immensely (indeed seductively)

powerful stimulus-response paradigm would surely not have been accepted as the basis of perception and behaviour. See also REACTION TIMES.

PERSONAL IDENTITY. In ordinary everyday affairs we are sometimes concerned with questions of personal identity. The police, for example, may want to know whether the man they have detained is the man who broke into the cricket pavilion. It may be a difficult question to answer. Perhaps the fingerprints on the doorjamb were smudged. But the difficulty is not of a sort which calls for reflection on what is meant by 'personal identity'. For the police, questions like 'Is this the same person?' are practical questions, not conceptual ones. The questions and answers involve the criteria of personal identity, but they are not about the criteria.

Conceptual questions about personal identity may arise either from philosophizing which throws in doubt our ordinary practice with 'Is this the same person?' question, or from extraordinary cases, real or imaginary, where the 'Is this the same person?' question cannot be answered on the basis of our ordinary practice. It is not unusual for philosophers writing on personal identity to refer to extraordinary cases with a view to persuading their readers that one sort of consideration should be treated as decisive. The contrast is usually between a mental criterion, such as *memory, and a bodily criterion.

The philosophizing which preeminently throws in doubt our ordinary practice with 'Is this the same person?' question is that of *Descartes, though the questions about personal identity to which his philosophy gave rise came to the fore only in the writings of his successors, in particular John *Locke (*Essay concerning Human Understanding*, bk. II, ch. xxvii) and David *Hume (*Treatise of Human Nature*, bk. I, pt. iv, sect. 6). To understand how Descartes came to set the scene for Locke, Hume, and subsequent philosophers writing on personal identity, it is necessary to sketch, very briefly, the relevant part of his philosophy.

Descartes was concerned, among other things, to replace the medieval, largely Aristotelian, conception of the world as inhabited by a multitude of things programmed teleologically according to their various fixed intelligible essences. For *Aristotle, as for *Plato, the paradigm of explanation was mathematical. The relations of numbers are necessary relations, and knowledge is of what is necessarily, and therefore unchangingly, the case. But despite their efforts, possibly inspired by the Pythagorean discovery of the numerical basis of musical concordances, to bring numbers and nature together conceptually, they remained distinct, with the result that science was not proof against scepticism. Descartes saw a way of reading the necessity of number relations into nature. He had invented analytical geometry, which shows how every geometrical object or relation can be

given numerical expression. It follows that if the extension of spatial, i.e. physical, objects is the extension of geometrical objects, and if 'matter' is defined in terms of this extension, then matter is thereby brought into the domain of what is necessarily true. Nature, *qua* matter, becomes through and through numerical. There were problems— such as how one bit of matter can exclude another bit of matter from the same place if there is no more to matter than extension—but Descartes thought they could be dealt with without having to add something nonnumerical to the definition, such as solidity. But one major problem remained. It does not follow from the truths of arithmetic and geometry being necessary that science is proof against scepticism. There is still a gap between justified subjective certainty and objective necessity. Descartes needed to find a criterion whereby he could recognize those things of which he could justifiably claim to be certain. He found it via the intuition 'I think, therefore I am'. This, he thought, is true without a shadow of doubt. What assures me of its truth is my clear and distinct perception of it. Provided there is not an allpowerful malicious demon who makes things appear clear and distinct to me which are not, I can therefore adopt this as my criterion.

Now, Descartes thought that someone who thinks 'I think, therefore I am' is certain not only that this thought is occurring but also that there is a being which thinks the thought. He went on to consider whether there is more, essentially, to this being than that it is capable of thought. Specifically, is it essentially a being with a body? He argued (fallaciously, according to many critics both contemporary and presentday) that it is not. Accordingly, he dismissed, as philosophically naive, what he described as 'that notion of the union of soul and body which everybody always has in himself without doing philosophy—viz., that there is one single person who has at once body and consciousness'. His own notion of a person was that of a particular thinking being which happens to be, but could equally well not be, united with a particular body. The significance of his replacement of our ordinary notion of a person with that of a thinking being which just happens to be united with a body is that it allows for the question 'How are such beings to be identified, and reidentified, if not by reference to the bodies they happen to occupy?'

Our ordinary practice with 'Is this the same person?' question is geared to the notion everybody always has of themselves, the notion that there is one single person who has at once body and*consciousness. It is not geared to the notion of a person as a being for whom a body is not conceptually necessary. Assuming that the question still makes sense, we need a new practice with 'Is this the same person?' to go with the new notion. Obviously it will be a very different practice. Given the origin in Descartes's philosophy of both questions, we may expect it to be rather like trying to find a meaning for 'Is this the same bit of matter, or has another, of exactly the same shape and size, taken its place?', with 'matter' defined solely in terms of extension.

Probably the most revealing attempt to find a meaning for 'Is this the same person?', with 'person' defined in the new, nonbodyimplying way, is that by Hume. He reformulates the personal identity question as the question 'whether in pronouncing concerning the identity of a person, we observe some real bond among his perceptions, or only feel one among the ideas we form of them'. This is revealing precisely because the question has been transformed into one a person can ask only about himself. Only he is aware of 'his perceptions'. So it is no longer the sort of question that could, on occasion, truthfully be answered with 'No; it is somebody else'. The sort of answer now catered for is 'There is a real bond among my perceptions' or 'There is no real bond, only a felt one'. It has become

a question about the unity of a person's consciousness rather than what we ordinarily understand as a question about someone's identity.

Hume opts for there being only a felt bond. There is felt to be a bond because causal relations exist between a person's experiences. 'The true idea of the human mind, is to consider it as a system of different perceptions or different existences, which are linked together by the relation of cause and effect, and mutually produce, destroy, influence, and modify each other.'

Ordinarily we would think of any causal relations between different experiences as following from their being the same person's experiences, with telepathy as a possible exception to the rule. Hume, if the question about the unity of consciousness is regarded as being one about personal identity, tries to reverse that conceptual order. It is hardly surprising that (in the Appendix to the *Treatise*) he should write: 'Upon a more strict review of the section concerning personal identity, I find myself involved in such a labyrinth, that, I must confess, I neither know how to correct my former opinions, nor how to render them consistent.' He has reaped the harvest sown by Descartes.

Locke says that 'personal identity consists ... in the identity of consciousness'. By 'consciousness' he means something that can be 'interrupted by forgetfulness', but also something that can be 'extended back' to actions done by people long since dead and buried. Locke says that a person who extends his consciousness back to actions done by someone in the distant past 'finds himself the same person' as the person who performed the actions. Exactly what he means by this is debatable, and has been debated at considerable length, but there is no doubt what question is most frequently raised by what Locke says on the subject. It is: 'Could memory be the sole criterion of personal identity?'

The standard argument against an affirmative

Page 613

answer is one which draws attention to the conceptual grammar of the word 'remember'. If a child says he 'remembers' being in a certain place at a certain time, and he was seen to be somewhere else at that time, we say he is wrong. It is part of the concept of remembering that we take what can be seen, the physical presence or absence of a person, as relevant to whether or not he really remembers something. Hence memory could not be the sole criterion of personal identity.

Given that our talk of personal identity is against the background of using a bodily criterion, what should we say if someone claimed to remember having been at some place before he was born, and his memories of it proved to be uncannily accurate? Can there be exceptions to the rule? We can have exceptions to the rule that promises are kept, and still understand what it is to make a promise. Is it the same with personal identity? Is reincarnation conceivable? This is only one of many extraordinary cases, real or imaginary, which may be said to call for decisions that are not implicit in our ordinary practice with 'Is this the same person?' questions.

Another whole range of such cases arises if we consider the possibility of transplanting brains, and, especially, of bisecting a brain and performing a dual transplant, so that two people claim to

remember doing what one person did. Are they both identical with the earlier person, and so with one another?

Two distinct approaches to such extraordinary cases are possible. We can regard the concept of personal identity as being like an Aristotelian essence, that is, such that if only we had sufficient intellectual insight into it we could see what the answer should be. Or we can say that the concept of personal identity we have is one which goes with the criteria we employ, coinciding in the vast majority of cases, and that if they were to start failing to coincide then the concept we have would become incoherent. Whether the conditions would exist for us to have a new concept, perhaps 'psychological continuity', which took over some of the uses of the old one, is debatable. There are lessons to be learnt from Hume in this regard.

PERSONALITY DISORDER. F. H. Allport in *Personality: a psychological interpretation*, reviewed some fifty definitions of normal personality, and it will come as no surprise to learn that definitions and typologies of personality disorder are almost as diverse. Generally the concept of abnormal personality refers to the affective and conative qualities of the individual, the mentally handicapped being omitted from further discussion. The boundary between personality deviation and neurosis is not easily defined, as most neurotics will have shown abnormalities of temperament that are relevant to the onset and form of their illnesses. Karl Jaspers made a distinction between personality development and disease process or psychosis. Those who have claimed some measure of continuity between personality and psychosis overlooked the lack of relationship between *the form* of the psychosis and the individual's premorbid qualities. Anxious personalities, for example, may well develop an anxiety or phobic neurosis but their symptoms do not progress to psychotic delusions and hallucinations. Like most attempts at making clearcut distinctions and definitions, the separation of psychosis from personality disorder on the one hand and the continuity of personality and neurosis on the other does not cover all the possible variants of psychiatric illness. The paranoid personality, whose suspicions and accusations may border on the delusional, may develop a psychosis whose content and form appear to be directly related to the subject's premorbid temperament.

Two measures of normality can be applied—the statistical and the ideal. Reliance on the latter results in some of the unattainable states of mind covered by the term

'mental health'. Hence one falls back on statistical measures which make the assumption that human traits and characteristic modes of behaviour are normally (Gaussianly) distributed in the population.

For example, it is natural to feel moderate anxiety when faced by a threatening situation. Some individuals, however, presumably placed at the top end of the Gaussian curve of the distribution of the trait for anxiety, respond to stresses, however slight, by the generation of excessive amounts of fear—the anxiety-prone personality. None the less, definitions of what is abnormal must be made, taking into account the cultural background of the individual whose behaviour may be unremarkable in one society but grossly deviant in another. For example, the degrees of paranoia and suspiciousness which appear to be endemic amongst the Dobu (Ruth Benedict, *Patterns of Culture*, 1946) would be quite abnormal in most Western civilizations. But, then, the Dobu are very efficient poisoners ...

K. Schneider (1958) described ten varieties of abnormal or psychopathic personality. The degree of overlap between these subgroups is considerable and the differences at times are not easy to discern. For example, the major traits of the affectionless and the explosive*psychopath clearly have much in common. For the purposes of discussion, the rather simpler classification of abnormal personality suggested by Curran and Mallinson (1944) seems preferable to Schneider's. They recognized three major classes of psychopathic personality: the vulnerable, the unusual or abnormal, and the sociopathic. The term 'unusual', omitting those with deviant sexual behaviour, relates to five major

Page 614

anomalies of personality: the schizoid, the cyclothymic, the hysterical, the obsessional, and the paranoid. None of these subdivisions is wholly separate from the others as they tend to overlap, as they do with neurosis and psychosis. The predominant characteristics of these variants of personality are described in most textbooks of psychiatry and psychology but some further comments are required to clarify some of their meanings.

Vulnerable personalities are individuals with a low capacity for coping with ordinary stresses and strains of everyday life. Sometimes the word 'inadequate' is applied to this kind of constitutional weakness but its use will obviously vary according to the individual's circumstances and the attitudes of the person who employs it. It is a word carrying overtones of disapproval and, therefore, best omitted from clinical nomenclature. As might be expected, the vulnerable personality is more liable to suffer from neurotic illness, particularly anxiety and phobic states. The word 'hysterical' in this context is unfortunate as persons so labelled do not necessarily suffer from the classic forms of hysterical neurosis (see HYSTERIA). Schneider preferred the term 'attention-seeking' and others have used 'histrionic' to indicate the self-dramatizing qualities of the person with this variety of personality disorder. It is a word more often used to describe women than men. Indeed, the qualities of the hysterical person are sometimes said to be a caricature of femininity.

Various mental mechanisms have been invoked to account for the different personality disorders. For example, the mechanism of projection is generally held to be basic to the behaviour and thinking of the paranoid personality. Repression and dissociation may be more important for the development of the symptoms of classic conversion hysteria, but such a formulation is probably less relevant to the characteristic behaviour of the hysterical personality. Obsessional personalities show a rigidity of mental structure which may be regarded as a defence against strong instinctual drives. (See also OBSESSIONS AND COMPULSIONS.) Although some individuals with marked personality disorder

suffer on that account, this is by no means an invariable consequence. For example, an obsessional temperament may be vital for the successful prosecution of enterprises requiring meticulous attention to detail. The sociable, energetic qualities of the cyclothyme may enable him to push through profitable schemes in industry which are beyond the scope of his more cautious colleagues.

The psychopathic or sociopathic personality has been discussed elsewhere and will not be described in detail here beyond noting that German authors use the word

'psychopathic' to denote all varieties of abnormal personality.

PERSONALITY TEST. There is a long tradition of attempts to define the more or less permanent characteristics, or temperaments, of individuals which arise out of their physical constitutions, and to which the behaviour tendencies observed in them can be related. Interest in this field was revived as a result of the work in the 1930s of R. B. Cattell, who distinguished the two groups of temperament traits, surgent and desurgent, corresponding to what C. G.*Jung had called extravert and introvert, and in the 1950s of H. J. Eysenck, who developed methods for assessing degrees of 'neuroticism' and 'extraversion'. (See NEUROSIS and EXTRAVERSIONINTROVERSION.) Both used tests in the form of questionnaires or rating scales that required subjects to respond to carefully phrased questions about themselves, the data thus assembled being analysed by elaborate statistical techniques to provide scores indicating the strength of the factor in each individual. However, the results of research in this field have had little impact on the development of psychology, whether in the laboratory or in the clinic. One reason for this has been the relatively low reliability (i.e. reproducibility) of the data; another, the controversial nature of the statistical techniques. There are formidable difficulties too in generalizing from responses made in the miniature situation of a test to make predictions about behaviour in the complex social setting of real life.

PHANTOM LIMB, See SPATIAL COORDINATION OF THE SENSES.

PHENOMENOLOGY is a term used in philosophy to denote enquiry into one's conscious and particularly intellectual processes, any preconceptions about external causes and consequences being

excluded. It is a method of investigation into the mind that is associated with the name of Edmund*Husserl, as it was he who did most to develop it, although when Husserl's system appeared on the philosophical scene, the word already had a long history and had undergone a conspicuous semantic evolution.

The first use of it goes back to Johann Heinrich Lambert (1728-1777), a disciple of Christian Wolff (1679-1754). Lambert published in 1764 a treatise on epistemology dealing with the problem of truth and illusion, under the rather pedantic title of *Neues Organon oder Gedanken über die Erforschung des Wahren und der Unterscheidung von Irrtum und Schein* (New Organon, or Thoughts on the Search for Truth and the Distinction between Error and Appearance), in the fourth part of which he outlines a theory of illusion that he calls 'phenomenology or theory of appearance'.

Page 615

Although he belongs to a period in the history of philosophy in which the question of the intuition of essences had not yet been raised, his implicit definition of phenomenology, taken literally, does not sound odd to the postHusserlian reader; except that to him, Lambert, an appearance (or phenomenon) is necessarily an illusion. More important, Lambert was acquainted with*Kant, and Kant in 1770 was writing to him about the need for a 'general phenomenology' which he conceived as a preparatory step to the metaphysical analysis of natural science. According to Spiegelberg (1960), what Kant called phenomenology was in fact synonymous with his idea of the critique of pure reason, though nothing allows us to suppose that he specifically used the term forged by Lambert to qualify phenomena as antithetic to noumena or things in themselves.

It is, however, with*Hegel's *Die Phänomenologie des Geistes* (Phenomenology of the Mind), published in 1807, that the term is used explicitly for the first time to label a philosophical work of fundamental importance. A significant step in its evolution from Lambert to Hegel may be found in J. G. Fichte's *Wissenschaftslehre* (Theory of Science), in which its role is to establish the origin of phenomena as they exist for*consciousness; and in Hegel's elaborate system, its basic task is primarily historical since it aims at discovering the successive steps of realization of selfconsciousness from elementary individual sensations up to the stage of absolute knowledge through dialectic processes.

The few authors worth mentioning who dealt with phenomenological problems between Hegel and Husserl are William Hamilton (1788-1856), who in fact equates phenomenology with psychology as opposed to logic, Eduard von Hartmann (1842-1906), whose studies on religious, ethical, and aesthetic consciousness were greatly inspired by Hegel's phenomenology, and, to some extent, Charles Sanders*Peirce, though his work on the classification of phenomena belongs more to*metaphysics than to an actual phenomenology of subjective experience. Except in the case of Hegel, phenomenology was not a major field of reflection until Husserl's monumental work.

Since Husserl's transcendental phenomenology is discussed in some detail in the entry under his name, it will suffice here to underline its distinctive features. In contrast with preexisting philosophies, it is no mere, closed, abstract construct that theoretically allows the philosopher to

pronounce on the conditions of principles of experience; it is rather an endless attempt to stick to the reality of experienced phenomena in order to exhibit their universal character. In order to succeed in the endeavour, Husserl has to discard the classic dualistic view, according to which the knowing subject reaches the world only through representation—a position typical of rationalistic and idealistic systems. Hence he refers, after**Brentano*, to the *intentional* character of consciousness, and condemns psychologism (the theory that psychology is the foundation of philosophy) in view of the contradiction it brings about: that the supposedly universal laws of logic and mathematics would be dependent on the concrete functioning of psychological mechanisms.

The Husserlian standpoint is thus a radical one, since it aims at 'going back to the things themselves' by claiming that there is no reason to suppose that phenomenon and being are not identical. In other words, the *noema* (object content) and the *noesis* (knowing act) are directly related by the**intentionality* of consciousness, so that every phenomenon is intuitively present to the subject. However, phenomena, as they are grasped by the subject, are always given under a particular *profile*. No object whatsoever is given in its totality as a simultaneous exhaustible whole, but every profile *conveys* its essence under the form of meaning for consciousness. In order to reach the essence of any object, one is bound to proceed to unceasing variations around the object as thematic reality, i.e. to discover the essence through the multiplicity of possible profiles. This procedure applies to all phenomena, ranging from current perceptual experience to the highly intricate constructs characterizing the various fields of knowledge, such as physics and psychology.

Every phenomenon belongs to a regional ontology by virtue of its essence, as revealed by the so-called *eidetic intuition*, the essence (*eidōs*) being the sum of all possible profiles. In the course of this process, consciousness operates as a *constitutive* moment, i.e. its activity in grasping the essence of phenomena is, perforce, part of the process of their emergence. Thus Husserl overcomes the classic dualism of subject and object. Reaching the universal essence of an object through eidetic intuition, i.e. discovering the basic structure implied by its very existence, is a process which Husserl calls *eidetic reduction*. This being granted, the next step consists in referring phenomena to subjectivity without falling back into psychologism, since the empirical subject, as referred to psychology's own regional ontology (or**Descartes's res cogitans*), belongs to a realm of contingent being, which cannot furnish by itself the necessary foundation for the organization of the absolute principles governing universal essences. Husserl is therefore bound to exclude belief in the natural world as the ultimate reference of all our intentional acts. This process is termed *phenomenological reduction*. It presupposes, in Husserl's terms, a provisional 'bracketing' (*Einklammerung*) of the natural and a description or explication of our intentional acts as referred to pure noematic structures. The final accomplishment of this process is the transcendental reduction, by which the fundamental conditions of every possible meaningful intentional relation must be elucidated. This is the core of Husserl's theory of transcendental subjectivity or *transcendental ego*.

Thus Husserl's phenomenology reconsidered

the philosophical problem of consciousness in a radical fashion and contributed thereby to the placing

of psychology—and the human sciences in general—within a new epistemological framework. Criticism of the onesidedness of both empiricist and idealistic standpoints could be developed so that the shortcomings of dualistic views, with all their derivatives such as mechanicism, parallelism, and phenomenism, became more apparent. As a fundamental theory of phenomena ranging from perception to creative thinking, it has provided a firm startingpoint for the integration of concepts of the subject at different levels: hence phenomenologically inspired hypotheses such as those which guided F. J. J. Buytendijk and V. von Weizsäcker in anthropological physiology. The French philosopher Maurice MerleauPonty's analyses of the experienced body (1942) and perception (1945) were phenomenological works that contributed to the transforming of the classical standpoints in psychology.

PHOBIAS. Persons to whom the label 'phobic' is applied fall into two main groups: (i) those who respond with unusually intense*fear to a specified situation, for example to animals of a certain species, but who show no other symptoms; and (ii) those who exhibit unusually intense fear in a number of situations, often difficult to specify. Whereas those in the first group are in general emotionally stable, those in the second are not; they are prone to bouts of fairly acute*anxiety and*depression which may last weeks or months. They are often reluctant to leave home, and are described as agoraphobic if adult or as school phobic if children.

Attempts to explain the origin of phobias have been of two main kinds. One, the learning theory approach, holds that when a person is intensely afraid of something that others do not particularly fear, it is because the object or situation in question has become associated in his mind with a childhood fear, as of loud noises or falling.

The other, the psychoanalytic approach, holds that the feared object or situation has become symbolic of something feared unconsciously. In the case of the 5yearold boy, Little Hans, who was afraid to go out of the house for fear that a horse would bite him, the explanation offered by Sigmund*Freud was that Little Hans's fear resulted from the repression and subsequent projection of his aggressive

impulses, comprising hostility directed towards his father and sadism towards his mother, and that 'the motive force of the repression was fear of castration'. Empirical studies have given little support to either of these theories.

Research shows that specific and limited phobias have usually been present from early childhood but are normally diminished during adolescence. Since the fear is specified, treatment by means of desensitization is often appropriate. (See BEHAVIOUR THERAPY.) The states of mind labelled agoraphobic, or school phobic, are much more complex than the specific phobias. These two conditions are closely related and are probably due to the same causes. Children who are school phobic, and nowadays referred to as school refusers, generally express much anxiety when pressed to attend school, their nonattendance being well known to their parents. Not infrequently their truancy is accompanied by, or masked by, psychosomatic symptoms of one kind or another: anorexia, nausea, abdominal pain, or feeling faint, for example. Fears of many kinds are expressed—of animals, of the dark, of being bullied, of mother coming to harm, of being deserted. Occasionally a child seems to panic, and anxiety, tearfulness, and general misery are common. As a rule, the children are inhibited and well behaved. Most come from intact families, have not experienced long or frequent separations from home, and have parents who express great concern for them and their refusal to attend school. Relations between child and parents may be close, sometimes to the point of suffocation.

There is now general agreement that the refusal is much more to do with anxiety about leaving home than fear of what might happen at school. Why do they have this fear of leaving home? Among the many explanations suggested, those best supported by evidence point to trouble within the family. For example, in some cases one or the other parent, most often the mother, is a sufferer from chronic anxiety and is glad to have the child at home as a companion. In others a child becomes alarmed about what might happen at home during his absence and stays there to prevent it. In some cases both these influences are active. We examine each further.

A mother (or father) who retains a child at home may do so deliberately and consciously or may be completely unaware of what she is doing—and why. In either case she is commonly found to have had a difficult childhood and to be seeking from her child the affection and security she herself had lacked. In doing this she is inverting the normal parent-child relationship—requiring the child to act as parent whilst she becomes the child. To someone unaware of what is going on, it may appear that the child is being spoiled, but a closer look shows the reverse: the mother is in fact placing a heavy burden on her child. It is sometimes found, moreover, that a parent who is treating her child in this way swings abruptly from a genuine concern for his welfare to hostility and threats. Thus, if the Page 617

child is to be helped, the parent must be helped to change. How best to do this is considered later.

In cases of a child staying at home for fear of what might happen while he is away—for example, he may be afraid of some harm coming to his mother—the problem is one of explaining why a child should think like that. Among psychoanalysts it has been usual to attribute the trouble to the child's harbouring unconscious hostile wishes towards his parent and being afraid lest his wishes come true. An alternative explanation is that the fear arises from actual events to which the child is being

exposed: for example, (i) an illness of his mother's which the child is afraid may prove serious or even fatal; (ii) the death of a close relative or neighbour that leads the child to fear his mother might die also; (iii) threats or even attempts by the mother to commit suicide (which occur far more frequently than is usually realized); (iv) threats by a parent to abandon him, used as a disciplinary measure. (Little Hans's mother is reported to have used various threats to discipline him, including threats that she would go away and never return.)

A first task in helping a child who remains at home is to get his parents to recognize any part they may be playing and to change their ways. Depending on the part played and on the nature of their own problems, this may be easy or difficult. A mother prone to invert her relationship with her child can often be helped to release him if she is treated with sympathy. When encouraged to talk about her own childhood, she is likely to tell of unhappy experiences of certain specific kinds: for example, the loss of her mother by death or desertion; long absences from home in an institution, hospital, or foster home; having been an unwanted child; being threatened with abandonment; or witnessing a parent threatening or attempting suicide. She has grown up anxious not to lose anyone to whom she becomes attached and tends therefore to cling tightly to them. A person who has developed in this way is often called 'overdependent' or 'immature' but is far more appropriately described as anxiously attached (in contrast to securely attached; see ATTACHMENT). Similarly, in cases of mistaken disciplinary measures, a parent may be helped to stop threatening the child when he or she appreciates the ill effects this has.

Most of the research on adults who are diagnosed as agoraphobic has neglected systematic study of what is happening in their families. In such study as has been undertaken, it is commonly found that the sufferer, usually a woman, is being subjected to the same sorts of pressure as the schoolrefusing child, and usually from the same source, namely her mother (though sometimes it is from the father or husband). Once established, the condition may persist even after the pressures that led to it have ceased.

One variety of adult agoraphobia was described by M. Roth in 1960 under the title of the phobic anxiety depersonalization syndrome. The majority of victims were middle-aged housewives who, often after a sudden traumatic experience, developed intense anxiety associated with feelings of unreality and depersonalization.

Thereafter their ability to go shopping alone was severely curtailed, especially if they were required to travel by public transport. Once inside a large store or supermarket they would become assailed with intense panic requiring their immediate departure from the shop. Their fears of travel and situational phobias could to some extent be allayed if accompanied by another person, even one of their children. The term 'housebound housewife syndrome' has come to be used for this variety of phobic anxiety. Further study of the family experiences, past and present, of these women is called for.

PHONETICS, the science of speech sounds, is traditionally divided into two branches: *acoustic*, concerned with the structure of the acoustic signal itself, and *articulatory*, concerned with the way these sounds are produced. The most important initial impetus was to develop a standard means for the accurate and convenient transcription of the sounds of various languages and dialects. Proper transcription was regarded as an essential tool for field linguists and missionaries dealing with new languages, and for recording dialectal variations of known languages (and 'correcting' them—e.g. Henry Sweet, 1908). The idea of an International Phonetic Alphabet (IPA), suitable for all languages, was first suggested by Otto Jespersen in 1886; the International Phonetic Association (which included Paul Passy and Sweet, as well as Jespersen) published the first IPA in 1888. This was based on the articulatory features of the sounds: the place of maximum constriction of the vocal tract, the manner of the constriction (completely closed for consonants like /p/; with the nasal passage open for consonants like /m/, etc.) and the onset of voicing (immediate in the case of /b/, but delayed for /p/). Daniel Jones's classification of the 'cardinal vowels' was similarly based on articulatory features, the height of the tongue, front or back of the mouth, with lips rounded or unrounded. The IPA system enables the transcription of sound distinctions which have no significance for the speaker of one language, though they do for the speaker of another. Thus the initial consonants in 'key' and 'cool' can be heard, and felt, to be different but do not, in English, constitute different phonemes (units of significant sound); in Arabic they do.

Although methods of analysing the frequency components of the acoustic signal had been known since*Helmholtz in 1862, no convenient way of plotting frequency, energy, and time was available until the development of the 'sonograph' in the 1940s by R. K. Potter and others. The analysis of the movement of the vocal organs during speech

Page 618

has in recent years been advanced by the use of highspeed film to record the opening and closing of the vocal folds during phonation (though the earliest use of this technique can be traced back to 1913) and by cineradiography (Perkell). Two surprising and paradoxical results have emerged from these methods of acoustic and articulatory analysis: first, there is no simple correspondence between acoustic parameters and the phenomenological sound. The English phoneme /d/, for example, has a quite different sound depending on the vowel that follows it. Second, there is no simple correspondence between the sound and vocal action used to produce it.

These fundamental puzzles have motivated the growth of experimental phonetics, which combines sophisticated analysis and synthesis of speechlike sounds with the investigative procedures of experimental psychology, with the aim of discovering which abstract characterizations of acoustic dimensions are critical in determining the sound contrasts meaningful in language (A. Liberman; K. N. Stevens). That is to say, what kinds of representation underlie the perception and production of spoken language?

B. L. B.

PHRENOLOGY, from the Greek words for 'mind' and 'discourse', is about reading character from the shape and especially from the 'bumps' of the skull. This has also been called 'cranioscopy', 'craniology', 'zoonomy', and '*physiognomy', though the last usually refers to reading character from faces. Phrenology was popular from the middle of the eighteenth to the middle of the nineteenth centuries; its principal proponents were Franz Joseph*Gall (17581828), who was a physician in Vienna and a more than competent anatomist (he was the first to distinguish the functions of the 'white' and the 'grey' matter of the brain); and Gall's student, Johann Kaspar Spurzheim (17761832), who with the controversial Scottish moral philosopher George Combe (17881858) spread the doctrine to England and America. It had such a vogue that by 1832 there were twenty-nine phrenological societies in Britain, and many journals in Britain and America, including the *Phrenological Journal*, a quarterly edited by Combe at Edinburgh from 1823 to 1847. There was, however, much criticism, such as from the philosopher, and early proponent of associative psychology, Thomas Brown (17781820), and phrenology was often lampooned in verse and on the stage.

Gall claimed to have discovered his phrenological principles inductively from people (and animals) of his acquaintance who had marked character traits associated with distinctive skull shapes, or 'bumps' that could be felt with the fingers. For example, the region he numbered as 1—Amativeness (*Instinct de la génération*), at the back of the head below the inion—he identified from its heat in a hysterical widow. Just above this region is No. 2—Philoprogenitiveness (*Amour de la progéniture*)—which Gall selected as the organ for the love of children because this occipital part of the skull is prominent in women and apes, in whom the love of infants is supposedly stronger than in men. To take an intellectual example: No. 22 (individuality), immediately above the nose, was named as the organ for recognizing external objects and for forming ideas from being large in Michelangelo and small in the Scots.

The twenty-six regions identified as personality organs by Gall (increased to as many as forty-three by later phrenologists) were based on very few instances.

Implausible excuses were made for exceptions; and for such matters as inability to distinguish the skulls of saints from those of sinners. Phrenology does, however, have considerable importance in the history of psychology and brain studies. Even its obvious failures are revealing.

Phrenology is based on the notion that mind is intimately related to physical brain function. It is thus opposed to Cartesian mind-brain dualism, and is in line with much modern neurological thinking, and with 'identity' accounts, which suppose that mind is an aspect of brain structure and function. Phrenology implies some kind of*localization of brain function; though what are thought to be localized in the brain, as read from the 'bumps', are *complete traits* of ability and character, rather than *processes* generating characteristics of behaviour and intellect. The implied notion of brain 'organs', such as Veneration, Wonder, Wit, Tune, Language, Memory, Vanity, Cautiousness, and so on, is misleading, because these depend on many underlying processes which, as we now know, are widely separated and in many cases never appear in the 'output' of the brain. Nevertheless, we do still speak of 'speech centres' (see LANGUAGE AREAS IN THE BRAIN), and evidence for speech in prehuman and early human skulls is sought from bumps in casts corresponding to those anatomical features associated with language in modern man.

Phrenology made psychological classifications which still survive. Spurzheim grouped human faculties in the following way: I. *Feelings*, divided into:

1. Propensities (internal impulses to certain actions).
2. Sentiments (impulses prompting emotions as well as action).

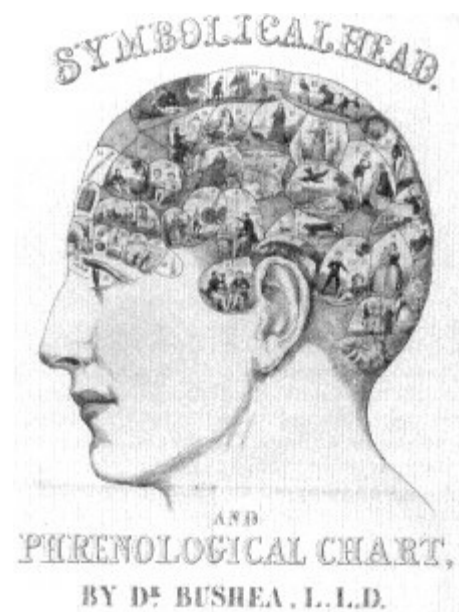

(i) Lower: those common to man and the lower animals.

(ii) Higher: those proper to man.

II. *Intellectual faculties*, divided into:

1. Perceptive faculties (knowledge by observation and through language).
2. Reflective faculties (knowledge by intuition and reasoning, especially by noting comparisons).

Although the phrenologists accepted and formulated*faculty psychology, they did not contribute

Page 619

to brain anatomy. This, in part, was because they did not say, simply, that the larger the 'bump' the greater the characteristic. Thus Spurzheim writes, in *Phrenology: in connexion with the study of physiognomy* (1824), under the heading 'Of the Heads of the Sexes': The body and face vary in the two sexes. Do their brains differ likewise? The talents and feelings of the male and female are commonly considered as dissimilar; indeed it is proverbially said that women feel and men think. The majority of modern authors, however, have attributed the phenomenon to the modified education which the sexes receive.

The female head is smaller than that of the male; it is commonly narrower laterally. The female cerebral fibre is slender and long rather than thick.

He continues:

Lastly, and in particular, the organs of philoprogenitiveness, of attachment, love of approbation, circumspection, secretiveness, ideality, and benevolence, are for the most part proportionately larger in the female; while in the male those of amativeness, combativeness, destructiveness, constructiveness, self-esteem, and firmness predominate.

But he then argues:

I say that the heads of men are wider than those of women, and then I state that I consider circumspection and secretiveness, whose organs lie laterally, as more generally active in the female than in the male. They who make this objection do not understand the phrenological principle, according to which the organs which are most largely developed in every individual display the greatest energy, and take the lead of all the other powers. Now, although the female head be so commonly narrower than the male, the organs of secretiveness and circumspection are still the most prominent, and thus contribute essentially to the formation of the female character.

Spurzheim concludes that phrenologists examining innate dispositions 'do not compare the heads of the sexes together, nor even those of the same sex; they judge of every head individually, and form conclusions in regard to the dispositions generally, according as the respective faculties are developed'.

The phrenologists generally stressed innateness of faculties. Spurzheim, while admitting that the education of the girls of his time was inferior to that of boys, argues that

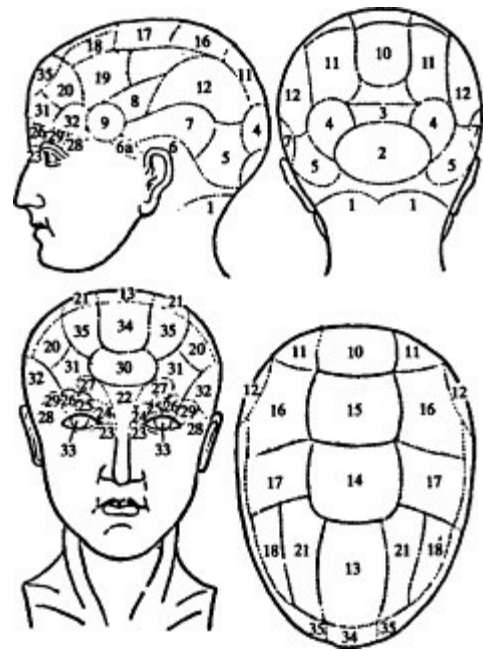

'girls are more commonly instructed in drawing, painting, and music than boys', and often spend much time at these occupations; 'nevertheless, no woman has hitherto produced such works as those of Handel, Mozart, Haydn, Titian, Rubens, Paul Veronese, Canova, and so many others'. He adds: 'The female sex appears to greater advantage in actions which result from feeling.' Now this argument depends on the assumption of faculty psychology, that skills such as painting are developed simply by practising that particular skill. But it is possible that other, and perhaps traditionally male, activities transfer knowledge and abilities to give males an advantage even for skills such as painting which are frequently practised by girls. This possibility could hardly have been considered by proponents of a faculty psychology based on localized organs of behaviour and personality.

Phrenology seemed to give promise of objective assessments and judgements of people; it was even proposed to select Members of Parliament from candidates having propitious bumps. It was suggested, as a joke, by the distinguished editor of *Blackwood's Magazine* and professor of moral philosophy at Edinburgh, John Wilson ('Christopher North'), that children's heads should be moulded—to accentuate their good qualities and remove evil. The suggestion was taken up by several practising phrenologists.

With the advent of experiments in which small regions of brain were removed, by careful operations pioneered by the French physiologist Pierre*Flourens, and by electrical stimulation with fine wires,

electrodes, pioneered by Gustav Theodor Fritsch (1838-97) and Julius Eduard Hitzig (1838-1907) on the 'motor cortex' of dogs (1870), it at last became obvious that functions are localized; but that localized functions are not simply related to behavioural skills, or to mental attributes or abilities.

However, although this became clear to many physiologists towards the end of the nineteenth century, it was resisted by some, and especially by the members of the *Gestalt school of psychology, who held that the brain works holistically, with perception given by perceived objects represented 'isomorphically' as brain traces like pictures; so that circles are represented by circular traces, houses by houseshaped traces, and so on. This was a rejection of functionally interacting processes of analysis and of inference-generating perceptions, in favour of notions more like those of the phrenologists. And such ideas die hard. One might say Fig. 1.

Page 620

Fig. 2.

The regions identified as personality organs, according to the classification of Gall, with additions by Spurzheim and Combe, were:

1. Amativeness
19. Ideality
2. Philoprogenitiveness
20. Wit
3. Concentrativeness

- 21. Imitation
- 4. Adhesiveness
- 22. Individuality
- 5. Combaticiveness
- 23. Form
- 6. Destructiveness
- 24. Size
- 6a. Alimentiveness
- 25. Weight
- 7. Secretiveness
- 26. Colour
- 8. Acquisitiveness
- 27. Locality
- 9. Constructiveness
- 28. Number
- 10. Selfesteem
- 29. Order
- 11. Love of approbation
- 30. Eventuality
- 12. Cautiousness
- 31. Tune
- 13. Benevolence
- 32. Tune
- 14. Veneration

33. Language

15. Conscientiousness

34. Comparison

16. Firmness

35. Causality

17. Hope

18. Wonder

that the current interest in 'cerebral dominance', with the left hemisphere of the cortex supposedly 'analytic' (responsible for skills such as arithmetic and logical thinking) and the right hemisphere 'synthetic' or 'analogue' (responsible for intuitive and artistic skills), is the dying kick of phrenology. (See SPLITBRAIN AND THE MIND.) Physiological experiments on localizing functions give very different functional maps from those of the phrenologists, (Figs. 1, 2) and are highly revealing and of great use in brain surgery; yet they too are subject to logical difficulties of interpretation. For ablation especially, there are difficulties in inferring from loss, or change in behaviour, what the missing region does in the normal intact brain. It is extremely difficult to isolate functions in interactive systems, and in systems where parts can take over the functions of other parts when these are overloaded or damaged. Moreover, it is logically necessary to appreciate what the functions are before they can be named or localized. Physiological functions are not units of behaviour, and so are not to be discovered simply from observation. What is required is an adequate theoretical understanding—an adequate conceptual model—of brain function, which is something very different from the localized mental faculties of the phrenologists.

Recently, however, the (Fodor, 1983) brain has been seen to be organized in 'modules' carrying out complex functions, such as face recognition. This is something of a return to phrenological ideas.

R. L. G.

Fodor, J. A. (1983). *The Modularity of Mind*. Cambridge.

PHYSIOGNOMY. The word 'physiognomy' is a compound of two Greek words meaning 'nature', and 'an interpreter'. Francis*Bacon described it as 'discovery of the disposition of the mind by the lineaments of the body'; and indeed this is the aim of portrait painting.*Aristotle wrote extensively on physiognomy, with many comparisons between human and animal characteristics, and many Latin authors discuss it as a descriptive science; but in medieval writings, physiognomy becomes linked with*astrology and necromancy. It was made illegal by George II, in 1743, and earlier Queen Elizabeth had decreed that 'all persons fayning to have knowledge of phisiognomic or like Fantasticall Ymaginacions' were liable to be 'stripped naked from the middle upwards and openly whipped until his body be bloudye'.

Nevertheless, Elizabeth set much store on delineation of character in paintings. Our own view, now, is surely as paradoxical, for we generally hold that physiognomy as a science is unfounded and yet we spend a great deal of time reading character from faces and pictures.

There are many examples, from Aristotle onwards, of people looking dull but being bright (and Aristotle admitted it of himself, saying that it was the practice of philosophy that brightened his native dullness); while the converse can also be true. But there are good grounds for associating expression with character traits and habits of thought. The point is that groups of muscles are associated with emotions, moods, and activities; and the use of facial muscles both modifies the countenance and produces permanent changes, such as lines and wrinkles. The first scientific study of this notion was by the distinguished Scottish anatomist surgeon and neurologist Sir Charles*Bell, whose *Essay on the Anatomy of the Expressions* (1806) related specific muscles to*facial expressions.

The idea was developed, with strong evolutionary implications, by Charles*Darwin in his still Page 621

highly important book *The Expression of the Emotions in Man and Animals* (1872). Darwin dismisses earlier writers on expression and physiognomy, such as the French painter Charles Le Brun (161990), who wrote *Conférence sur l'expression des différents caractères des passions* in 1667, and the Dutch anatomist Peter Camper (172289), but he does give full and just praise to the work of Bell. He also refers to the bestknown of the physiognomists, Johann Kaspar Lavater (17411801), born in Zurich, whose *Physiognomische Fragmente* (17758; translated by Thomas Holcroft as *Essays on Physiognomy* in 1793) went into many editions and was widely read. Lavater is interesting for his many drawings of faces, and his astute comments on the characters and lives of his examples, but there is a total absence of system or theory. Darwin refers also to Burgess's *The Physiology or Mechanism of Blushing* (1839), which points out that*blushing cannot be caused

'by any physical means', but that it must be the mind that is affected, 'for if we try to restrain blushing, this increases it'. Finally, Darwin refers to the French pioneer in electrophysiology, Guillaume Duchenne (180675), who was the first to describe Iocomotor ataxia, and was the founder of techniques using electrical stimulation for therapy. Darwin refers to Duchenne's *Mécanisme de la physionomie humaine* (1862), in which he 'analyses by means of electricity, and illustrates by magnificent photographs, the movements of the facial muscles'. Duchenne lent and allowed Darwin to copy his photographs, many of which appear in *The Expression of the Emotions*. He succeeded in showing the effects of contraction of individual muscles of the hand, and their effects in producing creases in the skin; and, perhaps most significant, in showing which muscles are and which are not under voluntary control. Both he and Darwin were well aware of the problem of how it is that groups of muscles are innervated for behaviour, gesture, and expressions. This could not be investigated experimentally before techniques of conical stimulation were developed.

The philosopher Herbert*Spencer contributed an account of facial expression and emotion somewhat similar to Darwin's (in *Principles of Psychology*, 1855), and Darwin quotes from it with approval:

Fear, when strong, expresses itself in cries, in efforts to hide or escape, in palpitations and

tremblings; and these are just the manifestations that would accompany an actual experience of the evil feared. The destructive passions are shown in a general tension of the muscular system, in gnashing of the teeth and protrusion of the claws, in dilated eyes and nostrils, in growls; and these are weaker forms of the actions that accompany the killing of prey.

Darwin's essential point is that the facial muscles of monkeys are similar to ours, but, as he puts it, 'no one, I presume, would be inclined to admit that monkeys have been endowed with special muscles solely for exhibiting their hideous grimaces'. Rather the 'grimaces' were originally of functional importance—and in many cases still are in us—as when muscles surrounding the eyes contract to protect the eyes from increased bloodpressure or from the blow of an assailant. Frequent use of such sets of muscles, either in action or in the simulation of imagination and emotion, will produce, gradually, permanent changes of expression. So there is strong evidence and a consistent theory for a biological basis to physiognomy. It is, however, very far from clear how accurately it is possible to read the subtleties of human character from facial forms and expressions having prehuman functional origins.

It is most curious that expressions of extremely different emotions can be so similar that they are indistinguishable in photographs—unless the context of the situation is available. Pictures of reactions of horror and uncontrollable laughter are easily confused when presented out of context. In normal life, no doubt, it is facial and verbal reactions to events—speed and appropriateness—that are crucially important signals for evaluating character and ability. This is the power of the cinema, for it presents the context of situations, and the timing of responses. There remains a considerable mystery just why and how static portraits convey so much of the character of individuals by their physiognomy.

R. L. G.

PIAGET, JEAN (1896-1980), Swiss psychologist born at Neuchâtel, Switzerland, became professor of child psychology at the University of Geneva, and director of the Centre d'Épistémologie Génétique; he was also a director of the Institut des Sciences de l'Éducation. He was the great pioneer of the study of cognitive development through childhood, and he virtually founded epistemology as an experimental science. He wrote a vast number of books, using writing as his principal aid to thought and inspiration for new experiments. The best are highly important, and are clearly written to be read, but some are clumsy vehicles of his thinking, though no doubt useful for the author and immediate colleagues at the time of writing.

J. H. Flavell (1963) describes how Piaget worked on and published some twenty-five papers on molluscs, of which about twenty were in print before he was 21.

Piaget's early studies in zoology and the behaviour of simple organisms evidently gave rise to his interest in comparing external with internal organizational principles, and in the nature of intelligence, which crystallized as he worked in Binet's laboratory in Paris on standardizing intelligence tests for children.

Although Piaget became one of the most famous psychologists of his time, psychology was not his main aim or interest; rather this was to unify biology and logic. To this end he investigated the development of concepts and language, and interactive behaviour with objects in children, and their internal mental manipulations of symbols. He saw knowledge as providing 'selfregulating' symbolic

Page 622

structures, developed by processes of 'assimilation' and 'accommodation'. There is something of*Hegel in his manner of discussion and thinking, which he calls

'dialectical constructivism': passing from *thesis* to its contradictory *antithesis* to the next step, the *synthesis*. This in its turn might serve as a new thesis, so his thinking climbs in a kind of staircase. It is however a spiral staircase, for the contextual premisses are reexamined each time the 'spiral' sweeps round, from successively higher levels of consideration. Piaget sees psychological development as this kind of spiral, with interacting antitheses generating new knowledge, rather than as an unfolding of innate properties by maturation, triggered or released by experiences, which is perhaps a more usual view. He thus adds empiricism to Hegel's a priori idealism for cognitive development.

'Assimilation' is the modification of perceptual inputs by existing knowledgestructures, while 'accommodation' is modification of the knowledgestructures to adapt to the input. The result is a lifelong quasistable equilibrium which is maintained by climbing to new generalizations along the spiral of the growth of mind. This is, essentially, a dynamic model of mind, with active exploration seen as the basis for learning and understanding and discovery.

The child goes through various stages of learning and development, and he is unable to proceed to later stages before critically important earlier stages have been passed, or lessons learned, or discoveries created by new syntheses. Piaget sets specific ages to some of these stages, but it appears that these tend to be somewhat late for most children. Paradigm experiments include the famous 'mountain' test, in which the child is asked to describe a model of mountains from the point of view not of himself but of someone in a different location—the tester, or a model person placed in the scene. He found that young children find this impossible. Equally celebrated experiments concern predicting what will happen to the levels or slopes of liquids, as glass jars are tilted or liquid is poured into jars of various diameters.

These are extremely interesting tests of understanding, and may be preverbal. There are, however, difficulties in ensuring that very young children understand exactly what is asked of them, and later experimenters have sometimes found that inability to perform the tests is due to lack of understanding of the instructions. (See REASONING: DEVELOPMENT IN CHILDREN.)

Broadly, children seem to go through a phase of*Aristotelian physics before they understand acceleration, inertia, and so on, as these are now understood by scientifically educated adults.

Piaget's work is important for considering*education, communication of ideas, and epistemology. By

applying cybernetic concepts of dynamic stability it may have implications and applications at several levels, for programming computers to be intelligent (see ARTIFICIAL INTELLIGENCE) as well as for teaching children.

Among Piaget's main works are *The Language and Thought of the Child* (1923; Eng. trans. 1926); *The Child's Conception of the World* (1926; Eng. trans.

1929); *The Child's Conception of Physical Reality* (1926; Eng. trans. 1960). His theory of visual illusions based on his notion of assimilation is described in *The Mechanisms of Perception* (1961; Eng. trans. 1969).

Boden, M. (1979). *Piaget*. London.

Flavell, J. H. (1963). *The Developmental Psychology of Jean Piaget*. Princeton, New Jersey.

PIAGET AND EDUCATION. Piaget's work on children's intellectual development owed much to his early studies of water snails. *Limnaea stagnalis* spends its early life in stagnant conditions. On transfer to tidal waters and in order to remain on the rocks the snail is forced to engage in motor activity, and this activity directly influences the development of the size and shape of its shell. This model of development through active adaptation has become the prototype for learning. Inherited patterns of motor activity (such as sucking, grasping) enable the infant to interact with the world but are themselves transformed as a result of this interaction. So too with knowledge. The complementary processes of 'assimilation' and 'accommodation' (see PIAGET) are invoked by Piaget to describe the course of adaptation and the stagelike nature of the development of understanding as the child strives for stability between new learning and old at successively higher levels ('equilibration').

Piaget insists on the fundamental importance of the child as agent of his own learning throughout development. In the early years knowledge of the outside world is assimilated to the structure of elementary actions, and later involves the reconstruction in thought of operations performed in action. This restricts the child's ability to think logically. By middle childhood (the junior school period) greater coordination of thought is achieved but is limited in its sphere of application to objects rather than to verbal propositions. According to Piaget's theory of stages, it is not until early adolescence that children become capable of formal reasoning and hypothetico-deductive thinking.

Although Piaget did not systematically apply his theory to teaching, his account of intellectual development has been used to reinforce and provide theoretical justification for aspects of earlier theories of education and practices, such as those advocated by Montessori and Dewey. His theory stresses that knowledge and understanding are derived from the active adaptation of children to their environment and not through direct instruction, and consequently that schools should provide children with opportunities to invent and to discover; it recommends a sequence of intellectual demands compatible with the forms of thought which define the stages of development described. Direct application of the theory has proved difficult, partly because Piaget's interest was in skills Page 623

not normally taught and partly because of lack of clarity or inconsistency on certain fundamental points. There is, for example, no empirical support for equilibration as a mechanism of learning, and Piaget was generally indifferent to more parsimonious accounts of the phenomena he described. Recent research to train children on various concepts has been more successful than the theory would predict. Piaget's account also underestimates social interaction and cultural transmission as constituents of education.

Nevertheless, some specific curricula derived from Piaget's work have been devised, notably by Lavatelli in the USA for children aged 4 to 7, by Weikart and others at Ypsilanti in Michigan, by Kamii and De Vries for preschool children, and in the Schools Council science 513 project in Britain. Stage theory has also been used to develop techniques to assess intellectual capacity (as in the British ability scales) in skills that are, according to Piaget, only minimally influenced by teaching, if at all.

Although Piaget's theory provides possible guidelines as to reasonable demands for children at different age levels, to ascribe to his influence alone the idea that children learn by manipulation, comparison, and reconciliation of discrepant events (proceeding from the equilibration concept) is mistaken. Despite the conscious extension of Piaget's ideas into education by the few mentioned above, many more have employed his theory to justify practices already in vogue with educationists seeking to emphasize discovery learning.

Meadows, S. A. C. (ed.) (1983). *Developing Thinking*. London.

PIERON, HENRI (1881-1964), founder of French experimental psychology. He was trained in philosophy and physiology, and became a leader in physiological studies of sensation and perception. He designed several ingenious optical and other instruments, and also was influential in personnel selection, vocational guidance, and animal psychology, as well as in psychophysics.

PLASTICITY IN THE NERVOUS SYSTEM. In everyday usage, when we say something shows plasticity we imply that it can be moulded or readily made to assume (and to retain) a new shape. Probably the term should not really be used in relation to living systems, since plasticity is something found in inert, inanimate material. The nervous system is living and changing all the time; and while it can readily be induced to change shape, by surgical or other traumatic means, it cannot be induced to maintain a new shape without being killed. Yet the concept of plasticity is used in relation to other growing systems; one talks about moulding the character of a young person, or moulding the shape of a tree by selective pruning. What is meant by such cases is that constraints are applied so that the form of the organism changes and future growth is differently channelled.

Plasticity in the nervous system means an alteration in structure or function brought about by development, experience, or injury. Such a statement is not sufficiently precise, however; in relation to the nervous system, we commonly imply a further restriction of meaning. We do not mean just *any* alteration. For instance, a massive and disorganized malfunction associated with extensive injury

would not be referred to as plasticity. To qualify for this name, an alteration has to show pattern or order. Plasticity here means patterned, or ordered, alteration of organization; one that makes some sort of sense biologically or to the investigator.

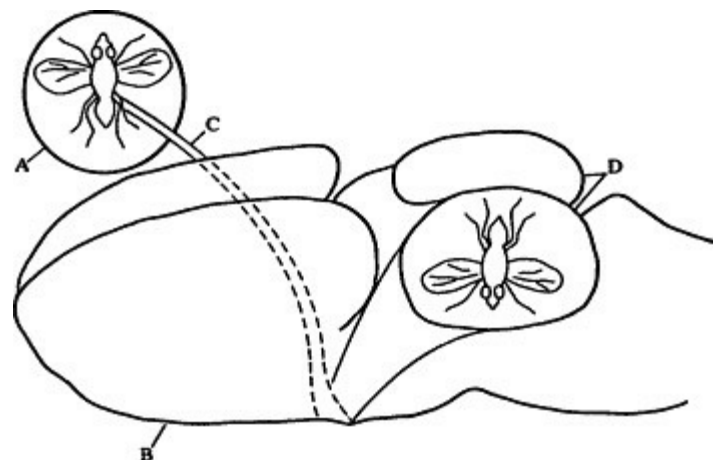

Neural plasticity can be mainly of structure or mainly of function. To the extent that the function of the nervous system reflects its structure, we assume that any plastic change in structure is associated with a change, at some level, in function and vice versa. In some cases, where our functional tests are inadequate, plasticity will appear to be mainly of structure; and in other cases, such as *learning and *memory, where our structural knowledge is inadequate, plasticity will appear to be mainly of function.

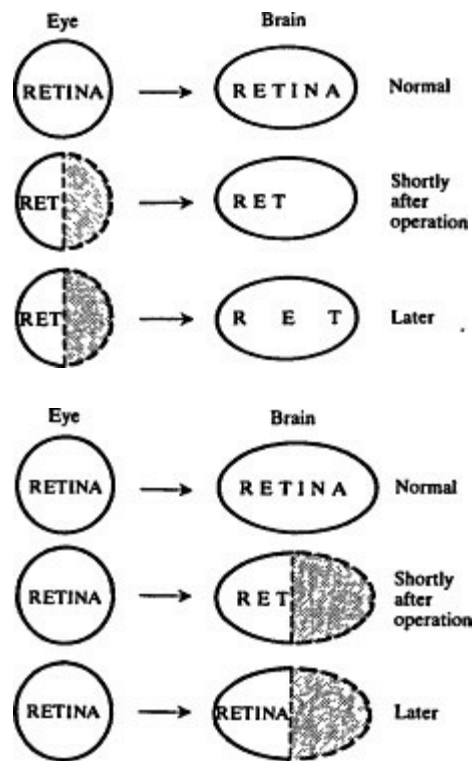

The term plasticity also implies that the changes are in some sense positive; we would normally mean more than just an ordered deficit following a localized lesion.

When we say that the nervous system is showing plasticity after injury, we imply that the structures or functions under discussion alter in some way to make up for this deficit; or to provide a new and abnormally ordered pattern. Comparably, when the plasticity takes the form of learning or memory, the functional alteration resulting from the input experience must be organized, this time in a functional sense. Functional changes that were merely chaotic would qualify for neither the term plasticity nor the term learning.

We now describe three situations in which parts of the nervous system show forms of plastic alteration: changes in eyebrian connections (i) induced experimentally in adult fish and (ii) during the initial development of the visual system, and also (iii) changes in the connections between the left and right optical tectum. These examples all come from the visual system in lower vertebrates and illustrate some of the changes that may occur in different situations.

Changes in eyebrian connections induced experimentally in adult fish. The ganglion cells of the retina are distributed in a twodimensional array across the back of the eye. In lower vertebrates (including fish) optic nerve fibres from these ganglion cells form the optic nerve connecting the retina to the main visual centre of the brain, the optic tectum. Here, the fibres distribute their endings across the surface of the tectum in such a way that neighbourhood relationships between adjacent ganglion cells in the retina are reproduced in the relationships between the endings of their

Page 624

Fig. 1.

Diagram showing the right eye (A) and the brain (B) of a *Xenopus* frog. Ganglion cells in the retina of the eye send their nerve fibres via the optic nerve (C) to the main visual centre, the optic tectum (D). These fibres form a 'map' of the retina on the surface of the optic tectum, and the way the retinal surface is represented on the tectum is indicated by the relative orientation of the fibres. Ganglion cells underlying each particular part of the retina send their fibres to terminate at the corresponding part of the tectum.

fibres on the tectum (Fig. 1). The entire sheet of retinal ganglion cells thus forms, through the distribution of its nerve fibres on the tectum, a neighbourhood-preserving 'map' of the retina across the entire extent of the tectal surface.

If half the retina is removed and the optic nerve is cut in a fish, when the retinal fibres regenerate (as they do, in lower vertebrates, within a few weeks) back to the tectum, they form a map of the remaining half of the retina across the appropriate half of the tectum (Fig. 2). The regenerating fibres will even ignore available, but inappropriate, termination sites left unoccupied by the part of the retina which has been removed (Attardi and Sperry, 1963). A similar phenomenon of the precise reestablishment of connections is demonstrated when half the tectum is removed (Gaze and Sharma, 1970). In this case, it is again only fibres from the appropriate half of the retina that are found to have

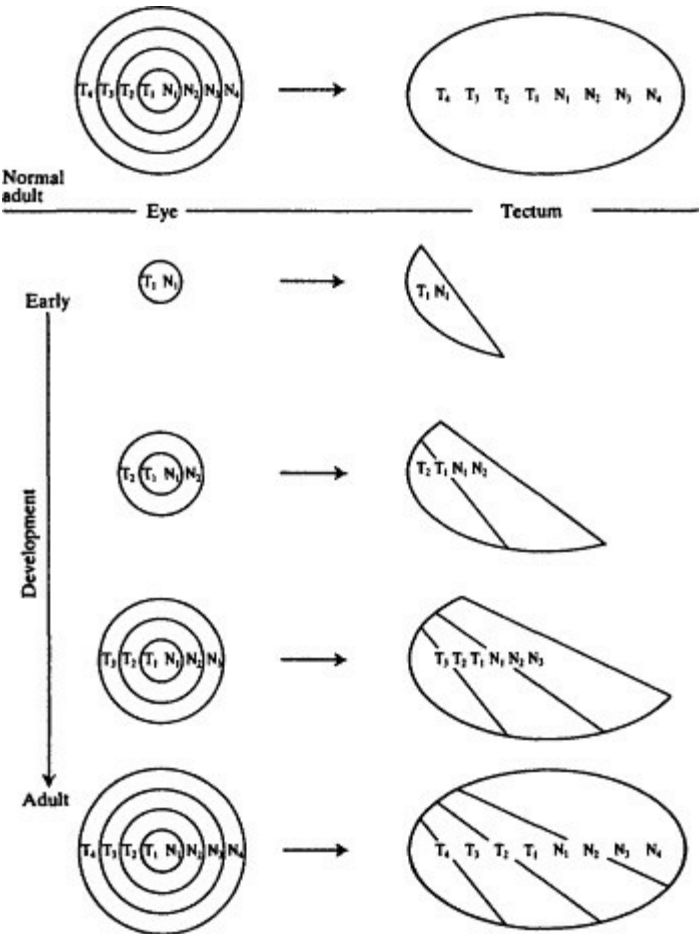

reestablished connections (Fig. 3). This shows, therefore, that the factors controlling the initial reestablishment of the nerve connections are acting in a quite uniplastic way; no change results other than that directly attributable to the surgical treatment. Removal of part of the retina or tectum always produces a corresponding gap in the retinotectal map.

If, however, one examines the result some considerable time (several months) later, one finds Fig. 2.

The result of removal of half the retina in a fish. At first, fibres from the remaining half retina form a partial map over the corresponding half of the tectum. Later, fibres from the remaining half retina spread out to form an expanded, but still properly ordered, map across the whole of the rectum.

Fig. 3.

The result of removal of part of the optic tectum in a fish. Initially, fibres from half the retina form a partial map over the remaining half of the tectum. Later, fibres from the whole of the retina form a compressed, but properly ordered, map over the remaining half tectum.

that the connection pattern between retina and tectum has now changed. Where only half a retina innervates a whole tectum, fibres from the half retina are found to have spread their terminals, in an orderly fashion (Fig. 2), across the whole of the tectum (Schmidt *et al.*, 1978). In similar fashion, where half the rectum has been removed (Gaze and Sharma, 1970), it is found that ganglion cells from the entire extent of the retina now form an organized but compressed map across the available rectal surface (Fig. 3).

Changes in eyebrian connections during the initial development of the visual system. In amphibia and fish the retinotectal system continues to grow for much of (in some cases, all of) the animal's life. The retina grows by the addition of rings of cells at its periphery, so that the oldest part is at the centre of the eye, close to where the optic nerve fibres leave the retina, and the youngest part is at the edge of the retina. The optic tectum, on the other hand, grows from front to back.

In the earliest stages of development, when both the retina and the tectum are very small, the few optic nerve fibres that then exist connect the early retina to the early tectum and make a 'map' which is properly ordered and properly oriented on the

Fig. 4.

The relationship between the growing eye and the growing optic rectum in *Xenopus* frogs.

The top diagram shows how the horizontal (temporonasal) axis of the retina maps on to

the anteroposterior axis of the tectum in a normal adult animal. The most temporal ganglion cells in the retina (T4) send their fibres to the front of the tectum and the most nasal ganglion cells (N4) send their fibres to the back of the tectum. When the retina first forms, it has

very few cells (T1, N1) and these connect with the small tectum then existing. The order

of the map is correct (i.e. similar to that in the adult) from very early stages of development.

Next, a further ring of retinal ganglion cells develops (T2, N2) and these connect with tectum in the same relative order: most temporal fibres (T2) to the front, most nasal fibres (N2) to the back. And so on. The result of the different modes of growth of eye and tectum is that there occurs a continual shift of fibre connections across the tectum as the system grows.

Page 626

tectum. The orientation of the map formed by the retinal fibres on the tectum is such that fibres coming from ganglion cells at the temporal margin of the retina (i.e.

furthest away from the nose) connect to the frontmost part of the tectum; while those at the nasal edge of the retina (nearest to the nose) connect towards the back edge of the rectum. This orientation persists throughout life, despite the continuing growth of the system (Fig. 4).

This would present no problems if the retina and the tectum were growing in a similar fashion. However, the fact that the retina grows in rings while the tectum grows from front to back in bands means that, during development of the visual system, there has to be not merely the addition of new fibres between the eye and the tectum, but also a continual shift of those fibre connections already existing on the tectum (Fig. 4). Thus during growth of the eye there is a continual addition of new ganglion cells round the retinal margin, including the temporal edge. Fibres from these new temporal ganglion cells must connect with the frontmost part of the tectum, which is where the problem arises. The front of the tectum is the oldest part and already holds connections from the preceding group of temporal fibres. Fibres from the nasal edge of the retina have no such problem. They grow to the back of the tectum where new cells are being added and so have plenty of room to connect. Obviously, as the system grows, something has to give; and what happens is that, on the arrival of new temporal fibres, all the previous fibres shift backwards across the tectum to make room for the newcomers (Gaze, Chung, and Keating, 1972). This type of shift of nerve connections during development has been demonstrated both in amphibians and in fish.

Changes in the connections between the left and right optic tectum, associated with the development of binocular vision in *Xenopus* frogs. In adult *Xenopus* there is a binocular visual input to the optic tectum on each side of the brain. From each eye the retinal ganglion cell axons send fibres directly to the tectal lobe on the other (the contralateral) side of the brain (Fig. 5a). The input to the tectal lobe on the same side, the ipsilateral visual input, is indirect, involving some form of second order nerve connections between the two lobes of the tectum (Fig. 5b). This intertectal connection system itself shows topographic order, such that terminations of retinal ganglion cell axons which arise in complementary positions in each eye (i.e. look out at the same point in visual space), are interlinked. The development of this intertectal fibre system occurs at a later stage than the direct contralateral visual input, and appears to be linked to the onset of metamorphosis, during which the initially laterally projecting eyes migrate dorsally and rostrally, providing partial binocular vision in the adult frog.

If, in embryonic life, one eye is surgically rotated by 180°, the connections that it forms with the contralateral tectal lobe are unaltered (Fig. 5c); but since the eye is now upsidedown and backtofront the visual information coming from the outside world through that eye will be inverted along both axes. If one examines the ipsilateral intertectal fibre pathway at around the time of metamorphosis in such an animal, one finds that, while the visual field map established through the *rotated* eye on its contralateral tectum is rotated as expected, the ipsilateral map from that eye is *normal*; and conversely, the contralateral map from the *normal* eye is normal while the ipsilateral map from the *normal* eye is rotated (Fig. 5d). This remarkable phenomenon has the effect (which could be closely related to its cause) that, after rotation of a larval eye, the binocular inputs to each tectum remain congruent. The result is that we obtain a plastic alteration in the intertectal connections underlying the ipsilateral visual input, and this change in connectivity is dependent upon the existence of binocular visual input during a formative period. In this case, therefore, we have a change in functional connections initiated by a *functional* interaction following a *structural* alteration to the eye (Gaze, Keating, Szekely, and Beazley, 1970).

In contrast to these observations in the lower vertebrates, observations concerning structural plasticity in the mammalian central nervous system have mainly been made during embryonic and neonatal life. In the mammalian central nervous system there appears to be a loss, at a specific time period in development, of the ability of axons to grossly alter their connections. This time limit for structural plasticity may be related to changes in the ability of axons to regenerate, believed to be caused by changes not in the neurones themselves but in the surrounding glial cells. Technical advances have made it possible to demonstrate that more subtle changes in the fine details of the connection pattern are occurring even in young adult animals. These changes involve the production and retraction of dendritic arbors, altering the morphology of the neurone and, in consequence, its synaptic relationships to those cells which have made functional connections with it. This ability for subtle alteration of what has generally been considered an apparently rigid structural connectivity pattern, adds even further complexity to the study of the formation of nerve connections.

Even more elusive are functional changes occurring in the 'established' nervous system. These may include changes in synaptic type, thereby altering the signal communicated to contacted neurones; or alteration in the 'strength' of synapse—which in turn may profoundly change the relative effect of one neurone on another. It is perhaps these latter mechanisms which are more important in the vastly more complex nervous systems of the higher vertebrates. Such functional plasticity may be a form of evolutionary tradeoff, where the smaller degree of variable 'wiring' is

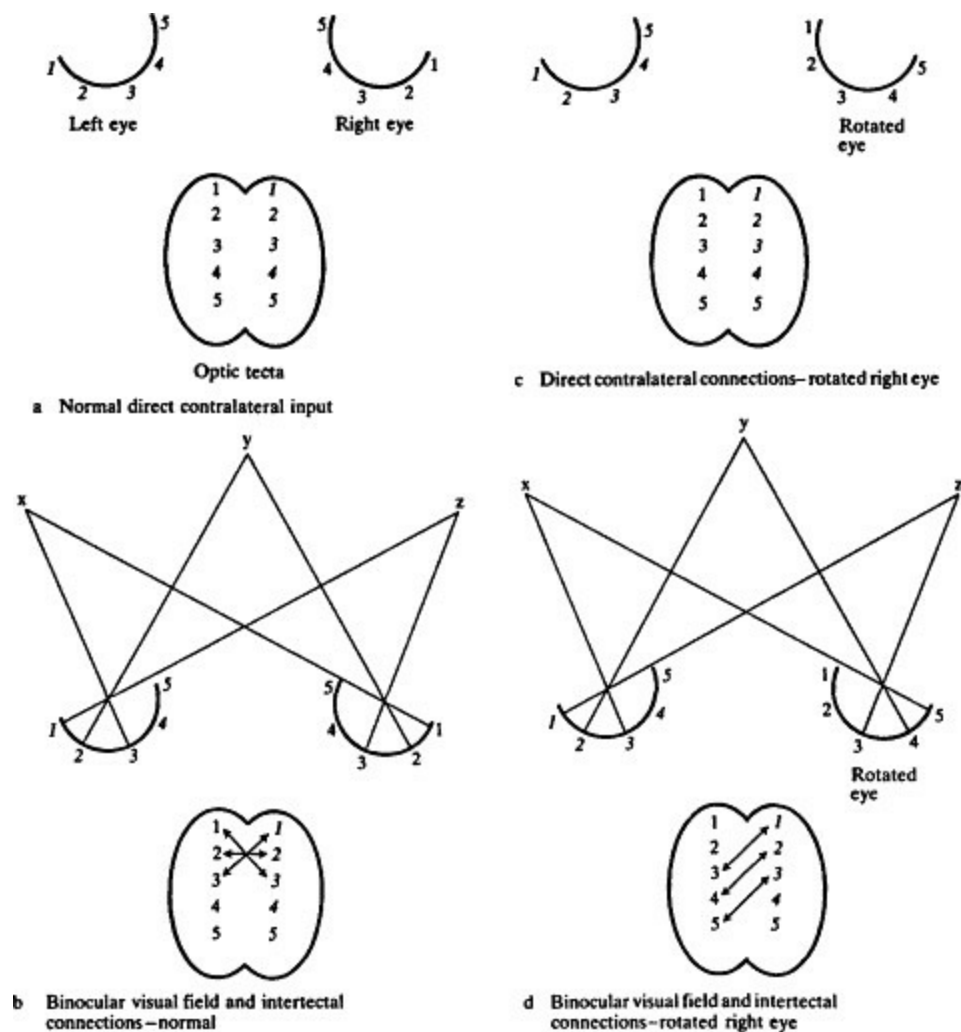

Fig. 5.

a. In a normal adult *Xenopus* frog fibres from ganglion cells distributed along the horizontal (temporonasal) axis of the retina send their fibres to the opposite (contralateral) optic tectum, as shown. Most temporal retinal cells (1 and 1) connect to most anterior rectum, while most nasal retinal cells (5 and 5) send their fibres to posterior tectum.

b. *Xenopus* frogs can see pan of the visual field with both eyes. Except for pans of the visual field along the midline of the animal, each point in visual space that can be seen by both eyes will be represented at a relatively different position on each optic tectum.

For instance, point X in the visual field is 'seen' by ganglion cells at position 3 in the left retina and position 1 in the right retina. These ganglion cells send fibres respectively to

position 3 on the right tectum and position 1 on the left rectum. Experiment shows that

these positions, on right and left tecta, are interconnected. This means that, in addition to the direct contralateral connection of each eye to its opposite rectum, there is also an indirect connection from each eye to the tectum on the same side (ipsilateral). Position 3 in the left retina, for example, sends fibres directly to position 3 on the right tectum. But position 3 on the right tectum itself connects, through other nerve fibres, with position I on the left tectum. The pattern of intertectal connections is as shown by the arrows.

c. When one eye is rotated by 180° in embryonic life, each part of the retina still connects, later in development, with the proper pan of the tectum. Thus retinal position I still connects with anterior rectum, although the position of the eye has been altered. But, since the eye

is rotated, the map of the visual field on the rectum is backtofront and upsidedown.

d. When one eye has been rotated in embryonic life, experiment shows that, later, the representation of the visual field seen through the rotated eye is rotated on the contralateral rectum. Thus point X in the visual field is seen by ganglion cells at position 3 in the left retina, but is now seen by ganglion cells at position S in the rotated retina. However, the map of the visual field on the ipsilateral tectum, as seen through the rotated eye, is normal. Conversely,

the visual fieldmap seen through the normal eye is normal on its contralateral tectum

but rotated on the ipsilateral rectum. Any point in the binocular visual fieldmaps, through each eye, to one position only on each tectum. This means that the pattern of intertectal connections is different from normal, as shown here.

exchanged for a greater flexibility in the 'programming' of the system.

PLATO (427/347 BC). Plato was born into a distinguished family whose members played a prominent part in the political life of Athens. It is probable that he himself expected to follow a political career, but at some point he came under the influence of that charismatic talker, *Socrates: Socrates was put to death in 399 BC, and it may have been this which changed the course of Plato's life and turned him to philosophy. He did not give up all political aspirations—indeed, he later meddled with unhappy results in the affairs of Sicily—but he seems to have had little to do with the politics of his native city.

His celebrated school, the Academy, probably opened its doors in about 385; and it soon attracted the brightest ornaments of intellectual Greece, among them *Aristotle. Little is known of the structure and nature of Plato's Academy; but it is not implausible to think of it as an institute for advanced research. A comic poet portrays the young academicians as attempting to classify the pumpkin: is it a species of tree? a kind of grass? a Vegetable? The caricature suggests that the natural sciences were studied in the Academy; there is good evidence for the study of mathematics; and of course philosophy, in all its branches, was the centrepiece. Plato himself doubtless spent much of his time in teaching and lecturing to his disciples and colleagues, and there are stories of a public lecture in which he managed to bemuse most of his lay audience.

Plato left behind him a body of philosophical writings, in dialogue form, unsurpassed for their literary elegance and their profundity. The notion of the *psyche exercised him throughout his life, and reflections upon one aspect or another of psychology can be found in most of his works; but the primary sources for his psychological theories are the *Phaedo*, the *Republic*, the *Phaedrus*, and the

Timaeus.

Two topics concerned him especially: the question of the immortality of the psyche, and the problem of its unity. The two questions are closely linked; for Plato, like many thinkers after him, believed that only a unitary and indivisible item could be eternal—anything divisible would at some time actually be divided and hence destroyed. A psyche with parts cannot be immortal; and since Plato held both that the psyche has parts and that it is immortal, he found himself in a perplexity from which he never really escaped.

The *Phaedo* represents Socrates, on the day of his death, talking to his friends about the nature of the psyche: he is determined to discover whether the psyche survives death, or whether, as certain theories dictate, it perishes when the body perishes. The dialogue produces a battery of arguments, developed with great sophistication, to show that the psyche is indeed immortal. The arguments—together with subsidiary reflections produced in the *Republic* and the *Phaedrus*—repay close study. They are none of them cogent, and they are too complex to be profitably summarized,' but one point about them is worth mentioning: in arguing for the immortality of the psyche, Socrates is arguing for his own immortality—in the *Phaedo* he believes that he has proved that *he will* survive his death. In other words, Socrates' psyche is the very same thing as Socrates: the one survives if and only if the other does. That is thoroughly consistent with the general Greek notion of psyche, and it shows that Plato, unlike many Christian thinkers, did not regard the person as a compound of body and soul, only one component of which can achieve immortality. My soul may be a *part* of me; my psyche *is* me.

The doctrine that the psyche has 'parts' is expounded in the *Republic*, the *Phaedrus*, and the *Timaeus*. According to the *Republic*, the psyche is composed of an appetitive, an emotional, and a rational part. Plato argues for this tripartite division from the existence of certain types of psychological conflict; for example, a desert traveller may feel thirsty and experience a strong desire to drink from a well, while at the same time his reason (observing that the well is insanitary) urges him not to drink. Since one and the same thing cannot at one and the same time possess opposite properties (a single and undivided psyche cannot at the same time both urge the traveller to the well and hold him back from the water), it follows that the psyche contains at least two distinct parts.

Plato's tripartition of the psyche has been compared to*Freud's distinction among the id, the ego, and the superego; and certainly it is very different in style from Aristotle's division of the various psychological faculties. Moreover, the basis of Plato's tripartition is logically dubious, and it is not clear if the tripartition is meant to be exhaustive or even exclusive. (Plato himself hints at a more refined and numerous partition, and elsewhere in the *Republic* he assigns appetites to the rational part of the psyche itself.) The fact is that Plato is not primarily concerned, as Aristotle was, with analytical psychology: his interest in the

psyche centres on its role as a source of human behaviour, and in particular of moral action. The 'rational part' of the psyche is the morally superior part—the part which ought to govern our actions; and Plato singles it out, not from a desire to develop a detailed psychological theory, but because he wants to attend to the place of reason in the ethics of human action.

In the *Timaeus* (and also in a short passage in the *Theaetetus*) Plato offers accounts of the psychological faculties which are similar in style and motivation to those of the*PreSocratics and of Aristotle. But those contributions to analytical psychology are not particularly original: *moral* psychology—the study of the psychological conditions of moral activity—was the focal point for Plato's interest in the affairs of the psyche.

Plato's dialogues have often been translated into English. The best complete translation is still the Victorian masterpiece of Benjamin Jowett (now available, in a revised and more accurate form, in paperback).

PLATONIC FORMS. The so-called 'theory' of Forms or Ideas is the name given to a group of Platonic doctrines, found in the *Republic* (c. 380 BC) and elsewhere. The central notion is that, over and above the particular objects that are, for example, beautiful, there is a separate Form—the beautiful itself. And in general, wherever a single term is applied to a group of particulars (e.g. beds, tables) there is a corresponding Form. Unlike particulars, which are subject to change and decay, the Forms are eternal and unchanging, and possess their properties in an absolute unqualified way.*Plato argued that true knowledge or understanding relates to the Forms alone; and the Forms must be apprehended not by the senses but by the intellect. Hence, the mind must be drawn away from the senses if it is to apprehend ultimate reality (a doctrine which had considerable influence on subsequent philosophy).*Aristotle criticizes the theory of Forms, arguing that what makes a man a man, for example, is a set of essential characteristics which do not have a separate existence, but must always be instantiated or embodied in particular individuals. Commentators sympathetic to Plato have suggested that the doctrine of Forms contains an important insight: that true scientific understanding must always attempt to go beyond particular observation and ascend to the more universal realm of theoretical models and mathematical laws.

POINCARÉ, JULES HENRI (1854–1912). French mathematician and philosopher, born at Nancy. The range of Poincaré's work was so great that the obituary number of the *Revue de Métaphysique et de Morale* (September 1913) devoted 130 pages—written by a philosopher, a mathematician, an astronomer, and a physicist—to outline his contributions. Bertrand Russell, in his introduction to the English translation of Poincaré's collected essays *Science and Method* (1908), contrasts Poincaré's

writings on science with most professional philosophers as having 'the freshness of actual experience, of vivid contact with what he is describing', which shows, for example, in his vivid account of mathematical invention. As Poincaré says in his essay 'Mathematical Discovery': 'This is a process in which the human mind seems to borrow least from the exterior world, in which it acts, or appears to act, only by itself and on itself, so that by studying the process of geometric thought we may hope to arrive at what is most essential in the human mind.' This leads him to ask how it is that many people do not understand mathematics, as it is founded on logic and principles common to us all. For his own discoveries Poincaré describes: 'appearances of sudden illumination, obvious indications of a long course of previous unconscious work', and he gives interesting firsthand examples. He holds that most creative work consists of unconscious selection of possibilities, the selection being guided by subtle rules for rejection which may be worked out during conscious activity. The result is direction and purpose, with a minimum of thinkingtime wasted on dead ends. Analogies are important for guiding (conscious or unconscious) thinking, but Poincaré holds that the ultimate guide for creative mathematics is a sense of aesthetic elegance. This, however, does have the snag that it can bias thinking towards errors when the truth is less than elegant.

Poincaré was concerned with how sensation and perception relate to physics; or rather, how physics is *derived* from our experience. Here his thinking in some ways paralleled that of Einstein, who derived some of his ideas from these deep questions of how knowledge can be gained, and how observations can suggest and test theories. Poincaré stressed the importance of hypotheses in science, and he was content to see truth as the unattainable end of a convergence.

POSSIBILITY. The concept of possibility can be firmly related to that of necessity, but very little else pertaining to these two concepts is a matter beyond dispute. If we take for granted that we understand what it is for a statement to be true, a statement is possibly true (states a possibility) if it is not necessary that it is not true.

At least one class of statements might be thought to be necessarily not true, namely those which involve an explicit contradiction. There is, however, a tradition in Western philosophy, stretching from*Heraclitus to*Hegel, which holds that there are real contradictions in nature, and that hence a contradiction sometimes states a possibility.*Aristotle (*Metaphysics*, Gamma 46) argued strenuously against the followers of Heraclitus on behalf of the principle of noncontradiction, and by far the bulk of Western philosophers, rationalist and empiricist alike, have accepted that contradictions are

necessarily not true. For them, there is firm foundation for a concept of logical possibility: any statement which does not involve a contradiction states a logical possibility. Two questions then arise: how far can one build on this foundation, and is there any more to (real) possibility than absence of contradiction?

The first question arises because not all contradictions are apparent. If one does not realize that a rooster is a male chicken, it will not be apparent that there is a contradiction involved in saying that a rooster has laid an egg. Such examples encourage the thoughts that nonapparent contradictions are all rendered obscure by linguistic ignorance and that ultimately possibility and necessity reflect only arbitrary rules for the use of words. To find out whether a statement is necessary, all that anyone who is fully in command of what words mean needs to do in order to establish the consistency of any description (and hence the logical possibility of what is described) is to *imagine* the state of affairs described.

Hume was thus able to develop a general strategy for undermining claims that some event *A* was the*cause of event *B* (i.e. made the occurrence of *B* necessary) by inviting his reader to imagine *A* not followed by *B*, thereby showing '*A* and not *B*' to be consistent and hence the description of a possibility. (This was the foundation of the argument in*Hume which gave rise to what is known as the problem of*induction.) The strategy assumes that we have nothing more to learn about *A*, which would reveal that for *B* not to follow would be a contradiction; and this in turn rests on the assumption that what we are talking about when we refer to *A*, or to any object, can be adequately conceptualized on the basis of how objects appear.

If we drop this assumption and make use of a framework (not unlike that found in Aristotle) in which our concepts of things have to be framed in terms of how the powers and capacities of those things restrict what is possible elsewhere, we must address the second question, i.e. that of further sources of restriction on what is a possibility. We can imagine (what appears to be) the sun standing still in the sky; but to think this out fully in the light of our knowledge of nature requires us to register the effects of halting the earth's rotation. Science reveals that such an event is not (naturally) possible without certain concomitant events. We can describe without (apparent) contradiction a world in which these events do not follow, and we can also speak without (apparent) contradiction of a world in which there is a perpetual motion machine; but if our science is well founded, neither of these is our world. Science, it seems, is engaged in spelling out for us what is naturally possible and naturally impossible.

It is evident from this that the issue of whether possibility and necessity are purely a matter of how we use language, or are also a matter of how the world is, is an issue closely bound up with what is thought to be involved in the scientific understanding of the natural world. Any approach such as that of traditional empiricism which bases knowledge on immediate appearances will be deeply suspicious of the notion of natural possibility or impossibility. But at the opposite pole an extreme realist may invite us to view the universe from the standpoint of a being (e.g. God) whose knowledge is complete. From such a standpoint there might seem to be no place for a notion of possibility beyond something like that defined by Diodorus Cronos (c. 300 BC): whatever is or will be true, which entails that no possibility is not at some time actualized. All other notions of possibility, in

other words, only reflect our limited perspective on the universe and should be treated as kinds of epistemic possibility, i.e. defined as what is consistent with some state of our knowledge.

There is, however, another way to conceive the position of a being whose knowledge is complete, particularly if He is also to be thought of as an allpowerful Creator.

In*Leibniz's view, God had knowledge of all the possible ways the world might have been, each a 'possible world', and He chose one of those to be the actual world.

This concept has given rise in recent decades to a notion in formal logic of a possible world, and a definition of a possible truth as one true in at least one possible world and of a necessary truth as one true in all possible worlds.

POSTULATE. See AXIOM.

PRAGMATISM is a largely American philosophic tradition, too divergent in doctrine to constitute a school, which stresses the purposive nature of

cognition and seeks in practical consequences the key to the meanings of concepts or the correctness of belief. The term was coined by the philosopher C. S. *Peirce, who applied it to a method, first published in 1878, for determining the meanings of 'intellectual concepts'. This method counselled us to consider the effects likely to have practical bearings which 'we conceive the object of our concept to have', for in those lie 'the whole of our conception of the object'. (Peirce thus anticipated verificationist themes which were to be prominent in quite different forms in logical positivism.) Peirce's method attracted the ready sympathy of his close friend William *James, who wrote in 1879 that a conception 'is a *teleological instrument* ... a partial aspect of a thing which *for our purpose* we regard as its essential aspect, as the representative of the entire thing' (*Principles of Psychology*, II, 335 n.).

Peirce, however, resisted the way James widened pragmatism to incorporate a theory of truth. This theory, which provoked intense controversy in the decades prior to the First World War, appeared to suggest that truth is nothing more than what works in practice. Doubtless James's vivid way of expressing his views (speaking of

'cash value' and of truths as having in common only the quality 'that they *pay*') contributed to the

tendency of his opponents to father on him hopelessly crude views;

but it remains exceedingly difficult to extract a coherent theory of truth from James's writings. The reason may be that truth as we commonly use the notion points to a divorce of cognition from purposive activity, so that a pragmatic spirit is best developed by leaving the notion of truth behind. This was the path taken by John*Dewey (e.g. in his *Logic* of 1938), who abandoned the notion of truth in favour of 'warranted assertibility'.

PRECOGNITION. See EXTRASENSORY PERCEPTION

PRESOCRATIC PHILOSOPHERS. The term 'PreSocratic' is conventionally applied to a heterogeneous collection of Greek thinkers who lived and worked in the period from *c.*600 to *c.*400 BC. These men in no sense formed a single sect or school; but they wrestled, each in his own way, with a common set of problems—

problems which we would now classify as scientific or philosophical.

None of their writings (some of which were in verse, some in prose) has survived intact: what we know about them is gleaned from the reports of later authors, and from the short quotations contained in those reports. Our knowledge of PreSocratic philosophy is thus fragmentary; and the interpretation of those fragments is generally subject to scholarly controversy. Moreover, many PreSocratic opinions and theories were certainly primitive, illinformed, and simpleminded. For all that, the PreSocratics are of primary importance to any student of Western intellectual progress: they first posed the questions which*Plato and*Aristotle later attempted to answer; and they thereby determined, indirectly, the whole course of Western science and philosophy. Above all, they began the tradition of rational enquiry which disdains any appeal to authority (whether human or divine) and which insists that observation and inference are the twin pillars of knowledge.

The PreSocratics were all polymaths, and their studies left few fields of human knowledge unsurveyed. They made precocious investigations into most of the issues which now fall under the heading of psychology or philosophy of mind: thus they discussed the nature of the 'soul' or*psyche and of the various psychological faculties;

they developed theories of perception (see PERCEPTION: EARLY GREEK THEORIES) and of thought; they pored over the related phenomena of memory, dreaming, and sleep. Aristotle's pupil, Theophrastus, wrote a critical appreciation of PreSocratic theories of the mind: a large part of his book has survived, and it gives us some idea of the scope and detail of those early intellectual adventures.

The main PreSocratic thinkers were these (the dates are at best approximate):*Thales (620/550 BC), Anaximander (610/550), and Anaximenes (570/500)—all from Miletus in Asia Minor;*Pythagoras

(570500);*Heraclitus (540480); Parmenides (520430),*Zeno (500440), and Melissus (480420)—the 'Eleatics';

Anaxagoras (500430); Empedocles (490430); Democritus (460370). Thales, the founder of Western thought, reflected on the nature of psyche, and argued that the magnet has a psyche (since it can initiate motion). Pythagoras advocated the doctrine of*metempsychosis. Heraclitus, an enigmatic thinker, avowed that the psyche was too profound to be fathomed by human thought—but he nevertheless offered certain speculations on its fiery nature. Empedocles and Democritus, the atomist, produced detailed theories of perception and of other psychological activities. Two minor figures deserve mention: Alcmaeon (510440), a doctor, taught that the various sense modalities are unified in the brain; and he produced an argument, which Plato later adopted, for the immortality of the psyche. Philolaus (470390), a follower of Pythagoras, suggested that the psyche is nothing more than an attunement or harmony of the body: a creature has a psyche (or: is alive) just so long as his physical constituents are harmoniously interrelated.

The fragments of the PreSocratics are translated in Jonathan Barnes, *Early Greek Philosophy* (1986); for discussion see Jonathan Barnes, *The Presocratic Philosophers* (2nd edn., 1982).

J. BA.

PRIMATE LANGUAGE. Is only man, *Homo sapiens*, capable of communicating by language? Clearly the answer must depend on what is meant Page 632

by 'language'—for all the higher animals certainly communicate with a great variety of signs, such as gestures, odours, calls, cries and songs, and even the dance of the bees. Yet animals other than man do not appear to have structured grammatical language. And animals do not, which may be highly significant, draw representational pictures. At best they only doodle. If animals (other than ourselves) could speak, or gesture with comparable effectiveness—or draw pictures—we would have immediate access to nonhuman minds. As it is, investigators of animal learning, understanding, and perception are forced into undertaking experiments which, however ingenious, are difficult to carry out and to interpret. Apart from anything else, it is not possible simply to ask an animal to press a button, or search for a solution to a puzzle, let alone ask it what it sees or hears or smells; or what it thinks of its cagemates, or of us and our experiments.

There are several historical attempts to teach animals human language; but until 1966 no such attempts yielded positive results. Then R. A. and B. T. Gardner, in extensive studies carried out in America,' considered the possibility that although primates might be unable (for anatomical reasons) to vocalize speech, perhaps they could learn to communicate by a human sign language. So they set out to teach an eleven months old female chimpanzee—Washoe—the American sign language used by deaf people, Ameslan.

After fiftyone months, Washoe had acquired 132 signs of Ameslan, being able to use them for indicating general classes as well as specific objects or events. Thus the sign for *dog* was used to refer to live dogs and pictures of dogs of many sizes, breeds, and colours, and for the sound of

barking (Gardner and Gardner, 1978, p. 38).

She would use the signs spontaneously, and it was estimated that her use of combinations of signs was comparable to that of the early word combinations of human children. (For a discussion of human development of language, see LANGUAGE DEVELOPMENT IN CHILDREN and LANGUAGE: LEARNING WORD

MEANINGS.) Washoe was brought up as nearly as possible in a child's environment, as the Gardners assumed that this would be conducive to humanlike development and learning. So her days were like a child's, with baths, play, schooling, and outings to interesting places. She had furniture, toys, tools, a kitchen, a bedroom, and a bathroom. It should, however, be noted that the Ameslan sign language is constructed differently from spoken or written language; generally having larger 'units' of meaning, so direct comparison with human, and particularly infant speech is not easy.

In 1972 the Gardners added four more young chimpanzees—Moja, Pelt, Tatu, and Dar, who were only a few days old—to study signing *between* animals. Washoe was nearly a year old at the beginning of her languagelearning, but the newcomers started a few days after birth: 'After seven months of exposure to the conditions of the project, her (Washoe's) vocabulary consisted of the signs, *comegimme*, *more*, *up*, and *sweet*. By contrast, both Moja and Pelt started to make recognizable signs when they were about three months old.

For example, Moja's first four signs (*comegimme*, *more*, *go*, and *drink*) appeared during her 13th week. The Gardners (1978) comment that though the acquisition of first signs for chimpanzees may seem early compared with children's first speech, this is not so for deaf children exposed to sign language from birth; for parents report that these deaf children's first signs appear between the fifth and sixth months.

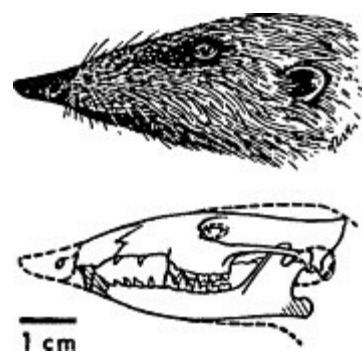

The Gardners (1978) compared the five chimpanzee's 10sign and 50sign vocabulary acquisition with reports in the literature of hearing children's 10word and 50word acquisition: 'The age for tensign vocabulary was five months for Moja, Peli and Tatu, and six months for Dar, but 25 months for Washoe; in the case of children, the age at ten words ranged from 13 to 19 months, with a mean of 15 months' (p. 50).

The Gardners report that the chimpanzees modified or extended their sign language, such as by signing *tickle* on the hand of another chimpanzee, or a human, and sometimes to give an object to a human who is then expected to tickle the chimpanzee with the object. Eye gaze and facial expression are also important adjuncts to the signs, and may be used to distinguish between a declaration and an interrogation. Repetition is also used, for example when a sign is ignored.

Although syntax is important in adult human language, sign order is much less in evidence in early child language, and is not important in the American sign language (Klima and Bellugi, 1979). So the application of syntax is hardly appropriate as a criterion for the chimpanzees' sign language. But it does not follow that order is beyond their capacity. Fouts, Shapiro, and O'Neill (1978), report that order can be trained, with production (by their chimpanzee Ali) of novel prepositional phrases for

objects. This was in doubleblind experimental conditions (the stimulus objects being hidden from the experimenter) which were also used by the Gardners. The essential claim is that as novel combinations of signs were used, and were used to 'describe' conceptually related novel stimuli, there was more going on than conditioning or instrumental conditioning. Suggestive here are *errors*. Most errors fitted two categories: semantic error, in which a sign of similar meaning was incorrectly used, such as *comb* for *brush*; and form errors, such as confusion between the signs *meat* and *oil*, which though very different in meaning are similar in their physical form.

There is criticism of these and further claims for language acquisition by chimpanzees, including: (a) the chimpanzees are cued to make the signs by the humans (the *Clever Hans phenomenon); (b) the chimpanzees do not sign spontaneously, which is quite unlike children; (c) the chimpanzees sign

Page 633

only for rewards; (d) humans are needed to teach them; they don't develop signing by themselves.

The author's experiments, with Loulis, were designed to answer at least some of these criticisms. The signs used were limited to seven: *who*, *what*, *want*, *where*, *which*, *name*, and *sign*. Apart from these, vocal English was used to communicate to the chimpanzee, to ensure that he could not acquire extra signs from humans.

These experiments suggest that chimpanzees can communicate with each other, for not only has Loulis acquired signs from Washoe and the other signing chimps he lives with, but Washoe and the other chimps have acquired new signs from each other in their chimpanzee-to-chimpanzee signing conversations. It was observed that a chimp would teach another chimp by demonstrating, for example the *chairsit* sign, several times, with a toy chair. Fouts (1984) has made video records, over randomly selected twenty minute periods, of what appears to be (612 occurrences of signs) chimptochimp sign conversation. The use of video recording prevents cuing by humans. Also, spontaneous signing has been observed many times (Fouts, Fouts, and Schoenfeld, 1984), and many of these were for social communication rather than (only 5 per cent) for food reward.

Some investigators, however, such as Terrace, Petitto, Sanders and Beret (1979) and Savage-Rumbaugh, Rumbaugh, and Boysen (1980), have failed to achieve evidence of language acquisition in chimps. Possibly they used ineffective procedures, such as inappropriate rewards. It has been suggested that language learning (and, for children, drawing) is intrinsically rewarding, for chimps as it is for human children; and that for both, extrinsic rewards such as food can impair

performance and learning.

Language and cognitive understanding (Premack, 1971) in chimps is controversial, some authorities altogether denying chimp language; but the possibility challenges any sharp break between human and animal cognition, which raises moral issues for how we should consider and treat animals even though normally we cannot talk to them.

PRIMATES, EVOLUTION OF THE BRAIN IN. The earliest placental mammals were small, nocturnal, insectivorous animals that lived in the Cretaceous period more than 100 million years ago (Fig. 1). They possessed acute senses of smell and hearing and long, sensitive snouts bearing vibrissae. Their eyes were small, laterally directed, and possessed very limited acuity. Their brains were somewhat larger than those of similarly sized reptiles, but the neocortex, which was to become the great focus of mammalian brain evolution, had undergone only very limited development (Fig. 2). The telencephalon was largely devoted to the olfactory bulbs and olfactory cortex. The early placental mammals lived in a landscape dominated by reptiles, but this was to change radically with the massive extinctions that devastated the ranks of the reptiles at the end of the Cretaceous. A host of

theories has been advanced to explain the sudden extinctions. Perhaps the most compelling, because of its strong support from geophysical data, is the theory advanced by L. W. Alvarez and his collaborators that a large asteroid struck the earth, resulting in the release of enormous quantities of dust into the atmosphere and thus a great reduction in sunlight reaching the earth's surface. The nocturnal, warmblooded mammals would have been much better equipped for survival during a period of sudden climatic cooling than were their reptilian contemporaries. Whatever the cause, 65 million years ago at the beginning of the Cainozoic era, the 'age of mammals', a large number of ecological niches lay vacant that formerly had been occupied by reptiles.

During the next 10 million years the basal stock of placental mammals began to differentiate into the various orders of mammals. The fossil remains Fig. 1.

The cortex ventral to the rhinal sulcus is largely devoted to the processing of olfactory input.

of the earliest Primates that bear a close resemblance to living Primates have been recovered from early Eocene deposits approximately 55 million years old. The skull and cranial endocast of one of these early Primates, *Tetorius homunculus*, is illustrated in Fig. 3. *Tetorius* possessed large bony orbits that completely encircled its eyes, and a cranium containing a large brain compared with its similarly sized contemporaries. The relative size and position of the orbits in *Tetorius* closely resemble living nocturnal prosimians such as *Galago* (Fig. 4). As can be seen in Fig. 5, *Galago* possesses large, frontally directed eyes with virtually as much binocular overlap, in the order of 120° to 140°, as is present in monkeys, apes, and man. The great similarity in the size and position of the orbits in *Galago* and *Tetorius* suggests that *Tetorius* also possessed large, frontally directed eyes and was crepuscular or nocturnal. The cranial endocasts of *Tetorius* and other Eocene Primates show that their brains possessed a conspicuous enlargement of the neocortex in the occipital and temporal lobes, which in modern Primates are known to be devoted mainly to the cortical processing of visual information (Fig. 4). Thus, by the early Eocene, there appeared in Primates the concomitant development of large, frontally directed eyes with improved acuity and an expanded visual cortex. The sensitive snout of the primitive placental mammals was greatly reduced in the early Primates. The functions of the snout as a tactile probe and an apprehender of insect prey were taken over by the hands. The olfactory system in the early Primates retained a comparable degree of development to that present in the early placental mammals. The size of the olfactory bulbs did not diminish relative to body size, but the occipital and temporal neocortex expanded so greatly that the olfactory bulbs became small by comparison (Figs. 2, 3, and 4).

These developments must reflect fundamental changes in ecological specialization that occurred in the evolutionary progression from the earliest placental mammals to the early Primates. Two theories have recently been advanced to explain the basic adaptations that served to differentiate Primates from the early placental mammals.

In the first, R. D. Martin has suggested that the early Primates, like the smaller living prosimians they closely resemble and the small arboreal marsupials

Page 635

of Australia and South America, adapted to a 'fine branch niche'; the prehensile hands and feet found in these animals developed to grasp the fine terminal branches of trees. Most arboreal mammals, such

as squirrels, run on the trunk and larger branches but are unable to grasp the finer branches. The second theory is based on the observation that, outside the order Primates, animals with large frontally directed eyes (owls and felids) are nocturnal, visually directed predators, which has led M.

Cartmill to propose that visually directed predation was the ecological specialization responsible for the developments in the early Primates. Cartmill's visual predation hypothesis is supported by the fact that the tarsier, the living Primate that most resembles the early Primates of the Eocene, is exclusively a predator (Fig. 6). It appears that both hypotheses have considerable merit. It seems probable that the early Primates did invade the 'fine branch niche', where they gained access to a rich array of insect and small vertebrate prey.

What are the advantages that frontally directed

Page 636

predator; it eats no fruit or vegetable matter.

Of the living Primates, the tarsier most closely

resembles the early Primates living in the Eocene.

eyes afford nocturnal, visually directed predators? Predators generally orient so that the prey is located in front of them so that they can propel themselves forward rapidly and carry out a coordinated attack with forelimbs and jaws, and it is likely that frontally directed eyes provide maximal retinal image quality, for the central part of the visual field where the prey is located, in the crucial moments before the final strike is made. Image distortion tends to increase the further an object is located off the optical axis of the lens system, and thus it is advantageous to a visually directed predator to have frontally directed eyes in which the optical axes are directed toward the central part of the visual field, so that the predator can utilize the maximum quality retinal image in the crucial moments before the strike, when it is evaluating the prey's movements, the prey's suitability as food, and the prey's ability to defend itself. The dimly illuminated nocturnal environment makes these optical factors particularly important, and rules out other mechanisms for improving retinal image quality such as stopping down lens aperture. Frontally directed eyes also provide a large binocular field over which binocular summation can be achieved, which may be of particular value in conditions of low illumination. The binocular input is also used to reconstruct a stereoscopic view of a large portion of the visual field. The advantages of stereoscopy to a predator are that it provides information about the distance of prey, and as B. Julesz has pointed out, it helps the predator to discriminate camouflaged prey from background (cf. VISION: THE EARLY

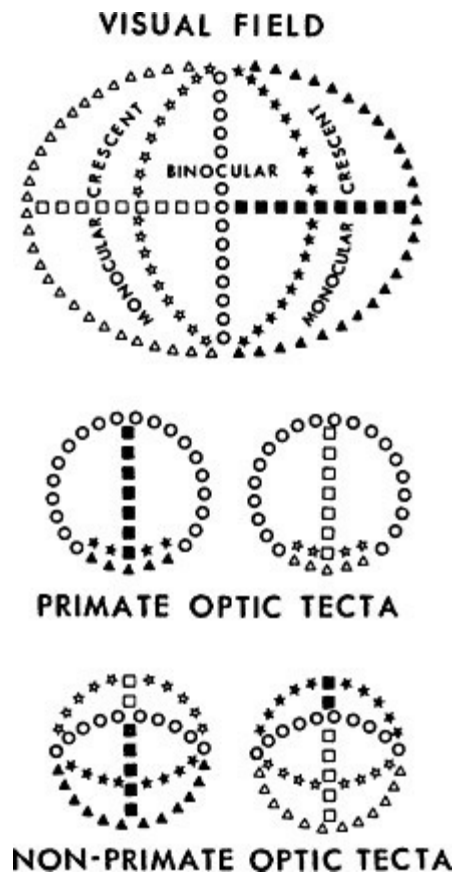

WARNING SYSTEM).

Almost all of the distinctive features of the Primate visual system relate to the frontal direction of the eyes and binocular integration, and since these features are present in all Primates, it is likely that they developed in the early Primates. These features include: (i) a high concentration of retinal ganglion cells in the central retina, and the greatly expanded representation of the central retina in the neural maps of the visual field in the brain; (ii) the representation restricted to the contralateral half of the visual field in each side of the optic tectum, differing from complete representation of the field of view of the contralateral retina found in each side of the optic tectum in all other vertebrates that have been investigated (Fig. 7); (iii) a relatively large retinotectal projection, which together with the unique visuotopic organization found in the Primate tectum, suggests that the optic tectum in the early Primates developed capacities related to the integration of binocular input; (iv) a distinctly laminated dorsal lateral geniculate nucleus in which inputs from the two retinae are brought into precise visuotopic register before being relayed to the primary visual cortex (VI);

and (v) a greatly expanded visual cortex containing a number of neural maps of the visual field (see LOCALIZATION OF BRAIN FUNCTION AND CORTICAL

MAYS).

Why does the visual cortex contain a series of separate representations of the visual field rather than a single map? In attempting to develop computer analogues of visual perception, D. Mart elaborated the principle of modular design. Mart stated that any large computation should be broken into a collection of smaller modules as independent as possible from one another. Otherwise, 'the process as a whole becomes extremely difficult to debug or improve, whether by a human designer or in the course of natural evolution, because a small change to improve one part has to be accompanied by many simultaneous changes elsewhere'. This modular principle has many counterparts in other biological systems. The palaeontologist W. K. Gregory noted that a common mechanism of evolution is the replication of body parts due to genetic mutation in a single generation which is then followed in subsequent generations by the gradual divergence of structure and functions of the duplicated parts. An analogous idea has been advanced by a number of geneticists. They have theorized that replicated genes escape the pressures of natural selection

Page 637

operating on the original gene, and thereby can accumulate mutations which enable the new gene, through changes in its DNA sequence, to encode for a novel protein capable of assuming new functions. Many clearcut examples of gene replication have been discovered, and DNA sequence homologies in replicated genes have recently been established. Using this analogy, the author and J. H. Kaas have proposed that the replication of cortical sensory representations has provided the structures upon which new information processing capabilities have developed in the course of evolution. Specifically, it has been argued that existing cortical areas, like genes, can undergo only limited changes and still perform the functions necessary for the animal's survival, but if a mutation occurs that results in the replication of a cortical area, then in subsequent generations the new area can eventually assume new functions through the mechanisms of natural selection while the original area continues to perform its functions.

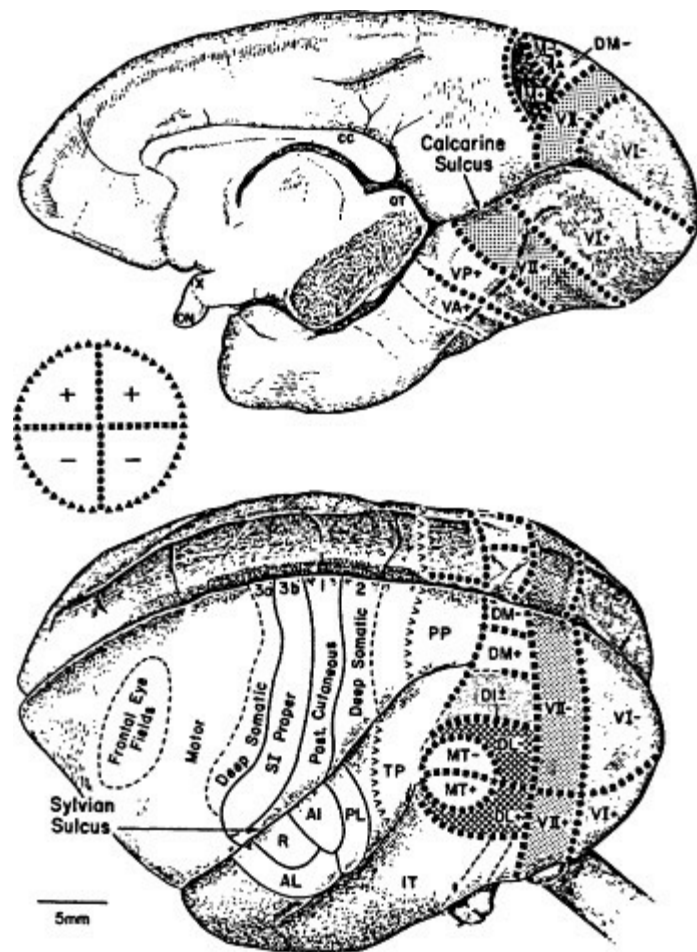

The primary visual cortex (VI) and the adjacent second visual area (VII) are present in all mammalian species that have been investigated. Thus, VI and VII were probably present in the early placental mammals that were the common ancestors of the various living mammalian orders. The full complement of cortical visual areas varies in different mammals from a minimum of two in a basal insectivore, the hedgehog (Fig. 2), to a maximum of twelve found in cats by Palmer, Tusa, and Rosenquist. At least nine cortical visual areas are present in the owl monkey, the Primate which has been mapped most completely (Fig. 8). Beyond VI and VII it is very difficult to establish homologies among the visual areas present in mammals belonging to different orders. The last common ancestor of the different mammalian orders lived no more recently than the late Cretaceous period more than 65 million years ago, and this ancestral mammal had only a very limited development of its neocortex. In addition, the adaptive radiation of mammals into different ecological niches with widely divergent behavioural specializations serves to make very difficult the discovery of diagnostic similarities among potentially homologous cortical areas in different mammalian orders.

Within the order Primates, it is easier to determine homologous areas in different species. The highly distinctive middle temporal visual area (MT) is present in prosimians and in both New and Old World monkeys and thus probably existed in the early Primates. MT neurones are selective for the direction of movement of visual stimuli and often are particularly responsive to moving fields of visual texture. MT may have developed as a specialized mechanism for detecting and tracking moving prey. MT may also participate in visuomotor coordination by analysing the visual flow patterns that the animal sees as it moves through its environment; MT

projects via the pontine nuclei to the cerebellum, a major centre for the control of body and eye movements. The evolutionary development of this system may be related to the special demands of locomotion in the 'fine branch niche'.

The dorsolateral visual area (DL) lies adjacent to MT and also appears to be part of the basic complement of visual areas common to all living Primates and thus probably existing in the early

Primates. In DL about 70 per cent of the neurones are selective for the spatial dimensions (length and width) of visual stimuli within excitatory receptive fields that generally are much larger than the preferred stimulus dimensions. The dimensional selectivity of DL neurones is independent of the sign of contrast in the receptive field, as they are equally selective to both light on dark and dark on light stimuli, the amount of contrast, and the position of the stimulus within the excitatory receptive field. It suggests that DL contributes to *form perception*. This hypothesis is consistent with the

Page 638

Fig. 8.

The representations of the sensory domains in the cerebral cortex of the owl monkey. Above is a ventromedial view of the right hemisphere, below is a dorsolateral view of both hemispheres. On the left is a perimeter chart of the visual field. The symbols in this chart are superimposed on the surface of the visual cortex. Pluses indicate upper quadrant representations; minuses, lower quadrants. The row of Vs indicates the approximate border of visually responsive cortex. AI, first auditory area; AL, anterolateral auditory area; CC, corpus callosum; DI, dorsointermediate visual area; DL, dorsolateral crescent

visual area; DM, dorsomedial visual area; IT, inferotemporal cortex; M, medial visual area;

MT, middle temporal visual area; ON, optic nerve; OT, optic tectum; PL, posterolateral

auditory area; PP, posterior parietal cortex; R, rostral auditory area; VI, first visual area;

VII, second visual area; VA, ventral anterior visual area; VP, ventral posterior visual area;

X, optic chiasm. The main connections of the visual areas are as follows. VI projects to VII and MT. VII projects to DL, which in turn projects to IT. MT projects to all visual areas except VII and IT. MT and PP project to the frontal eye fields.

fact that DL, of all the visual areas, has the most expanded representation of the central visual field where the most acute recognition of form takes place, and with the discovery (by Weller and Kaas) that DL is the main source of input to inferotemporal cortex. Inferotemporal cortex (IT) has been strongly implicated in the analysis of complex visual stimuli and the learning of visual form discriminations.

The small amount of neocortex possessed by the early placental mammals and the great variation in the number of cortical visual areas reported for different mammalian species suggests that some of the areas beyond VI and VII developed at different stages in evolution and independently in different lines of descent. One clear example of variation within the order Primates is among the areas immediately anterior to VII. In the prosimian *Galago*, only one map of the visual field, the dorsal area (D), is located in the position occupied by three separate maps, M, DM, and DI, in the owl monkey (see Fig. 8). The existing data suggest that Page 639

there exists a core of areas including VI, VII, MT, and DL and possibly one or two others that are common to all Primates, but that there also exist areas present in some species but not in others. It is probable that each area performs a distinct set of functions in visual perception and visuomotor coordination, and that an area possessed by one species (or larger taxon) and not by another will endow its possessor with behavioural capacities not present in the other. A major task for the future will be to determine what are the distinctive functions of these cortical areas and how they relate to the behavioural and ecological specializations of their possessors.

The early Primates probably were small nocturnal predators living in the fine branches; some Primates have retained this mode of life, but most have become larger, diurnal folivores or frugivores. Frugivorous diet is correlated positively with brain size and the amount of neocortex relative to body size in Primates. This association between frugivorous diet and enlarged brain and neocortex may be related to the special demands imposed because a fruiteater's food supply is not constant, since different plants bear fruit at different times and at different locations in the complex matrix of the tropical forest. It is clear that an animal guided by memory of the locations of fruitbearing trees can more efficiently exploit the available fruit resources than would be possible otherwise. Thus natural selection would have favoured the development in frugivorous Primates of capacities for visuospatial memory, which may be localized in a particular area or set of areas.

Another, even more significant behavioural specialization is the development of complex systems of social organization in many Primate species. The neural substrate for the mediation of social communication is bound to be an important focus of evolutionary change in the brains of Primates. The order Primates is divided into the strepsirhines (lorises, lemurs, galagos), which tend to have relatively simple forms of social organization, and the haplorhines (tarsiers, monkeys, apes, and humans), in which social organization tends to be much more complex. In strepsirhines, as in most mammals, the rhinarium, the space between the upper lip and the nostrils, is furless, moist mucosal tissue that is tightly bound to the underlying maxillary bone and is divided along the midline by a deep cleft (Fig. 5). Since strepsirhines share this type of rhinarium with most other mammals, it is very likely to have been the primitive condition in Primates. By contrast, haplorhines possess a furry rhinarium and a mobile upper lip that is capable of participating in facial expression. Strepsirhines, like most primitive mammals, have scent glands and scentmarking behaviours that play a very important role in their social communication, and while haplorhines also use olfactory cues to some extent, they rely much more heavily on the use of visually perceived facial expressions and gestures, which allow much more rapid and subtle communication. Strepsirhines also tend to have much larger olfactory bulbs than do haplorhines. Thus it appears that as complex systems of social organization evolved in haplorhine Primates, social communication was increasingly mediated by the visual

channel at the expense of the olfactory. One expression of this evolutionary development is the sensory input to the amygdala, which controls the neuroendocrine functions of the hypothalamus and thus emotion. Primitively, the main input to the amygdala was from the olfactory bulb, but in haplorhines the main input is from the temporal lobe and particularly from inferotemporal cortex, which is a highlevel processor of visual information. Neurones responsive to the specific configurations of faces have been recorded in the amygdala and temporal cortex. The clinical condition prosopagnosia, the inability to recognize familiar faces with relatively little impairment of other visual functions, which is usually associated with lesions located near the occipital temporal junction (see SPLITBRAIN AND THE

MIND), suggests the development of a specialized system for processing the information in faces. Finally, in man, another system of social communication, language, has developed along with specialized cortical regions in the temporal and frontal lobes (see LANGUAGE AREAS IN THE BRAIN).

PROBLEMS: THEIR APPEAL. People enjoy the mental stimulation of a good problem, and for some it becomes a powerful need—a cerebral restlessness epitomized in fiction by Sherlock Holmes. It makes little odds whether the problem is trivial or profound, vague or precise, so long as it tempts us to resolve a state of puzzlement or contradiction. Harlow et al. (1950) have shown that even

monkeys spend considerable time in the manipulation of puzzles, without any extrinsic reward when left to their own devices. Does curiosity constitute a biological need? White (1959) and Berlyne (1971) have developed the theory that one reason for seeking the stimulation of novelty is to ward off boredom. The challenge of the

Page 640

problematic is manifested in a wide variety of forms, and here we contrast the response to two problem situations of a very different kind in order to see what they have in common.

The solution to a formal problem generally demands the postulation of a hypothesis, the assumption that something is true without knowing whether it is true. Its consequences can then be tested to see whether they fit the facts. The following is a very precise problem which *critically* requires this ability (Wason, 1977). (For a fascinating development of this problem, see Smyth and Clark, 1986.) If the individual does not think about it hypothetically he finds himself in a lookingglass world where everything seems the wrong way round.

In front of you imagine four designs made up of two colours and two shapes:

Blue circle

Blue diamond

Red diamond

Red circle

The problem is this: 'In these designs there is a particular shape and a particular colour such that any of the designs which has one, and only one, of these features is called a THOG. If the *blue diamond* is a THOG, could any of the other designs be THOGS?'

The problem hardly seems difficult. The *red circle* obviously could not be a THOG, and the other two could be THOGS because each has one feature of the *blue diamond*. That is the commonsense solution and it is wrong; it is the mirror image of the correct solution. If the *blue diamond* is a THOG, then the *red circle* is a THOG, and neither the *blue circle* nor the *red diamond* could be THOGS.

There is more than one path to the solution, but the following one is probably the clearest. Postulate a hypothesis about the pairs of features consistent with the *blue diamond* being a THOG. It could not be ['blue' and 'diamond'] and it could not be ['red' and 'circle']. These hypotheses have both, or neither, of the features contained in the *blue diamond*, and the problem states that a THOG has just one. Try ['blue' and 'circle'] as a candidate. It would stop the *blue circle* being a THOG

(it has both features) and also the *red diamond* (it has neither feature), but it would make the *red circle* a THOG because 'circle' is one of its features. The only other hypothesis compatible with the blue diamond being a THOG is ['red' and 'diamond']. By the same argument it would rule out both the

red diamond and the *blue circle* but it also would make the *red circle* a THOG because 'red' is one of its features. The solution is rather elusive because the reasoner has to keep clear the distinction between the designs and the features which constitute them.

Elsie Mimikos showed that students with a science education do better on this problem than students with an arts education. A subsequent experiment convincingly replicated this result. Twentyfive out of thirtytwo science graduates solved it compared with only three out of thirtytwo arts graduates. It would seem that the precise hypothetical thinking which is involved may be alien for the latter group, although there is no imputation that the problem is in any way a test of intelligence.

The formal elegance of the 'Thog problem' prevents it from resembling most of the problems we encounter in daily life. It tests a highly specific skill—that is all.

Problems do not generally come like this, in neatly packaged form. They have to be discovered, and it is difficult to investigate this process experimentally. Moreover, the problems used by the psychologist to study thinking usually have one right answer. In real life problems are seldom like this; they have many different grades of adequate answer. Art, furthermore, provides a realm in which problems do not have right answers at all. It may be objected that this is to stretch the meaning of the word 'problem' metaphorically, but artists (and poets) do often discuss their work in these terms.

In a unique longitudinal study of artistic creativity, Getzels and Csikszentmihalyi (1976) were struck by the fact that students of fine art seemed primarily motivated by selfdiscovery. It might be expected that they would discuss the rewards of the artist in aesthetic terms, in terms of 'beauty', 'harmony', or the creation of 'order'.

Instead they talked about them much more in terms of 'discovery' and 'understanding', and this suggested that their work was structured around 'discovered problem situations'. The investigators developed an ingenious technique to test this idea. Thirtyone fineart students were asked to compose a stilllife drawing based on a selection from a number of objects which were placed on an adjacent table. The first task of each student was to choose some of these objects, and arrange them on another table to form the subject of his composition. The investigators made the assumption that the choice of objects corresponded to a 'problemfinding' stage. They observed the number of objects chosen, the way in which the student explored and handled them, and their uniqueness, i.e. the extent to which each had been chosen by the other students. These indices were assumed to reflect the characteristic ways in which a person approaches an unstructured aesthetic task. They were used to test the hypothesis that individuals who considered more problematic elements, explored problematic elements more thoroughly, and selected the less common among them, would formulate a visual problem which would result in a more original drawing. Five art critics, who knew nothing about the experiment, then independently rated each drawing for originality, aesthetic value, and craftsmanship. The main result confirmed the prediction. The problemfinding process results in drawings which are judged to be more original, but not necessarily of higher craftsmanship. In fact, the correlation between the problemfinding scores and 'originality' was highly significant.

This result is really surprising: the quality of the final product is related to behaviour *before* the

drawing started. It was corroborated by sub

Page 641

sequent interviews. Those artists who stated that when they started to work they had no clear idea about what they would do, produced drawings which were highly rated for aesthetic value and originality; those who stated they already had a problem in mind when they approached the task were rated low on the same dimensions.

It was corroborated by measures of time taken during the experiment. The only such measure significantly related to the quality of the drawings was time spent in choosing objects, as opposed to time spent in arranging or drawing them.

In science the result would hardly be surprising because its theories are based on explicitly formulated problems, while the products of art are based on the attempt to come to grips with unformulated private problems. Copernicus's questioning of the commonsense observation that the sun revolves around the earth was also highly original. But in the long run his doubts would have had no more value than a delusion had they not also been shown to be true. After problems have been discovered in science the testing of possible solutions can proceed deductively in order to see whether they can be falsified. It is precisely this ability which the 'Thog problem'

attempts to catch in a small way. A scientist would probably regard it as trivial because skill in solving it involves no imagination. And yet this skill involves an analysis of the structure behind the surface of things. Without it, a person finds the solution incredible in its outrageous assault on common sense—the *red circle* has *nothing* in common with the *blue diamond*. How different it is from the production of a work of art subject only to aesthetic appraisal! We should not allow the difference to conceal a more fundamental similarity. In both science and art the individual is driven by an insatiable curiosity which refuses to accept things as they are, and which forces us to think about them in a new way. The origin of this curiosity is manifest in the appeal which artificial problems exert upon us.

PROBLEMSOLVING. A great deal of the art of problemsolving is to understand the kind of question that is posed and the kind of answer that is demanded. It is for this reason that psychologists prefer problems with unique solutions, and that they try to ensure that individuals understand what they have to solve.

There are several theoretical points of view about problemsolving, but none are really complete because each tends to be restricted to different problem domains, and there is little definitive agreement about what constitutes a problem. The*Gestalt theorists (e.g. Wertheimer, 1969) believed that a problem occurs because of the way in which a situation is initially perceived, and that its solution emerges suddenly from reorganizing it in such a way that its real structure becomes apparent. On the other hand, many contemporary psychologists have been impressed by ideas borrowed from research on*artificial intelligence. They conceive the mind as analogous to a computer program which operates in discrete steps ('informationprocessing') to reduce the difference between existing states and 'subgoals'. Their pioneering efforts were devoted mainly to a small number of computable games and puzzles, and they were not deterred by the fact that computer programs played poor chess. See Newell and Simon (1972), and, for criticism, Dreyfus (1972) and Weizenbaum (1976); and COMPUTER CHESS for recent improvements. For an account of the fundamental difficulties of computer chess, see Hartson and Watson (1983, ch. 6). My own interest has been to devise problems in which the initial response may ensnare the capacity to see the point.

The difficulty of writing about problemsolving is that one may either insult the reader's intelligence, or create states of frustration. Hence I shall not report the solution to my first problem. Instead I shall take the reader by the hand (if he will pardon the condescension) and ask him to solve with me two related, simplified problems.

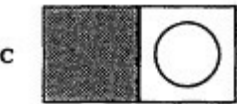

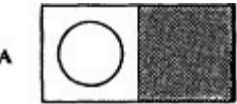

These may alter the way in which he conceived the original problem. Of course, he may find the first problem trivial, but then I hope his boredom will be alleviated by the knowledge that others find it rather puzzling. I could say a lot more at this point, but that would be to lay all my cards on the table. Consider the first problem.

Problem 1. I formulated this problem in 1966, and the present version was devised for the 1977 Science Museum Explorations Exhibition in London. Earlier versions contained some confusing features. The problem is generally known as 'the selection task'.

You are shown a panel of four cards, A, B, C, D (Fig. 1), together with the following instructions: Which of the hidden parts of these cards do you *need* to see in order to answer the following question decisively? FOR THESE CARDS IS IT TRUE THAT IF THERE IS A CIRCLE ON THE LEFT THERE IS A CIRCLE ON THE RIGHT? You have only *one* opportunity to make this decision; you must not assume that you can inspect cards one at a time. Name those cards which it is absolutely

necessary to see.

Please record your solution, and then consider the next problem.

WHITE

BLACK

MANCHESTER

LEEDS

TRAIN

CAR

Fig. 1.

Problem 1: the Science Museum Problem.

Problem 2. This problem is based on JohnsonLaird and Wason (1970). A more recent, intensive

investigation of the issues may be found in Wason and Green (1984). In front of you are two boxes, one labelled WHITE and the other labelled BLACK (Fig. 2). There are fifteen white shapes in the white box and fifteen black shapes in the black box, and the only shapes are triangles and circles. Your problem is to prove the following sentence true, as economically as possible, by requesting to inspect shapes from either box: IF THEY ARE TRIANGLES, THEN THEY ARE BLACK.

The students who were tested in this experiment tended to ask first of all for a black shape—they were handed a black triangle. The task turned out to be fairly easy;

on average only six black shapes were requested. Of course, when individuals asked for a white shape they were always handed a white circle. Somebody in my class said recently: 'The best strategy is to alternate your choices between the two boxes.' This would have been a perverse strategy, especially if one were to apply it consistently by exhausting the contents of both boxes. In fact, insight came rapidly, and all the individuals Fig. 2.

Problem 2.

exhausted the supply of fifteen white circles, and requested no more than nine black shapes. Moreover, they tended to do so with a broad grin, as if they had penetrated a secret, or seen the point of a joke. In order to prove the truth of the sentence 'If they are triangles, then they are black', it is merely necessary to establish the absence of a white triangle. The contents of the black box are gratuitous.

What is the connection between problems 1 and 2? In the first place, problem 2 is only concerned with half the amount of information in problem 1. In problem 2 no decision has to be made about 'triangles' and 'circles' which corresponds to the presence and absence of a 'circle on the left'. Secondly, problem 1 involves a single and ultimate decision for its solution, but problem 2 involves a series of decisions so that an earlier error can be corrected. Thirdly, problem 2 involves a number of concrete objects rather than the consideration of symbols positioned on cards.

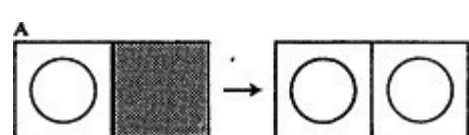

Are you still satisfied with your solution to problem 1?

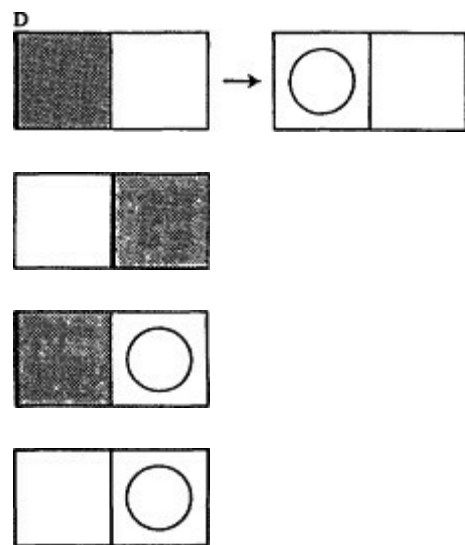

Problem 3. This problem is based on Wason and Shapiro (1971). There are four cards on the table in front of you, showing (respectively) 'Manchester', 'Leeds',

'Train', 'Car' (Fig. 3). The students who were tested in this experiment had first of all examined a larger set of cards (from which these four had been selected), each of which had on one

Fig. 3.

Problem 3.

Page 643

side a town (e.g. Chicago), and on the other side a mode of transport (e.g. aeroplane). They had been asked to satisfy themselves that this condition obtained on every card. The four cards were then placed on the table, and the individuals were instructed to imagine that each represented a journey made by the experimenter.

They were then presented with the experimenter's claim about her journeys: EVERY TIME I GO TO MANCHESTER I TRAVEL BY TRAIN.

The problem is to state which cards need to be turned over in order to determine whether this claim is true or false. The solution is 'Manchester' and 'Car' because only 'Manchester' associated with a transport other than 'Train', or 'Car' associated with 'Manchester' would disprove the claim. This thematic problem proved much easier than a standard, abstract version which was structurally equivalent to problem 1. However, recent attempts to replicate this effect have not been at all clear. For a general discussion, see Griggs (1983).

What is the connection between problems 1 and 3? In both a single decision has to be made about four cards, so in this sense they are both unlike problem 2. But in problem 3 the cards are not simply cards. They represent four different journeys and their two sides are connected intrinsically in this respect. This means that the material of the problem is intimately related to experience, and the solution can be guided by it. For a more detailed account of these, and similar, experiments see Wason and JohnsonLaird (1972).

Still happy about the solution to problem 1? If it did cause any difficulties, it seems fairly likely that any error will now have been corrected because that particular problem has been broken down into two much simpler ones, each of which eases the original burden of thought. But suppose, just for the sake of argument, that the solution to problem 1 is still wrong—for instance, it might be cards A and C. In the original experiments based on it I devised therapies which induced contradictions between the first attempted solution and a subsequent evaluation of the material. The card, corresponding to A, which everybody had (rightly) selected, would have been revealed thus:

'What does this tell you about the answer to the question?' ('For these cards is it true that if there is a circle on the left there is a circle on the right?') Everybody said that this told them the answer is 'yes'.

Then the card, corresponding to D, which nearly everyone had (wrongly) omitted, would have been revealed thus: Conflict: a card which had been chosen allowed the answer 'yes', but now a card which had been ignored indubitably forces the answer 'no'. The majority of individuals remained unmoved—they refused at this point to incorporate D into their solution. When prompted, they made remarks like, 'It's got nothing to do with it', and 'It doesn't matter'. All the available evidence is present, but the correction tends not to be made.

We went on informally to discuss the potential consequences of B and C which were never fully revealed. B had nearly always been omitted (rightly) and C selected (wrongly).

'Can you say anything about the answer from this card [B]?':

'It's got nothing to do with it because there's no circle [on the left].'

'Can you say anything about the answer from this card [C]?':

'There has to be a circle under it for the answer to be "yes".'

'What if there is no circle?'

'Then the answer would be "no".'

What could be the selfsame card has a different meaning according to whether it had been selected initially. The individual is confronted with the possibility of both cards being like this:

But only when this contingency derives from C is it assumed (wrongly) to be informative. It is evidently the individual's intention to select a card which confers meaning on it.

Reality, for the individuals who made these kinds of error, is determined by their own thought. That is not, perhaps, surprising. What is very surprising is that this reality is so recalcitrant to correction. See Wason (1977) for further discussion. For a recent and much more comprehensive account of the issues raised by this problem, see Wason (1983). It is as if the attention mobilized in

Page 644

the initial decision is divided from their subsequent attention to facts, or possibilities. The solution, cards A and D, is systematically evaded in ways which are not yet

properly understood. There is even the finding that the origin of the difficulty might arise through differences in the functioning of the two hemispheres of the normal brain. When corrective feedback is induced in the left ('analytic') hemisphere it is more effective than when it is induced in the right ('synthetic') hemisphere.

Our basic paradigm (problem 1) has the enormous advantage of being artificial and novel; in these studies we are not interested in everyday thought, but in the kind of thinking which occurs when there is minimal meaning in the things around us. On a much smaller scale, what do our students' remarks remind us of in real life? They are like saying 'Of course, the earth is fiat', 'Of course, we are descended from Adam and Eve', 'Of course, space has nothing to do with time'. The old ways of seeing things now look like absurd prejudices, but our highly intelligent student volunteers display analogous miniature prejudices when their premature conclusions are challenged by the facts. As Kuhn (1962) has shown, the old paradigms do not yield in the face of a few counterexamples. In the same way, our volunteers do not often accommodate their thought to new observations, even those governed by logical necessity, in a deceptive problem situation. They will frequently deny the facts, or contradict themselves, rather than shift their frame of reference.

Other treatments and interpretations of problemsolving could have been cited. For instance, most problems studied by psychologists create a sense of perplexity rather than a specious answer. But the present interpretation, in terms of the development of dogma and its resistance to truth, reveals the interest and excitement generated by research in this area.

PROGRAMS AND PLANNING. It is safe to predict that concepts of computation will play an increasing role in the articulation of theories of the mind. Here we introduce the basic notion of a 'program' which underlies computation and relates it to the mental activity of planning. It is emphasized that computer science is an evolving subject, and that the analysis of mental activity is already feeding back into computer science to yield notions of programs of increasing subtlety and flexibility.

A program for an ordinary electronic computer executes one instruction at a time: to transfer inputs to memory, to combine pieces of data, to control output devices, and—crucially—to choose the next instruction on the basis of a test. Because of these tests, the 'overt behaviour' of the program—the temporal sequence of reading of inputs and emission of output values—will depend on both the input values and data values already stored internally. This dependence yields the basic logical property of algorithms: a program can be specified in a form shorter than any normal execution upon particular data.

By contrast, normal English usage often takes 'preprogrammed' as a synonym for 'stereotyped', and for many people, the word 'program' is synonymous with the notion of a 'fixed sequence', so that each fixed behavioural sequence is a different program. However, for the computer scientist, it is the program that provides the formal description of the process which generates different output sequences on the basis of differing values of inputs and internal parameters. To take a simple example, consider a man walking to the door. Depending on where he starts, his overt behaviour might require three steps or thirty—and each such sequence would constitute a 'program' in the fixed sequence sense. But it seems more insightful to hypothesize that a single program in the computer scientist's sense underlies all these behaviours. In one formalism, we might represent it as:

DO *advance one step* UNTIL *door is reached*. (This can be recognized as a notational variant of the TOTE unit—TestOperateTestExit—of Miller, Galanter, and Pribram, 1960, p.

26.) Here we explain all behaviours of the class in terms of a program with one action, *advance one step*, whose execution is repeated under the control of a single test, *is door reached*?

If we regard this program as a hypothesis about human behaviour, we turn attention from the release of patterns with fixed numbers of steps to Page 645

the study of ways in which perceptual mechanisms testing *is door reached*? may 'gate' motor mechanisms. At a simple level, such 'gating' differs little from negative feedback, but when we move to planning behaviour in a complex environment, the loops within loops seem to call for the richer vocabulary that computer science can help to provide. We turn then to a look at this vocabulary.

For certain motor tasks, a sufficiently highlevel choice of strategy need not involve specification of the details of execution at the muscular level. For example, *Lashley (1929, p. 137) notes that animals which have learned a maze prior to injuries to the motor system continue to traverse it, although muscular activity may be changed completely—one animal had to roll over completely in making each turn, yet made no errors in traversing the maze. Again, in writing a word, we use a completely different set of muscles, depending on whether the instrument available is a pencil or whether it is a paintbrush on the end of a long pole. How is it that we can still produce our characteristic mode of writing with these two different systems? Computer scientists find it expedient to program a computer not in the machine language that directly controls the basic operations of its machinery but rather in terms of some highlevel language. They provide the computer with a translation program called an 'interpreter' that will enable the computer to translate each instruction from the highlevel program and then execute it. In much computing, the process of translation is relatively straightforward—multiplication of matrices, or sorting a sequence of numbers into a histogram can be carried out by standard procedures which (once the size of the matrices or the length of the sequence is given) do not depend on the idiosyncracies of the situation. However, the study within AI (*artificial intelligence) of *planning*—programming a computer to go from goal specifications to a plan for achieving the goals—may be viewed as the study of *contextdependent* translation.

Consider, for example, our program above as one way of compiling the higherlevel instruction *go to the door*. Such a compilation is appropriate only if the system is facing the door and there are no obstacles *en route*. Otherwise, the position of the 'organism' and the layout of obstacles within the room must be taken into account in determining a path.

We shall illustrate the AI approach to highlevel planning of movement by considering a mobile robot equipped with a television camera and wheels. The planning problem for this robot enables it to respond to a command such as 'Push the large cube to the door' by (i) forming a plan that will take it to the cube without bumping into obstacles, and then will allow it to push the cube to the door without bumping into obstacles; and, then, (ii) executing the plan. A separate problem, then, is the design of a visual system (Hanson and Riseman, 1978) to locate the obstacles.

To simplify the planning problem for the mobile robot, we may schematize its task as that of selecting a number of intermediate points (called nodes) to pass through in sequence, *en route* to its goal. A path is then a trajectory that links up these nodes in order. Clearly, the nodes must be so chosen that, in moving from one point to the next, the robot does not bump into any obstacle. When given a task specified in a highlevel language, the robot must find a path that achieves the task and that is also, ideally, as short as possible.

The simplest form of this problem is to find the shortest path from one specified place to another. What makes the problem interesting is that the space may be so complicated that it is impossible to consider all alternatives. Instead, workers in AI have sought ways to 'grow' paths, considering for each point along a possible trajectory a limited number of candidates for the next segment. It should be emphasized that this process of pathgrowing is made within the computer during the *planning* stage. At the completion of this pathgrowing process, a single path results, and it is this that directs

the actual movement of the robot. In most AI research projects, all relevant details about the 'search space' are represented in the 'internal model' within the computer. In biological organisms, the internal model is only approximate, and sensory input must be used in model updating and, where necessary, replanning. In building on such AI approaches to model the neural control of movement in animals and to build more adaptable robots, we study the extent to which planning and execution would be interwoven within the action-perception cycle (see SCHEMAS).

Doran and Michie (1966) proposed a path-growing program that used the idea of a *heuristic distance*, which is defined as an indication, rather than a guaranteed measure, of distance to the goal. For example, the straightline distance is a heuristic distance for the real distance when one avoids the obstacles. The Doran-Michie approach proceeds by exploring alternative paths, giving first preference to the exploration of paths whose next node has the least heuristic distance to the goal node.

However, while this algorithm always yields a path from the start node (which represents where the system is) to the goal node (which represents where the system is to be), it cannot be guaranteed that the path obtained is the shortest. This problem was overcome by Hart, Nilsson, and Raphael (1968), who developed an algorithm that gave first preference to the exploration of paths whose next node had a minimal sum of distance already traversed from the start node plus heuristic distance to the goal node.

In later work, Fikes, Hart, and Nilsson (1972) studied generalized robot plans. Very briefly, the idea is to store information about the changes in the relationship between the robot and the environment brought about by a sequence of actions that are part of a successful plan. As time goes by, and other plans are made, various constants within both the sequence of operations and the prescription of its effects are replaced by variables, Page 646

in such a way that the robot has available a number of MACBOPs: high-level operations that will let it meet many familiar planning problems. Sacerdoti (1974) has built on this study to define a problem solver called ABSTRIPS, which uses planning in a hierarchy of abstraction spaces. It usually proves far more efficient to plan the overall stages of a series of movements, and then refine the plan with greater and greater detail, making modifications only when necessary, than to grow the overall plan step by step, with each step defined at the lowest level. The importance of these studies is clear. The first shows how AI provides techniques which we may refine into a theory of 'learning from experience'. The second gives us a clue as to how to analyse the relation between a 'plan' in its colloquial sense of a high-level 'strategic'

specification of a course of action, and the detailed step-by-step unfolding of that action when the plan is executed.

With those programs written by AI researchers to explicitly embody aspects of the planning process, we are well on our way to an even more abstract type of program—a *program synthesizer*, which takes as its input samples of behaviour (e.g. input-output relations) and generates programs that can yield this type of behaviour. In fact, we may regard the generation of MACROPS as an example of program synthesis. To summarize, then, we have the following levels of program sophistication. (i)

Straightline program: executing a fixed predetermined sequence. (ii) Program: executing a sequence of actions whose composition may depend on online testing of internal and external values. (iii) Planning (= contextdependent interpretation): knowing what to do, in general terms, find a solution tailored to the current situation. (iv) Program synthesis from examples; starts by finding out what is the problem to be solved.

Yet another style of programming comes with the study of *concurrent programming*, stimulated by the technological concern with playing out computation over a network of concurrently active, communicating, computers. In brain theory and AI we speak of *cooperative computation*. A classic example in brain theory is the KilmerMcCulloch (1968) model of the reticular formation of the brain as a set of interacting modules that could reach a global consensus without any single module having executive control. To put the AI problem in picturesque terms, consider that you have a library of books, and need to get the references to solve a problem.

The cooperative computation approach is the analogue of having each book become an *active* process, with the books responding to user questions, and 'talking' to each other, until they agree on what is required. Arbib and Caplan (1979) have analysed the relevance of such techniques to the study of language mechanisms in the human brain.

And this is only the beginning of the evolution of computing concepts relevant to the construction of theories of mind and brain.

PROJECTIVE TECHNIQUES derive their name from the psychoanalytic concept of *projection*, the mechanism whereby psychological states or processes in the self are seen as pertaining to an object in the outside world. Projection is most commonly regarded as a defence mechanism, a means whereby the*ego protects itself from anxiety, associated with unpleasant or unacceptable thoughts and feelings, by attributing them to others. This aspect of projection, however, is not part of the rationale of projective techniques, which can be used without necessarily accepting the tenets of psychoanalytic theory. A more helpful definition of projection in this context is the process whereby the individual 'projects' something of himself or herself into everything he or she does, in line with

Gordon Allport's concept of expressive behaviour. The aim of projective techniques is, then, to provide stimuli or situations, to which variations in response may be interpreted in accordance with a set of rules.

The two bestknown projective techniques are the Rorschach inkblots and the Thematic Apperception Test (TAT).

The Rorschach test consists of a series of ten symmetrical inkblots, five in black and white only, and five introducing colour. The subject is asked to report what he or she sees in each blot in turn; at the end of the series an 'inquiry' allows for clarification of the responses. Responses are classified within each of three 'scoring'

categories: *location*, *determinants*, and *content*. *Location* refers to how much and which part of the blot area has been used; *determinants* to the structural qualities, namely form (shape), colour, shading, and inferred movement; *content* to the types of object seen, with particular emphasis on human, animal, and anatomical percepts. Total incidence of each type of response is noted, and various ratios and percentages calculated. Traditionally considerable importance is attached to scoring, but recently there has been a move towards increased interest in content, treated in the same way as other material obtained in clinical interview.

Material for the TAT, devised by the American psychologist H. A. Murray as an adjunct to his 'needpress' theory of motivation, consists of blackandwhite pictures representing personal and interpersonal situations, the subject being required to make up a story about each in turn. In Page 647

its original form the test is administered individually, in two series often pictures each; the response is given orally, with provision for prompting, if required. More recently there has been a trend towards a single shorter series and group administration with written response; nonstandard pictures are also sometimes used. Since relatively little importance is attached to formal scoring, such flexibility is permissible, and indeed thematic apperception is probably best regarded as designating a group of procedures rather than a specific test.

Murray's own system of analysis rests on his concepts of *need*, a hypothetical force or process in the organism, and *press*, a force or other element in the environment which activates a need in the perceiver. Incidence of the expression of need and press variables, as well as others, such as 'outcome', in the subject's TAT material may be compared with norms, which will obviously vary with populations and circumstances of testing. For this reason, among others, many users of the TAT prefer to use systems of analysis which they consider better suited to the purpose in hand.

Other projective methods include Word Association (in which the subject speaks or writes the first word that comes to mind in response to a stimulus word), Sentence Completion, and various 'activity' methods, principally drawing (most commonly of the human figure) and structured play, as in the sandtray procedures familiar in child guidance and child psychiatry settings.

In all of these, as well as in the Rorschach and the TAT, it is possible to achieve some measure of

quantification of the data, and so to claim that measurement has taken place. Measurement, however, is not a primary concern of projective psychology, a fact reflected in the choice of the term 'techniques' rather than 'tests' in the title of this entry. Interpretative hypotheses are, of course, attached to Rorschach variables, and to other projective 'indicators'. In some cases, as in the formulation of a set of 'signs' of brain damage, criteria for validation are available, and would appear, in that particular case, to have been met. In others, particularly when a form of response relates to experience rather than to behaviour, demonstration of validity presents more serious problems. In the cognate field of reliability, test-retest reliability presupposes personality to be static, and in statistical terms can be applied only to single category scores; whereas the projective standpoint has always been that a protocol must be interpreted as a whole. 'Tester effects' may also be quite powerful, but may be understood if one regards projective testing as a channel of communication between particular individuals in a specific situation. Free expression is impeded by use of a forced-choice format, or by the imposition of statistical control, as in the Holtzman Inkblot Technique, a variant of the Rorschach, in which the number of responses (itself a variable considered important in standard Rorschach practice) is controlled by limiting the subject to a single response to each of a longer series of stimuli.

Attempts to make projective testing conform to psychometric standards have in general met with relatively little success; many projectivists indeed believe that such an aim is illusory. Projective techniques are properly regarded as an aid to, rather than an instrument of, diagnosis or other decision-making process. They may be found useful in counselling, in psychotherapy, particularly of the type known as client-centred, and in some forms of personnel selection—in short, in any situation in which

'understanding' is regarded as relevant. In English-speaking countries they have declined in popularity from their peak in the 1950s, partly perhaps because they are on the whole unamenable to computer analysis. In continental Europe, on the other hand, interest continues to be high.

B. SE.

PSEUDODEMENTIA. Some deeply depressed, elderly people may appear to be suffering from a progressive**dementia*. This impression is created by the general slowness of thought and activity and loss of interest in everyday pursuits which may accompany depressive illness. It may be difficult to engage such a person in a meaningful conversation because of the effect of the illness upon ability to attend and concentrate on what is being said. Similarly, self-neglect and loss of weight may be attributed to a dementing process rather than to a functional psychosis. But although psychological tests of cognitive function may be poorly performed, the overall results are not likely to be consistent with the picture of general decline in mental function typical of a true *dementia*. Moreover, treatment of the depression can result in a rapid restoration of mental abilities, a development incompatible with true *dementia*.

People with**Parkinson's disease* can undoubtedly develop *dementia* of varying degrees of severity, but some are so slowed up by the illness that they may give an impression of *dementia* when a diagnosis of *bradyphrenia* (slowness of mind) is more correct. These patients manifest a loss of

concentration, a decreased ability to associate ideas, and a general slowing of thought processes that viii include difficulty in concept formation and slow*shortterm memory scanning. Bradyphrenia is usually associated with*depression, which will contribute to the picture of psychomotor retardation.

A more controversial variety of pseudodementia is referred to as hysterical pseudodementia. Strictly speaking the term 'dementia' is inappropriate, as individuals so diagnosed may give the impression of suffering from a mental illness which does not necessarily involve a progressive decline of all mental functions. Relatives may say that the individual 'acts silly' by making absurd remarks or behaving in a bizarre or stupid manner. Making a distinction between this kind of conduct and straight malingering is far from easy, but Lishman

Page 648

(1978) comments that hysterical pseudodementia is most often seen in persons of limited intellectual 'endowment. The behaviour is most likely to surface when the individual finds himself in a situation beyond his comprehension or in a new and unpalatable environment which he cannot handle. For example, dullards finding themselves drafted into one of the armed services may well have difficulty in coping with the demands of discipline and other exigencies of military life. Their capacity for carrying out the normal activities of everyday life may be unimpaired, and any 'hysterical' symptoms that appear will rarely persist once discharge from the service is ordered.

In considering the problem of simulated illness, it must be remembered that diagnosis in psychiatry is very largely based on what the patient says about his symptoms.

Moreover he may exhibit certain kinds of behaviour from which it could be inferred that he is mentally ill. Psychiatry suffers from an absence of laboratory tests, and cases lack physical evidence to confirm or refute an original diagnosis. If a person says that he is anxious, depressed, and contemplating suicide, or is hearing hallucinatory voices, it would be an unwise physician who turns him away rather than admit him as a patient. In any case, it is difficult to simulate mental illness consistently, even for an individual who is fairly knowledgeable about psychiatric topics.

One variety of what is sometimes erroneously classed as a pseudodementia is the Ganser syndrome. This rare condition was originally described by S. J. M. Ganser in Germany in 1898—a description based on three patients awaiting sentence in prison. For this reason it has often been called a prison psychosis, although there is no evidence to show that it is peculiar to prisoners; indeed, it certainly occurs in individuals not involved in criminal proceedings. The characteristic features include a clouding of consciousness, a tendency to give 'approximate answers', with elaboration that seems inappropriate. This socalled 'talking past the point' or '*vorbeireden*'

is sometimes found in patients recovering from head injuries. The 'approximate answers' seem to indicate that the subject knows the correct reply but is feigning mental illness: for example, when asked how many legs a cow has, he will reply 'three' or 'five'; he seems to be perfectly aware of the correct answer and to deliberately avoid saying it. In some instances the answers appear more random than approximate. Although the *syndrome* is rare, the *symptoms* are not uncommon and may

feature in a number of mental disorders, but particularly when there is a history of recent brain damage. Assertion that the Ganser syndrome, or its symptoms, are varieties of hysterical pseudodementia is incompatible with the fact that those who display them have genuine psychiatric illnesses. These are often found to be organic in origin or, in some cases, prove to be symptoms of schizophrenia.

PSEUDOHALLUCINATION. The term was first used in 1885 by Kandinsky and was elaborated by Karl Jaspers in his book *Allgemeine Psychopathologie* (1913), in which he described a pseudohallucination as lacking 'leibhaftigkeit', variously translated as 'concrete reality', 'substantiality', or 'corporeality'. Jaspers claimed that true hallucinations are corporeal and appear in objective space, while pseudohallucinations lack corporeality and appear in subjective space. It has been suggested that the hallmark of a pseudohallucination is that it is accompanied by insight into the lack of an objective counterpart, and it is certainly recognized that pseudohallucinations are by no means confined to the mentally ill. Thus examples include longdistance lorry drivers at night, seeing nonexistent objects or animals in their paths and swerving automatically to avoid them, but realizing their mistake immediately afterwards. Monotony combined with prolonged solitude can produce pseudohallucinations and may be experienced by lonely explorers or by singlehanded sailors on long voyages. Sedman (1966) defined pseudohallucinations as hallucinations perceived through the senses but recognized by the patient as not being a veridical perception. Sedman found that such experiences were closely linked to the ego, and recognized as being of the self and not true percepts. In most instances the contents were meaningful, giving comfort and helpful advice. His investigation was based on psychiatric patients and not on normal populations, so his findings do not include the pseudohallucinations of the recently bereaved, who may hear the voice of the deceased or have a 'sense of presence' which is, however, quickly realized as erroneous. PSYCHE. The Greek word *psyche*, from which our terms 'the psyche' and 'psychology' derive, is generally translated by 'soul'; but the translation is in several respects misleading. *Psyche* is intimately connected to the notion of life: all and only living things possess a psyche; and to have a psyche is to be alive. (To have a psyche is to be *empsychos*; and *empsychos* is appropriately translated by 'animate'. Note that 'animate' derives from the Latin *anima*, which, like *psyche*, is conventionally Englished as 'soul'.) Thus a psyche is a principle of life, or an 'animator'. In addition, a psyche is a

Page 649

principle of individuality for living things; that is to say, anything which possesses my psyche is the very same living thing as I am—Socrates and Socrates' psyche are identical. The psyche, in sum, is the living self.

Different Greek thinkers offered different accounts of the nature of *psyche*: most of the*PreSocratic philosophers were materialists, primitive or sophisticated—they held that psyche was a special portion of air or fire, or perhaps a special parcel of particles or atoms.*Plato supposed that the psyche was an entity quite distinct from such crass corporeal stuffs: his view of the nature of *psyche* is comparable to*Descartes's notion of the soul as a separate spiritual substance.

Of all Greek theories, that of*Aristotle is the most refined (though some of its features are anticipated in Philolaus's doctrine that the psyche is an attunement). Aristotle offers two connected definitions of *psyche*. The first, couched in the terminology of his metaphysics, runs thus: 'If we are to say something which applies in common to every psyche, it will be the first actuality of a natural organic body.' (Roughly speaking, he means that to have a psyche is to be a natural body, equipped with the organs of life, and capable of functioning.) His second definition reads as follows: 'A psyche is a principle of the aforesaid things [i.e. of the various faculties of living things] and is defined by them—by the faculties of nutrition, perception, thought, and motion.' (Roughly: to have a psyche is to be capable of selfnourishment—

including growth and reproduction—of perception, of thought, and of independent motion; or rather, to have a psyche is to have at least some of those capacities.) Aristotle's first definition emphasizes the connection between *psyche* and the body; his second definition indicates the existence of interdependent psychic 'parts' or faculties—and those faculties, in Aristotle's view, turn out to be hierarchically ordered. Both definitions fit well with Aristotle's predominantly biological and physiological approach to the notion of *psyche* (though it is a celebrated and perplexing aspect of his psychology that thinking, or some special type of thinking, is to some extent untouched by corporeal contamination).

In one important respect at least, the Greek notion of 'psychology' is strikingly different from the modern notion. For the Greeks, all living things, including plants and the lower animals, have, by definition, a psyche; so that the general study of 'psychology' will aspire to give a unified account of all that distinguishes animate from inanimate objects. Modern psychologists may be said, at the risk of oversimplification, to deal with 'the mind': for the Greeks, the primary distinction is between what is alive and what is not alive (and the primary problem is the connection between living and nonliving matter); for the moderns, the primary distinction is between what possesses mind and what does not

(and the primary problem is the connection between 'the mental' and 'the physical'). Despite that fundamental difference, the particular problems discussed by ancient psychologists frequently overlap with those of their modern successors; but the difference is significant—and it prompts an intriguing question: did the ancient Greeks hit upon a more fruitful and unitary way than ours for tackling the problems of the mind?

J. BA.

PSYCHIATRY applies knowledge from the biological and social sciences, e.g. genetics, pharmacology, and psychology, to the care and treatment of patients suffering from disorders of mental activity and behaviour. It emerged as a branch of medicine in the first half of the nineteenth century when some of those kept under social control for the protection of society in workhouses and other institutions were recognized as curable, i.e. susceptible to moral treatment, or requiring the firm although therapeutic use of restraint, and as lying therefore within the province of medicine. One of its first tasks was to classify mental disorders. After the First World War its practice, hitherto based in Britain on the county*asylums, was extended, although still based on the hospital services, to provide treatment for those living in the community and suffering from disorders not requiring admission to hospital. The term, usually restricted in Britain to the work of suitably qualified medical practitioners, is used more widely in North America to cover the work of other mentalhealth professions such as clinical psychology and psychotherapy.

PSYCHOANALYSIS. During the last years of the nineteenth century*Freud gave up the use of hypnotism, because its effects proved capricious and encouraged dependency, and developed a new method, which he referred to at first as psychical analysis. This method, which relies on the interpretation, or analysis, of what a patient says or omits to say, while freely associating under instruction to report his thoughts without reservation, is the essence of what became the specialized form of psychotherapy known as psychoanalysis (see also FREE ASSOCIATION). The first volume of papers on psychoanalysis, *Studies in Hysteria*, published in 1895, brought together a series of casehistories, including that of Fräulein Anna O. which have subsequently been much discussed, an account of a new method of examining and treating hysterical phenomena and of the 'cathartic method', and some 'theoretical reflections', which introduced the concepts of unconscious ideas, ideas inadmissible to consciousness, and splitting of the mind. (For a discussion of the Anna O. casehistory, see BREUER.) Page 650

Freud immediately applied his new method to the study of dreams, and published in 1900 an account of his analysis of his own dreams in *The Interpretation of Dreams*, which he came to regard as his

most important book. 'Insight such as this', he remarked, 'falls to one's lot but once in a lifetime.' It presented the concepts that became the essence of a comprehensive theory of mental life: the meaningfulness of seemingly chaotic and absurd mental activity, wishfulfilment, the*Oedipus complex, infantile sexuality, regression, the*Unconscious, resistance,*repression, defence, projection, and symbolism, as well as the similarities of dreams and mental disorders (see FREUD ON MENTAL STRUCTURE). The decisive step lay in the demonstration that phenomena which might be dismissed as accidental, capricious, or meaningless products of disorder in the brain can be explained by reference to past experience and the motives revealed by psychoanalysis. He elaborated on the essential concepts in *Introductory Lectures on Psychoanalysis* (1922).

Freud gathered round him in Vienna a group of colleagues who shared his views and who published accounts of their own experiences in psychoanalytic practice.

There were notable defections, Alfred*Adler in 1911, who led the development of 'individual psychology', and Carl Gustav*Jung in 1913, who led the development of

'analytic psychology'. The Clark Lectures in 1909 in America by Freud and Jung brought psychoanalysis to the notice of the Englishspeaking world, but psychoanalysis did not become widely known in England until the 1920s. It then aroused as much interest among scholars in the humanities as among physicians.

Notable among those who made distinctive contributions to psychoanalysis in Britain was Melanie*Klein, who explored the development of relationships in early infancy and showed how fantasy and the inner world are built up. In the twenties and thirties Freud examined civilization, religion, and literature in the light of the findings of psychoanalysis.

Psychoanalysis was dominated in its early development by the biological ideas of the time, e.g. the derivation of energy from instincts. The shift in emphasis, starting in the 1930s, from biological or intrapsychic, to social or interpersonal, processes and objectrelations, and from the origins of symptoms to those circumstances of the

'here and now' determining their persistence, reduced greatly the differences in method and theory from other schools of psychotherapy, from which, however, psychoanalysts still maintain their independence.

Since it requires several sessions a week over two or three years with a trained therapist, psychoanalysis is a lengthy and therefore expensive form of treatment that is available to few patients. Its effectiveness is open to question. Its original purpose was to circumvent the resistances to the recall of the painful experiences thought to underlie*neurosis. Later, greater importance was attached to the transference of feelings into the relationship with the therapist. There has been little systematic research to evaluate the benefits achieved in these ways. Comparisons made of the effects on symptoms and attitudes produced by psychoanalysis with those produced in other ways have so far proved controversial and inconclusive. See also FREUDIANISM: LATER DEVELOPMENTS.

PSYCHOLOGY. *Psyche, personified by the ancient Greeks as the goddess loved by Eros, means breath and hence soul or mind. Psychology, when introduced as a term in the eighteenth century, described the branch of philosophy covering the study of the phenomena of mental life, i.e. what is perceived, through*introspection, as taking place in the mind, and of such activities as perceiving (see PERCEPTION), *remembering, *thinking, and reasoning.

'The science of mental life, both of its phenomena and their conditions' was William*James's definition. The strength of his classic *The Principles of Psychology*, published in 1890, lies in its descriptions, as the result of 'looking into our minds and reporting what we there discover' of 'feelings, desires, cognitions, reasonings, decisions and the like'. For half a century *The Principles* provided much of the material for textbooks such as R. S.*Woodworth's *Psychology: the study of mental life*, which went on into the 1950s as a standard text. The main chapters of contemporary texts are still about perceiving, remembering, thinking and language, and concepts and reasoning, as well as emotions, needs, and motives, learning, coping behaviour, and conflicts, skills, and attitudes and beliefs in relation to social and cultural factors.

Herbert*Spencer had given in 1874 a wider definition of 'objective psychology', which he said forms with physiology the two subdivisions of zoology, this and botany being the two divisions of biology. Objective psychology 'deals with those functions of the neuromuscular apparatus by which organisms are enabled to adjust inner to outer relations' and includes 'the study of the same functions as externally manifested in conduct'.

Page 651

'Subjective' psychology 'deals with the sensations, perceptions, ideas, emotions, and volitions that are

the direct or indirect concomitants of this visible adjustment of inner to outer relations'.

Spencer and James both struggled with the ancient problem of the relation between mind and body. James accepted dualism as a strategem, not as a conviction.

Certain mental processes cannot be reduced to physical processes, he insisted; otherwise there would be no science of psychology. 'When the brain acts a thought occurs.' 'Mental phenomena lead to bodily processes.' 'No mental modification ever occurs that is not accompanied or followed by a bodily change.' Contemporary explanations in psychology sometimes reduce the phenomenon or the behaviour to what is regarded as the essential physiological or biochemical process (see REDUCTIONISM IN PSYCHOLOGY); more often they relate it to the conditions or the contexts in which it occurs or to the system of which it is a part.

In James's time there were turningpoints in the development of several branches of psychology. Wilhelm Wundt had founded in 1875 the first laboratory devoted to the experimental study of sensation, memory, and learning. Francis Galton's *Inquiries into Human Faculty*, first published in 1883, had opened up the study of individual differences in mental functions. Lloyd Morgan's *Animal Life and Intelligence*, published in 1890, and E. L. Thorndike's *Animal Intelligence*, published in 1911, pioneered comparative studies of learning. Studies of the effects of lesions of the brain on mental functions were being pioneered by David Ferrier, Herman Munk, and Hughlings Jackson. Psychoanalysis with its concept of the unconscious was just over the horizon.

Soon after James's death in 1910, attention was drawn away from his work by the emergence of several confident schools, particularly behaviourism, physiological psychology, Gestalt psychology, psychoanalysis, purposivism (see MCDUGALL and PURPOSE), factor analysis (see SPEARMAN), and ethology. Behaviourism especially narrowed the definition of psychology so as to exclude subjective psychology, on the grounds, based on a narrow definition of science, that the phenomena of mental life are not susceptible to scientific study—that is, psychology should restrict itself to the study of those aspects of behaviour that can be directly observed and measured or graded.

For nearly half a century few scholars, except in the older universities in Britain, engaged with the formidable problems of method in psychology, which James had admitted could be no more than the hope of a science. Interest in mental phenomena revived again in the 1960s, partly as a result of the emergence of schools of phenomenology, such as Husserl's.

The meaning given to the term psychology changed gradually, first to insist that the study should be systematic, observations being made under prearranged conditions that allow reliable conclusions to be drawn, and, secondly, to include the responses of the subject to external events or stimuli, whether these occur naturally or are manipulated by an experimenter. Interest grew, under the influence of Kenneth Craik, in an interactional approach, in which behaviour is seen as exchanges between man and machine or man and man (see CYBERNETICS). The dividing line between objective and subjective psychology became blurred.

In most universities there is now a department of psychology, in which an assortment of research

methods is applied in the study of the behaviour, including the mental activity, of intact organisms, humankind especially. Comparative studies of the behaviour of animals (see ETHOLOGY) are shared with the department of zoology.

The psychology department is likely to have a place in the faculty of science, with links with other departments of biology, with which it shares work on the physiological mechanisms of behaviour, in the faculty of social sciences, in which it shares work on the behaviour of individuals in social groups, in the faculty of education, in which it shares work on mental development and learning processes in childhood, and in the faculty of medicine, in which its work lies in applications in the diagnosis and care and treatment of the sick.

It is one of several branches of science applied in*psychiatry to the care and treatment of the mentally disordered. Psychopathology is the branch of psychology that seeks to explain disorders of mental activity and behaviour in terms of psychological processes, whereas neurology and*neuropsychology relate them to the site, extent, and character of faults in the structure or function of the central*nervous system. Psychology contributes to many other branches of knowledge, among them, in the faculty of engineering, to*ergonomics, and in the faculty of law,*criminology. Since the 1920s, students of the humanities, such as literary critics and historians, have increasingly turned for their interpretations to psychological and, especially, psychoanalytic theories.

D. R. D.

PSYCHOMETRICS. See PSYCHOPHYSICS; QUANTIFYING JUDGEMENTS.

PSYCHOPATHIC PERSONALITY. Strictly speaking, this term should be applied to all varieties of abnormal personality (see PERSONALITY DISORDER).

Schneider (1958) defined the psychopathic personality as an abnormal personality who either suffers because of his abnormality or makes the community suffer because of it. In the UK and the USA greater emphasis has been placed on the second part of this definition, mainly because of the frequent involvement of such persons in breaches of the law. American authors prefer the terms 'sociopath' and 'antisocial psychopath' which more clearly define the individual by virtue of his criminal propensities. In the UK, before the Mental Health Act of 1959 the

Page 652

psychopath was an entity unrecognized by law, but the Act defined psychopathic disorder as 'a persistent disorder or disability of mind (whether or not including subnormality of intelligence) which results in abnormally aggressive or seriously irresponsible conduct on the part of the patient, and requires or is susceptible to medical treatment'. Although a good deal of controversy surrounds the last seven words of this definition, quite clearly the Act considered psychopathic disorder to be a form of mental illness. If such a person is 'ill'—and he would be the last person so to regard himself—it is up to the medical profession to treat him. The Mental Health Act of 1983 apparently recognizes the questionable value of medical treatment, as the phrase is omitted from its definition of

psychopathic disorder. None the less, the term stays under the general heading of mental disorder.

Numerous attempts have been made to identify the principal characteristics of the psychopath. The term in a general sense is often applied to adolescent or young adult males who appear unable to conform to the rules of society. The qualities of this sort of person's psychological makeup include an inability to tolerate minor frustrations, an incapacity for forming stable human relationships, a failure to learn from past experiences, however unpleasant they might have been, and a tendency to act impulsively or recklessly. Henderson (1939), in a wellknown essay on the subject, divided psychopathic personalities into three categories: the predominantly inadequate, the predominantly aggressive, and the creative. They are by no means mutually exclusive but, whereas the first two have gained general acceptance and receive more psychiatric attention, far less has been heard about the creative psychopath, whose sometimes erratic behaviour may seem less significant than the creations of his fertile imagination. He is less likely to come before the courts or to the attention of the mental health services, for his eccentricities are not usually regarded as indicative of mental disorder.

The question of whether, in the long run, psychopaths do learn from experience was considered in a followup study of children who showed persistent antisocial behaviour in St Louis (Robins, 1966). Of those who survived—there was a high mortality from accidents, suicide, and alcoholism—a significant number appeared to be keeping out of trouble by middle life, finding that relative conformity was preferable to constant conflict with society and the law. Whether maturation or learning from experience was the more responsible for this beneficial change is uncertain, but it does appear that some so-called antisocial psychopaths do ultimately learn to mend their ways. There was little evidence that medical treatment had made much contribution to this outcome.

It is often said—erroneously as it happens—that our presentday concept of psychopathic personality originates from the introduction of the diagnosis of moral insanity into English medical and legal theory and practice by J. C. Prichard, a Bristol physician, in 1835. At the time, Prichard and many others were considerably influenced by Gall's writings on phrenology which localized human propensities to specific parts of the brain. Among these propensities was included the moral faculty, and it was widely assumed that moral insanity was caused by a derangement of that part of the brain concerned with making a choice between good and evil.

Prichard, however, was using the term moral insanity to denote emotional disturbances—delusions and hallucinations—that were devoid of the usual hallmarks of insanity. None of his cases bore the remotest resemblance to the presentday psychopath, but because he used the word 'moral' it was widely believed that this form of insanity was responsible for the actions of individuals who exhibited a persistent tendency to indulge in criminal behaviour. Hence the plea of moral insanity in the courts in attempting to exculpate the offender from the full penalties of the law. Understandably, it was not an excuse which found much favour with the judges of the day. As they reasonably pointed out—and it has continued to be pointed out—it was impossible to decide whether a crime had been caused by the innate wickedness of the offender, or whether it resulted from a fit of moral insanity.

The Mental Deficiency Act of 1927 softened the term 'moral imbecile'—incorporated in the earlier Act of 1913—to 'moral defective', but retained in its definition the words 'mental defectiveness

coupled with strongly vicious or criminal propensities', and added, and 'who require care, supervision and control for the protection of others'. This was the forerunner of the psychopathic disorder definition in the Mental Health Act of 1959. Because many of those so constrained were not devoid of normal intelligence, placing them in hospitals for the mentally defective was neither appropriate nor beneficial.

Why *psychopathic* personality? As already mentioned, Schneider used the term to denote all varieties of abnormal personality, but his subgroups of explosive, affectionless, and weakwilled come close to Henderson's categories of aggressive and inadequate psychopaths. Koch in Germany in 1891 introduced the term

'psychopathic inferiority' as a catchall phrase implying a constitutional predisposition not only to neurosis but also to abnormalities and eccentricities of behaviour. At the time of his writing, psychiatric thought was dominated by concepts of degeneration and the hereditary transmission of 'the taint of insanity'. As such degeneration was often attributed to parental excesses, particularly alcoholism and sexual profligacy, it is understandable that what at first sight appeared to be persistent immoral or criminal behaviour became linked with the prevailing notions about psychopathic inferiority and moral insanity. Although in Britain the Royal Commission on the Law relating to Mental Illness, 1954-7, repeatedly used the word 'psychopath', it avoided

Page 653

making any precise definition of what the word meant. Baroness Wootton (1959) considered that the modern psychopath is the linguistic descendant of the moral defective, which takes us back to nineteenth-century writings on moral insanity. Whatever word is used, it has to be admitted that making clear distinction between the mentally healthy offender and the presumably mentally abnormal one is not an easy task.

The question thus arises whether psychopathic personality should be classed as a form of mental disorder. Opinions differ widely; but as the psychopath now has legal status the existence of such a condition has understandably been put forward in criminal proceedings as a plea for mitigation of sentence. In some cases of homicide, the verdict has been reduced from murder to manslaughter on the basis of diminished responsibility as defined in the Homicide Act of 1959. But many psychiatrists would have reservations about claims that psychopathic disorder is a mental illness on a par with neurosis or psychosis. While it could be argued that it amounts to an abnormality of mind which could seriously impair the responsibility of an offender for his alleged homicidal act, what is 'abnormality of mind' in this context? The subject was clarified by Lord Chief Justice Parker, who said that it meant 'a state of mind so different from that of ordinary human beings that the reasonable man would term it abnormal'. He went on to indicate that such an opinion applied to a person's acts, his ability to decide whether they were right or wrong, and his capacity for exercising willpower to control such behaviour in accordance with rational judgement. None the less, as Nigel Walker (1965) comments, 'It is clear ... that while a diagnosis of psychopathy is now recognized by English courts as an acceptable basis for a defence of diminished responsibility, the psychopath's chances of succeeding in this defence are by no means high'.

The causes and treatment of psychopathic disorder are as contentious as its legal implications. Theories of aetiology have included brain damage in childhood, late maturation of the central nervous system, and adverse circumstances of upbringing, particularly difficult relationships with parents and those in authority. As far as treatment is concerned, there is little evidence that a purely psychiatric approach to the problem has been successful. Controlled studies are hard to come by, but one such investigation found that firm but sympathetic handling in a disciplined environment was better than a more permissive approach based on group therapy and a selfgoverning type of regime. As the psychopath appears to lack the inner controls normally developed during childhood and adolescence, this result is hardly surprising. Time, however, seems to be a significant factor in treatment, an observation which could be interpreted as favouring the late maturation theory of psychopathic disorder. But in all probability learning over a period of years may also play a part in this process of maturation.

PSYCHOPHARMACOLOGY. The use of drugs that act on the mind is as old as the recorded history of man. Alcohol in the form of fermented beverages such as mead was probably already popular in the Palaeolithic age, about 8000 BC, and grape wine from about 400300 BC.*Opium is referred to in Sumerian tablets of around 4000 BC, and marijuana was known in China at 2737 BC. The hallucinogenic properties of the magic mushroom (teonanacatl) were known from 1000 BC in Mexico, while in Northern Europe and Asia the inebriant properties of the fly agaric mushroom, *Amanita muscaria*, feature in Norse legends. The concept that drugs can be used medically to restore mental health is, in contrast, the result of a very recent revolution in pharmacology, following the discovery in the 1950s of new classes of drugs, the tranquillizers and antidepressants, and their widespread use in the treatment of mental illness.

Staggering quantities of psychoactive drugs are now consumed for medical purposes. About half of the female population of the United Kingdom over the age of 60

regularly uses sedative drugs to put them to sleep each night. Benzodiazepines in the form of Valium

(diazepam) and related substances by day, and Mogadon (nitrazepam) and Dalmane (flurazepam) for night sedation, have largely replaced barbiturate sedatives and hypnotics. The success of these 'tranquillizers' can be gauged by the astonishing quantity consumed, amounting to tens of billions of doses throughout the world each year. These substances have a definite although mild calming effect, they relieve anxiety and diminish aggression, and they are relatively safe—in contrast to the barbiturates, which all too commonly lead to death from overdose. Because these newer drugs are relatively safe, and since almost all of us feel anxious from time to time, the extravagant success of the benzodiazepines during the 1960s and 1970s is not hard to understand. More recently, with the recognition that prolonged use of benzodiazepines can lead to addiction, there has been a growing reaction to their widespread use.

The most remarkable modern development in this field, however, is the discovery of drugs that are successful in the treatment of some of the fundamental symptoms of psychosis and depression. The first drug found to have such effects in schizophrenic patients was chlorpromazine Page 654

(Largactil, Thorazine), and from this a large number of other so-called 'major tranquillizers' with similar effects have been developed. Since the first favourable reports on chlorpromazine appeared in France in 1952, such drugs have been adopted widely for the treatment of schizophrenia. More than 100 million schizophrenic patients have been treated with chlorpromazine since 1953. The major tranquillizers have definite beneficial effects on some of the most fundamental symptoms of schizophrenia: patients show less disordered thinking, suffer from fewer delusions and hallucinations, exhibit more appropriate emotional behaviour. They are not simply quietened or sedated, and indeed other sedative drugs such as the 'minor' tranquillizers (benzodiazepines) do not exhibit these effects. It is not surprising that the massive use of chlorpromazine and similar drugs has had an enormous impact on the treatment of schizophrenia. (For further discussion, see SCHIZOPHRENIA: EVIDENCE FOR AN ORGANIC CAUSE.) The mental institutions have been transformed from sombre places with a largely custodial function to hospitals with open doors in which community therapy and rehabilitation techniques have been introduced. The 'number of patients so severely ill as to need more or less permanent hospitalization has also diminished strikingly—to the extent that separate psychiatric hospitals may no longer be necessary in future.

Other groups of drugs have been discovered to have beneficial effects in treating the melancholia of depressed patients. Two major classes of antidepressants have been introduced since the late 1950s—one derived from the substance iproniazid and the other from imipramine. Both groups of compounds have beneficial effects in depression, although these actions are usually less dramatic than those seen with the antipsychotic drugs. A remarkable discovery, made by Dr John Cade in Australia in 1949, has been that the symptoms of mania can often be treated very effectively by administration of small doses of an inorganic salt—lithium carbonate. Continued treatment with lithium carbonate reduces the frequency of recurrence of manic episodes in individuals who would otherwise show a regular cycle of such illness.

The problems of madness have not been solved by the drugs—we still do not understand what causes schizophrenia or depression, or even the nature of these illnesses. The idea that abnormalities in brain chemistry may underlie mental illness has, however, derived strong support from the finding that

psychosis can be treated with simple chemicals. Much research effort is currently directed towards discovering precisely how the antipsychotic and antidepressant drugs alter brain chemistry.

It is now widely accepted that antipsychotic drugs act by blocking the effects of one of the chemical transmitter substances used by brain cells to transmit signals to one another. The transmitter blocked by chlorpromazine and related drugs is dopamine, and this finding has suggested the possibility that in schizophrenia excessive amounts of dopamine secreted in the brain might represent an immediate causative factor for the psychotic state. (See DOPAMINE NEURONES IN THE BRAIN.) On the other hand, antidepressant drugs seem to act by enhancing the effects of other chemical transmitter substances, noradrenaline and serotonin, in the brain—

suggesting that these chemicals may be available in abnormally low amounts in the brains of depressed people.

In general, however, our knowledge of the mode of action of many psychoactive drugs is limited. This applies particularly to nicotine, cannabis, and the hallucinogens, but both barbiturates and alcohol act as central nervous system depressants. With respect to barbiturates and benzodiazepines it is likely that their depressant effects on neural activity are mediated by the neurotransmitter gammaaminobutyric acid (GABA), but other neurotransmitters may also be involved. Rather surprisingly, less is known about the precise mode of action of alcohol on the brain beyond the fact that it appears to depress synaptic transmission.

The fact that simple chemical substances can have such profound influences on the state of the mind, as between madness and sanity, between depression and euphoria, between normal perception and the vivid hallucinations induced by lysergic acid diethylamide (LSD), has obvious philosophical implications for the relation between the mind and the chemistry of the brain. It is clear that subtle changes in brain chemistry can have profound effects on the state of consciousness, and it behoves us to understand more of such subtleties.

Drugs are also consumed very widely for nonmedical reasons. Of these alcohol, nicotine, and caffeine are relatively universal—others, whose use is strictly controlled by legislation, such as the hallucinogens, barbiturates, amphetamines, marijuana, phencyclidine, cocaine, and opiates, are, nevertheless, also quite widely taken. These compounds have a bewildering variety of different psychic effects. Alcohol and barbiturates are depressants, leading to a feeling of relaxation, loss of inhibition, and to inebriation and sleep. Others are stimulants, such as nicotine and the more powerful amphetamines; these are performance-enhancing drugs. LSD, mescaline, phencyclidine, and the many other hallucinogens are in a class apart because these compounds can produce bizarre changes in perception—they replace the present world with another that is equally real but different, often with vivid sensory hallucinations. There are other drugs whose actions are primarily euphoriant, notably cocaine, morphine, heroin and other opiate drugs, and—in a milder form—marijuana. They replace the present world with one in which the individual experiences no problems, and often intense pleasure. The most powerful euphoriants, the opiates and cocaine are medically dangerous drugs—largely because their continued use leads inevitably to tolerance and

*addiction, i.e. larger and larger doses become necessary to achieve the desired effects, and the organism becomes physically dependent on continued drug use, so that stopping the drug may precipitate very unpleasant withdrawal symptoms. It should be remembered, however, that morphine and related opiates still have important medical uses in the control of pain. Opium has long been regarded as a sovereign remedy for the relief of pain and other symptoms. As Thomas Sydenham, the English physician, wrote at the end of the seventeenth century, 'I cannot forbear mentioning with gratitude the goodness of the Supreme Being who has supplied afflicted mankind with opiates for their relief.' Almost certainly it is the insanitary habits and unsterile modes of use as well as the actions of the drugs as such, that make opiates such a hazard to the life and health of the addict today.

We may one day discover how to eliminate the problem of addiction, and we will then be faced with the difficult decision as to whether 'safe' euphoriant drugs should be allowed widespread availability and use. Several millennia of experience with alcohol suggests that strict control of the availability of such substances would inevitably be needed. The 'soma' of Aldous Huxley's *Brave New World* may be nearer than is generally realized. There is little doubt that legislation controlling the use of marijuana will gradually become less prohibitive, and that modern plant breeding could work wonders with the Indian Hemp plant to produce 'superpot'. It is also clear that society has not yet decided what its attitudes should be to the general availability of chemically induced pleasure.

Ray, O. S. (1972). *Drugs, Society and Human Behavior*. St Louis.

PSYCHOPHYSICS originally meant the study of the sensations evoked by physical stimuli. As an example to illustrate the distinction between a stimulus and a sensation, the amount of light reflected by this page is its luminance, and can be measured with a light meter such as photographers use; the sensation evoked by that reflected light is the experienced brightness of the page, and may be deceptively related to the luminance, as photographers know well. Psychophysics is concerned with the *brightness* of the stimulus, and its other subjective qualities, and, secondly, with the relation of that brightness to the physical luminance.

The term 'psychophysics' was introduced by Gustav*Feebrier in his *Elemente der Psychophysik* (1860), in which he conceived an indirect method of measuring sensations. If a luminance L can just be distinguished as greater than L_1 , then, to a close approximation, L / L_1 is constant; this is Weber's law (formulated as the 2

WeberFechner law). If one supposes that all just noticeable differences (e.g. between L and $L + \Delta L$) are subjectively equivalent, then the *sensation* (in this case, of 1

brightness) must increase as the logarithm of the physical stimulus magnitude; for if $L / \Delta L$ is constant, so also is $\log L / \log L + \Delta L$.

Fechner's logarithmic measure was universally accepted until the 1930s, at which time it was questioned for a purely practical reason. At that time the decibel scale for the measurement of auditory intensity was newly developed. On this scale 20 dB represents a 10fold increase in the amplitude of modulation of sound pressure, or a 100fold increase in acoustic power; and, since the range of acoustic powers to which the ear may be exposed is typically 1:10¹², a logarithmic scale is convenient.

Decibel measurements are always relative to a reference point, which is usually taken as about equal to the faintest sound that the ear can detect. So, a naive application of Fechner's law would suggest that 50 dB should sound half as loud as 100 dB; but it is generally agreed that 50 dB sounds much quieter than that. To enable acoustic engineers to communicate meaningfully with their customers, the 1930s saw some research on how people assign numbers to ratios of sound levels and this research led to the development of the sone scale by S. S. Stevens in 1936. Loudness in sones grows as the 0.3 power of the physical sound power.

Subsequently, in the 1950s, S. S. Stevens and his collaborators developed the methods and ideas of the 1930s to devise power law scales of the sensations, evoked by more than thirty different sensory attributes, substantially those for which Weber's law holds. When subjects judge the ratios of stimuli, the numbers assigned vary as $N = aX^b$, where X is the magnitude of the stimulus being judged and b is an exponent characteristic of the attribute. This exponent varies from 0.33 for luminance to 3.5 for electric shock.

Inspired by Fechner's use of the just noticeable difference as a unit of sensation, there has evolved a very great body of experimental work and practical knowledge about human discrimination of all kinds of sensory attributes; and following from Stevens's power law, there has developed a comparable body of facts and figures about human judgement. For practical purposes, psychophysics has come to refer to these two large accumulations of data and models. But, notwithstanding its long

history, basic theoretical principles are only just beginning to emerge.

On mature consideration it can be seen that sensation is not, in fact, measurable independently of the physical stimulus from which it is derived. Fechner's logarithmic transform exists only as a mathematical construction, having no operational validity; and conformity to Stevens's power law depends on getting the experiment 'right'.

These two assertions can be supported by a demonstration and a simple experiment.

Panel a of Fig. 1 shows a black and white

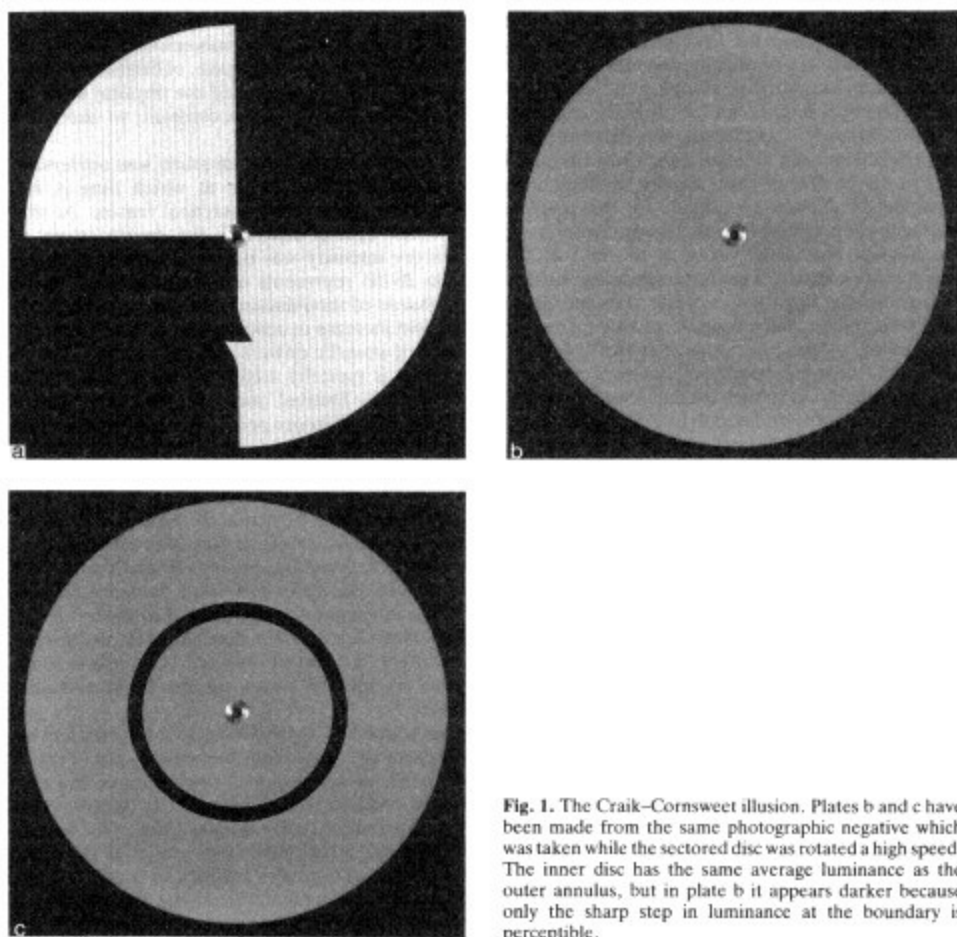

Fig. 1. The Craik-Cornsweet illusion. Plates b and c have been made from the same photographic negative which was taken while the sectored disc was rotated a high speed. The inner disc has the same average luminance as the outer annulus, but in plate b it appears darker because only the sharp step in luminance at the boundary is perceptible.

Page 656

Fig. 1.

The CraikCornsweet illusion. Plates b and c have been made from the same photographic negative which was taken while the sectored disc was rotated a high speed. The inner disc has the same average luminance as the outer annulus, but in plate b it appears darker because only the sharp step in luminance at the boundary is perceptible.

sectored disc which, when spun rapidly, appears as in panel b. Intermittent illumination interrupted at

a sufficiently rapid rate is not distinguishable from uniform illumination of the same timeaverage illuminance. So the centre and periphery of the rotating disc must have the same luminance—but their brightnesses are manifestly different. Now if the boundary between the centre and periphery of the rotating disc be covered with an opaque annulus (panel c), the brightnesses of the centre and the periphery are immediately seen to be equal. Remove the annulus (panel b) and they are again different. This phenomenon is known as the Craik-Cornsweet illusion. It depends on the kinky profile of luminance at the boundary of the figure, which may be appreciated from the shape of the black sector on the stationary disc.

There is an abrupt step in luminance which is easily perceived, and two ramps which are not. And so the centre appears darker than the periphery. When this profile is obscured by the annulus, centre and periphery appear equally bright. It follows that we do not see relative brightness only from a comparison of the two luminances in question, but from the *perceived change* in luminance at the boundary. That is, the sensation of brightness is obtained by a differential process from the physical stimulus. This idea was first proposed as long ago as 1865, by Ernst Mach.

The Craik-Cornsweet illusion is known to have analogues in the attributes of sound intensity and frequency, and in the length and spacing of lines. It is probably a general feature of human sensory perception. And the differential process which it reveals explains Weber's law, why the just noticeable difference increases in direct proportion to the stimulus magnitude. The logarithmic transform is a matter of the imagination only.

If our sensory experience is differentially coupled to the physical world, what of Stevens's power law? An elegant experiment by W. R. Garner addresses this point.

Thirty subjects listened to a standard tone at 90 dB and then a comparison tone. The comparison tone was to be

judged 'more' or 'less' than half as loud as the standard, and from each subject's judgements of a series of such comparisons was estimated that intensity of tone that would have been judged 'more' and 'less' equally often—a subjective half-loudness value. One group of subjects listened to comparison tones varying between 75 and 85 dB, and having half-loudness values within that range. Another group listened to comparison tones between 65 and 75 dB which all had half-loudness values within *that* range; and likewise for a third group listening to tones between 55 and 65 dB. Only one subject complained that the comparison tones presented did not straddle the half-loudness value, and she was happily reassigned to the third group.

It is apparent that most people have no idea what 'half as loud' means. Not wishing to appear foolish, the subjects in Garner's experiment assumed that some comparison tones must be more, and some less, than half as loud as the standard (else the experiment made no sense) and adjusted their criteria of judgement accordingly. They were conned. Their judgements depended on the immediate context rather than on the loudness of the stimulus. In experiments on the estimation of sensations the influence of context is very powerful and the accuracy of judgement is typically poorer by one to two orders of magnitude compared to that accuracy revealed in the measurement of just noticeable differences. The

accuracy of judgement of single stimuli has been found, with many different attributes, to be equivalent to the identification of no more than five different stimulus levels.

In conclusion, there is no way to measure sensation that is distinct from measurement of the physical stimulus. Sometimes we are deceived—Fig. 1 presents an example—and such examples present intriguing problems to the experimental psychologist. Attempts to 'measure' sensation have taught us that judgements of quantity are astonishingly poor. For this reason photographers use exposure meters; and cars are fitted with speedometers, so that the driver merely has to judge that the needle is adjacent to the mark representing 30 m.p.h., rather than 25 or 35—a 'Yes or No' kind of judgement that is reliable. We habitually make our judgements of quantity with the aid of a measuring instrument, a ruler or scalepan, and, in practice, problems arise only with those attributes which we feel intuitively ought to admit a continuum of values, but for which no measuring instrument exists—attributes like the merit of essays written in an examination or the aesthetic value of a painting. Such problems are nicely illustrated by the auction prices of Old Master paintings. The authenticity of such a painting can often be determined with great reliability; but sometimes the provenance is reappraised and the market value of the painting, physically the same, with its aesthetic qualities entirely unchanged, can vary at least 30fold in consequence. In the auction room aesthetic merit is of very little account, precisely because it cannot be accurately assessed; in its stead, provenance, a 'Yes and No' matter, is almost everything.

PSYCHOSIS. The word 'psychosis' seems to have been coined in the midnineteenth century and to have meant originally any kind of mental disturbance arising from whatever cause. But after the turn of the century its meaning was restricted by excluding both the mental consequences of familiar physical illnesses (such as*delirium associated with fever) and the neuroses. In contemporary psychiatric terminology, 'psychosis' is a classificatory and descriptive term, referring to a specific range of illnesses and symptoms, the illnesses being those in which the patient's basic competence as a person is called in question, the symptoms being those which seem to indicate some gross disorder of perception and thought (such as*hallucinations and*delusions). A psychosis is, therefore, any mental illness which is liable to render its victim *non compos mentis*, and unfit to plead in a court of law; and a symptom is 'psychotic' if it betrays misapprehension and misinterpretation of the nature of reality.

If, for instance, someone asserts that he is Napoleon, or emperor of Canada, or has had sexual intercourse with God, he is psychotic, since such assertions are by common consent untrue and anyone making them seriously must be misapprehending the nature of reality and failing to distinguish between his fantasies and the facts of the case. In contrast, if someone asserts that he spends time imagining that he is Napoleon, or daydreaming that he has established an empire in Canada, or that he

has dreamt he was emperor of Canada or has had intercourse with God, he is not psychotic, for he has correctly distinguished between his own imaginings and the nature of the external world. Similarly, if someone asserts that he has committed terrible crimes (when he hasn't) and deserves lifelong imprisonment for having done so, he is psychotic, but someone who complains of feeling irrationally guilty is not; nor is a religious person who has a lively sense of original sin.

The International Classification of Diseases 1955 (see MENTAL DISORDERS: CLASSIFICATION), published by the World Health Organization and used by the National Health Service in Britain, lists eight specific psychoses. Four of these, the so-called organic psychoses (senile, presenile, arteriosclerotic, and alcoholic), are generally agreed to be the result of degenerative changes in the brain. They excite little interest within the psychiatric profession and practically none at all with the general public. The other four, the so-called functional psychoses—*schizophrenia, manic depressive psychosis (see DEPRESSION), involutional melancholia, and*paranoia—arouse considerable controversy within the profession and

Page 658

great interest with the general public, partly because their symptoms are dramatic, but more importantly because research has (as yet) failed to discover any convincing, as opposed to plausible, causes for them—and in the absence of any specifiable physical causes it is possible and legitimate to question even whether the medical model is the appropriate one to apply to psychosis.

However, the majority of psychiatrists do seem to believe that the functional psychoses are true medical diseases and that, one day, physical causes will be found for them—and that as a result, rational, effective treatments will become available. If they are right, not only will an enormous amount of suffering be relieved, but the claims of the medical profession to be the appropriate people to care for and treat the mentally disturbed will finally be vindicated. In fact, the advent of effective drugs for the treatment of schizophrenia and manic depressive psychoses has given considerable support to the possibility that biochemical rather than structural changes in the brain could be causes of these diseases. The medical model therefore gains some plausibility from these discoveries.

But, it must be stressed, at least two nonorganic, nonmedical conceptions of psychosis are also in circulation. One, held by some but not all psychoanalysts, argues that the functional psychoses are not in principle all that different from the neuroses; it is merely that the fixation points are earlier, the regressions deeper, the infantile traumas more massive, the defence mechanisms more primitive. If the analysts who hold this view are right, the functional psychoses are psychogenic, not organic, illnesses, and their symptoms require interpretation in terms of their concealed meanings, not explanations in terms of cerebral dysfunction.

The other, nonorganic conception, held by antipsychiatrists, 'family process' therapists, and the postLaingian counterculture generally, explains the functional psychosis of any single individual as the endresult of complex and skew interactions within his family that have driven him into bizarre and incomprehensible behaviour, which is then 'disauthenticated' by being labelled 'mad' or 'psychotic'. This theory exists in more than one form. In one the psychotic patient is the victim of a villainous

schizophrenogenic parent, usually the mother; in another he is the overt casualty of a deeply concealed family tragedy. This last is a sociopolitical theory which locates pathology not in the body or the mind of the individual patient but in the power politics of society and the family.

PSYCHOSOMATIC DISEASE: A MEDICAL VIEW. The successes achieved in the 1920s and 1930s in the treatment of diabetes mellitus with insulin, of pernicious anaemia with liverextract, of malnutrition with vitamins, and of infectious diseases with antitoxin and their prevention by immunization, all encouraged the reductionist view that the objective of scientific medicine should be the discovery of the essential internal disorder underlying the symptoms, and the specific treatment for it. However, this model was soon recognized to be too simple. For many diseases the causes appear to be multiple and complex, some lying in internal and some in external conditions and others being, in a loosely defined sense, psychological. The interest in psychological processes grew in the 1930s, as the psychodynamic theories derived from psychoanalysis became more widely known. The term 'psychosomatic' was then applied to diseases in which disorder in the function of an organ was thought to be due to, or associated with, psychological factors. A definition of psychosomatic medicine was given in 1939 in the editorial introducing the first number of the journal *Psychosomatic Medicine*. Its object was 'to study in their interrelation the psychological and physiological aspects of all normal and abnormal bodily functions and thus to integrate somatic therapy and psychotherapy'. The journal's intention was to promote an approach to causes and treatment, rather than to make distinctions between classes of disease. Nevertheless, certain diseases were identified as psychosomatic—for example, atopic dermatitis, anorexia nervosa, bronchial asthma, essential hypertension, gastric and duodenal ulcer, myocardial infarction, and ulcerative colitis. It should be said, however, that the inclusion of some of these conditions under the rubric of psychosomatic disorders has been questioned.

The stress/strain analogy became popular. Just as stress, an external force, produces strain in a material, so forces in the physical, biological, or social environment produce strain in the mental and physical functions and behaviour of organisms. The strain effects are potentially adaptive, the form taken by the adaptation depending on the organism's constitution and past experience, and hence they are idiosyncratic. The analogy is, however, misleading in one respect at least. For whereas the effects constituting strain in a material cease as soon as the stress ceases, there is no return in the organism to the status quo, because stress causes reorganization or

'reprogramming' of the adaptive mechanisms. The organism acquires new habits, for instance, or a new immunity.

Support for the psychosomatic approach comes from epidemiological studies of the incidence of diseases among those subjected to more or less defined stresses.

Gastric ulcer, for instance, was noted in the First World War to be unduly common among soldiers who had recently been in action in the trenches. Recorded deaths from gastric and duodenal ulcer rose in the Second World War

Page 659

during the period of heavy air raids. When stocks go down in New York, diabetes goes up, it was remarked. The survivors of fires and floods and of imprisonment, and the bereaved, among others, have been shown to have rates of morbidity and mortality greater than those in comparable populations. Many diseases not directly related to the known effects of the stress are then unduly common—for example, heart disease, cancer, disease of the gastrointestinal tract, and pulmonary tuberculosis, as well as suicide and accidents. So many diseases have now been included in such lists as to discourage any inclination to distinguish between those diseases which are psychosomatic and those which are not.

Experiments on mammals have shown that such stresses as confinement, restraint, and frustration affect the function of almost every organ. The temporary separation of newborn mammals from their mothers results in high rates of morbidity and mortality. It is well known that in man emotions such as anger, fear, and anxiety tend to be accompanied by changes throughout the body in almost every function. The effects of various stresses on functions of the stomach, colon, skin, and cardiovascular system in particular have been studied experimentally in healthy human subjects. Some of the effects are mediated by the autonomic nervous system, some by the endocrine system, and others through behaviour such as refusing food or eating to excess. Some create the conditions in which the disease arises—for example, by affecting the resistance to infection—while others form an inherent part of the disease. Research has tried to give some definition to the psychological factors, although this has proved difficult, and to elucidate the processes involved in each pattern of disease. There is no distinctive psychosomatic process, but rather a wide variety of processes. For this reason the use of the term 'psychosomatic' has declined.

The pattern of responses has been shown in experiments on mammals to vary with the character of the stress. In human patients, on the other hand, there tends to be a remarkable consistency in the psychosomatic disease, which tends to recur in a stereotyped form. The pattern is peculiar to each patient and more or less fixed. It could be argued that a genetic predisposition as, for example, in the asthma—eczema syndrome, to some extent determines the type of psychosomatic disorder that is likely to recur. Evidence from studies of children suggests that the pattern is laid down before the child is 6, 'organvulnerability' being decided by this age. From time to time there may be a 'syndromeshift'. Thus a patient who has had several *attacks* of atopic dermatitis develops bronchial asthma, or perhaps, later in life, rheumatoid arthritis. A sufferer over many years from migraine

develops ulcerative colitis, or a patient who has had a recurrent peptic ulcer develops essential hypertension. It has often been suggested that each pattern of disease is associated with particular traits of personality, but systematic studies have largely failed to show correlations. However, recurrent diseases like asthma and ulcerative colitis may be held to influence the style of life a person adopts and so indirectly affect his medical state.

PSYCHOSOMATIC DISEASE: PHILOSOPHICAL AND PSYCHOLOGICAL ASPECTS.

Diseases are designated as psychosomatic if two conditions are fulfilled: if (i) the symptoms are accompanied by demonstrable physiological disturbances of function and (ii) the illness as a whole can be interpreted as a manifestation or function of the patient's personality, conflicts, life history, etc. The first condition distinguishes psychosomatic illness from psychoneurosis, particularly conversion hysteria, in which, by definition, the physical symptoms are not accompanied by demonstrable physiological disturbances. The second condition distinguishes psychosomatic illness from physical diseases pure and simple, which are explicable solely in terms of bodily dysfunction without reference to the psyche of the patient.

Although the word 'psychosomatic' was used by Coleridge, and its reversed form 'somapsyche' occurs in the original Greek of the New Testament, the concept of psychosomatic disease dates properly from the first half of the twentieth century, when it became necessary to have a concept that cut across the division of diseases into physical (somatic) and mental (psychical) which had been established by*Freud and*Breuer's demonstration that the psychoneuroses were not functional disturbances of the central nervous system but symbolic expressions of psychical conflict. Given the resulting tendency to assume that illnesses were either physical and all in the body, or mental and all in the mind, the term 'psychosomatic disease' became necessary to categorize illnesses resembling psychoneuroses in being expressions of psychical conflict but yet had solid, demonstrable physical signs and symptoms.

As the preceding two paragraphs perhaps reveal, psychosomatic disease is logically and philosophically speaking a most tricky concept, since its meaning and precise implications necessarily depend on each particular user's basic assumptions about the relationship between body and mind. Presumably a materialist must hold that all diseases, including so-called mental ones, are ultimately somatic, and an idealist must hold that all physical illnesses are ultimately mental, while those who hold that physical and mental events belong to different causal sequences have to explain,

if they believe in the possibility of psychosomatic disease, how the leap from one to the other

Page 660

is effected. However, in actual practice, the term is only used to categorize illnesses which present with physical signs and symptoms but none the less require the clinician to explore the patient's biography and state of mind. It is never used to refer to illnesses which present with mental symptoms but are none the less due to physical causes as, for example, depression caused by a brain tumour.

Georg Groddeck (1866-1934), the maverick German psychoanalyst, is often regarded as the father of psychosomatic medicine. His way of formulating the relationship of body and mind was to assume that both are the creations of a third, impersonal force, *das Es*, the It: the body and mind are a joint thing which harbours an It, a power by which we are lived, while we think we live.... The It, which is mysteriously connected with sexuality, Eros, or whatever you choose to call it, shapes the nose as well as the hand of the human, just as it shapes his thoughts and emotions.... And just as the symptomatic activity of the It in hysteria and neurosis calls for psychoanalytical treatment, so does heart trouble and cancer.

Rather similarly, another maverick psychoanalyst, Wilhelm Reich (1897-1957), held that all illnesses were the result of imprisonment of spontaneous bioenergy within characterarmour imposed by a repressive, authoritarian society. More soberly but less imaginatively, many workers during the last fifty years have produced evidence, much of it statistical, suggesting that many physical illnesses occur predominantly in individuals who have rigid personalities, who are subject to stress, who have recently experienced upheavals in their lifestyle, or who have lost all connection with other people. Psychoanalysts such as Franz Alexander and Flanders Dunbar in the USA attempted to relate specific psychosomatic disorders to specific emotional conflicts and personality patterns. This theory of psychosomatic illness has not been generally supported by recent work, although there is some evidence that coronary artery disease occurs more often in individuals with a particular personality makeup—the so-called type A personality. This concept is still controversial and the mode of interaction between personality and cardiac disease is not fully understood.

However, psychosomatic disease remains an elusive concept. Many, perhaps most, clinicians feel that there is something in it, but the problem of formulating correctly the nature of the relationship between body and mind implicit in it has proved recalcitrant.

PSYCHOSURGERY. This term is used to denote operative procedures on the brain specifically designed to relieve severe mental symptoms that have been unresponsive to other forms of treatment. Although surgery for mental illness had been attempted sporadically—mostly in the form of trephining—since early times, it was not until 1935 that the Portuguese neurologist Egas Moniz, in association with the surgeon Almeida Lima, performed the first systematic series of operations known as prefrontal leucotomy, severing the connections between the prefrontal cortex and the rest of the brain. Although the operation was crude, of the first twenty cases seven recovered and seven improved. The best results were obtained in cases of agitated*depression, a finding which has been repeatedly confirmed by later workers. Unfortunately, some patients developed adverse personality changes, an effect which could have been predicted from the case of Phineas Gage, a competent worker in the USA who, in 1847, had the misfortune during a rockblasting operation to have an iron bar blown through the front part of his head. He survived this extremely violent form of prefrontal leucotomy but, on recovery, was found to have undergone a profound change in personality. He swore in the grossest manner, behaviour not previously indulged in, and his overall qualities as a likeable individual were severely impaired. Despite these changes to his character he did not show any decline in intelligence or memory. Although patients treated by prefrontal leucotomy did not usually show such severe impairment of personality as Gage did, it is undeniable that adverse alterations in behaviour occurred sufficiently often to arouse opposition to the operation.

None the less, it was taken up enthusiastically in the USA by Freeman and Watts (1942) and with rather less vigour in the UK, where it was carried out on 10,365

patients suffering from mental illnesses between 1942 and 1954 (Tooth and Newton, 1961). It was stated that only 3 per cent showed undesirable sideeffects and that more than 40 per cent had been ill for at least six years. The operation was performed in only a few centres, a fact which seems to imply that, regardless of its alleged usefulness, attitudes opposing it were strongly held by medical staff in many hospitals. By 1961 the annual frequency of leucotomy had fallen substantially.

As time has gone by there have been many modifications of the original operation, and today it has been almost entirely replaced by exact stereotactic procedures which allow very small lesions to be placed in certain key areas of the brain. Such methods are designed to alleviate symptoms without causing undesirable changes in personality. Comparatively few patients are treated each year by psychosurgery, largely because of the development of more effective drugs (see PSYCHPHARMACOLOGY) and behavioural (see BEHAVIOUR THERAPY) methods for the treatment of mental illness.

What kinds of symptoms are most susceptible to surgical intervention? The phrase 'tortured selfconcern' is often quoted to indicate the degree of distress which has failed to respond to less drastic treatments. The best results have been obtained from patients suffering from severe chronic*anxiety, agitated depression carrying a high risk of suicide, and those afflicted with incapacitating*obsessivecompulsive disorders.

Although there is every indication that, with careful selection and postoperative management, many patients with these apparently intractable symptoms have benefited from the more precise forms of psychosurgery, very strong opposition has been mobilized in some quarters against any form of surgery for the relief of psychiatric symptoms. Such opposition has been most vigorously expressed in the USA, where in some states these operations are forbidden by law. Peter Breggin, a psychiatrist in Washington, has claimed that there is no scientific justification for the operation and that the price paid in terms of blunted emotions and other personality changes is too high. Furthermore he has argued that psychosurgery could be used as a means for controlling antisocial behaviour and the activities of political dissidents. While there may be too few skilled in stereotactic surgery to permit its extensive use for political and social reasons, in India and Japan operations on the amygdaloid nucleus of the brain have been performed to control 'hyperactivity' in children. Although there is no doubt that outbursts of unbridled violence can be caused by diseases of the limbic brain, there is very little evidence that psychosurgery has been systematically applied to control such symptoms in the UK. And at present the requirements of Section 57 of the Mental Health Act of 1983 would almost certainly prevent any form of brain surgery being carried out expressly for the purpose of controlling antisocial, aggressive, or politically dissident behaviour.

Others have been concerned not only about the irreversible nature of the operation and permanent alteration of the personality, but also that in some way the patient's immortal soul would be damaged. Perhaps such considerations are best left to the theologians and the Almighty. A charitable view might be taken of man's efforts to relieve his fellow creatures of suffering. Be that as it may, given the safeguards that limit psychosurgery to the alleviation of distress, there seems to be a place for it as one form of effective treatment.

Although psychosurgery has been used for the treatment of deviant sexual behaviour, drug dependence and alcoholism such methods can only be condemned partly because they are unlikely to be effective but also because of uncertainty over whether such kinds of behaviour fall within the ambit of psychiatric illness. In any case they are unlikely to cause 'tortured selfconcern' to those who are so afflicted although the disturbing effects of these behaviours upon relatives can not be denied. But psychosurgery to allay the anxieties of relatives has not yet achieved wholehearted support even from its most enthusiastic practitioners.

PSYCHOTHERAPY, ASSESSMENT OF. What happens to untreated patients? It must surely always have been true that a proportion of neurotic difficulties eased, or resolved, or were adapted to, in relation to the happenings of everyday life. Paradoxically, an issue only arose because, following Sigmund*Freud, a group of persons claimed special expertise in the curative role and this expertise tended to be somewhat uncritically accepted, especially in the USA. However, it was the English psychologist H. J. Eysenck who in 1952 turned the issue into a challenge.

Eysenck suggested that psychoneurotic difficulties tended to resolve 'spontaneously', i.e. regardless of treatment. Backed by an analysis of data such as the discharge rates of neurotics from mental hospitals and the outcome of insurance claims for psychological disability, he suggested that approximately two-thirds of neurotics recovered without treatment. Both his statistics and his basic analysis of data were challenged. An influential paper (Bergin and Lambert, 1978) suggested that, while spontaneous recovery certainly takes place, the likely figure was nearer 46 per cent. The exact figure is intrinsically unknowable because it depends on the type of patients considered, the disorders from which they suffer, the length of followup, the criteria of recovery used, and the objectivity of their assessment. Considering only severe hospitalized neurosis, for instance, Simms (1978) made a careful twelve-year followup of 146 neurotic former inpatients and compared their symptomatic and social status (work, marital, sexual) with a matched control group of patients operated upon for varicose veins. A satisfactory outcome was achieved by only 42 per cent of the neurotics compared to 90 per cent of the surgical group. Thus the figure for neurotics is not dissimilar to that of Bergin. Malan et al. (1975) developed this trend further, being concerned to assess in detail the *quality* of recovery of untreated patients. Forty-five untreated neurotic patients were followed up and carefully assessed symptomatically and psychodynamically. Fifty-one per cent were judged improved symptomatically and 24 per cent showed at least partial psychodynamic improvement.

It seems probable, therefore, that one-third to one-half of neurotic patients who have no systematic psychotherapy improve symptomatically. A smaller percentage, perhaps one-quarter, show constructive personality changes. In any case, the outcome of this debate has been wholly

constructive. Psychotherapists of all allegiances now tend to look more critically at their therapeutic results. In particular, from a research point of view, the necessity of including adequate control groups, either untreated or treated by another type of therapy, is accepted.

The assessment of psychotherapy. Psychotherapy and psychotherapists faced up to, and recovered from, the crisis of identity induced by Eysenck's challenge.

Comprehensive examination of available objective data by Bergin (1971), Malan (1973), and Luborsky et al. (1975) suggests that the results of psychotherapy, even if not as outstanding as enthusiasts would hope, demonstrate that it is effective and has a valued place among psychiatric treatments. It is also now clear how complex and difficult is the assessment of psychotherapeutic

outcome.

Bergin contrasted the spontaneous remission rate of 30 per cent with 65 per cent for all forms of psychotherapy other than psychoanalysis and with the 83 per cent which is the overall rate for psychoanalysis. But these were, admittedly, rough figures. Others attempted the double task of assessing outcome studies for the adequacy of their design, and noting the therapeutic results, particularly from controlled trials. Malan, discussing these reviews of control studies, concluded that the evidence for the effectiveness of psychotherapy was relatively strong, especially for psychosomatic conditions. However, for the neuroses and personality disorders—for which this form of therapy was developed—the evidence was weak. His own careful studies at the Tavistock Clinic in London over a period of many years, and repeated on two groups of patients, established the effectiveness of brief psychodynamic psychotherapy. He also made explicit a number of the criteria for selection of patients, as well as points of therapeutic technique.

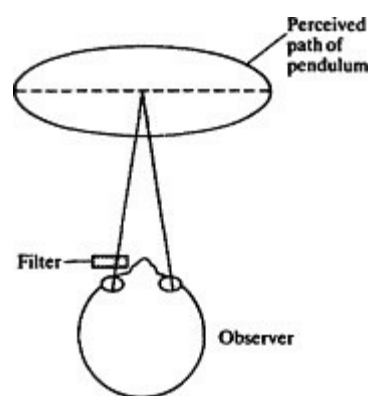

Luborsky et al. critically reviewed comparative studies of psychotherapy. When comparisons were made between different psychotherapies, most studies failed to show significant differences in the proportion of patients who improved. However, controlled comparative studies indicate that a high percentage of patients who go through any of the psychotherapies do gain from them. From both individual and group psychotherapy, about 80 per cent of the studies show positive results. In addition, combined treatments (for psychosomatic conditions such as peptic ulcer or asthma) often did better than single treatments—a further plea for eclecticism rather than rigid ideology in psychotherapeutic practice. Luborsky et al. emphasized, as Frank et al. (1978) had for many years, the components common to psychotherapies, especially the helping relationship with the therapist. Luborsky et al. also stressed that the quality of outcome from therapy to therapy is important, as well as the amount of improvement. Again, this is an area for further careful consideration in the future.

It seems clear that research into psychotherapy needs to become more analytic, and must try to assess the multiple and interacting factors involved, such as the therapist, the patient, their relationship, the social situation, the type of treatment, the type of disorder, and the experience of the therapist.

A study by Sloane et al. marks a significant advance. Ninetyfour persons suffering from moderately severe neuroses and personality disorders were carefully assessed clinically, using structured rating scales, and also on psychological tests. A close friend or relative was also interviewed, for an outside informant's view. Patients were randomly assigned to a waiting list or to one of three experienced behaviour therapists (see SEHAVIOUR THERAPY) or analytically oriented psychotherapists. The controls were promised therapy in four months and were kept in touch. Patients were treated for four months (an average of fourteen sessions) and then reinterviewed and tested. Two measures of psychological change were used, one aimed at symptom assessment and the other at work and social adjustment. The assessors who had originally seen the patients reassessed them, and were 'blind' as to which treatment had been used. Informants were also interviewed, and reassessed the patients. Further followup was done one and two years after the original assessment. Major trends were: symptomatic improvement in the control group, and the two experimental groups at four months showed the treatment groups to be significantly more improved; but there was no difference between psychotherapy and behaviour therapy. On work and social adjustment, there was no significant

difference in amount of improvement between the three groups. Assessment of overall improvement showed 93 per cent of the behaviour therapy group, compared to 77 per cent of the waiting list, or psychotherapy groups, improved or recovered. After one year, improvements were maintained or continued in most patients. Sixtyone patients were seen at the twoyear followup; the great majority in all groups increased or maintained symptomatic improvement and personality adjustment. Special interest attached to the control group which had contact and interest maintained but no formal therapy. Both of the formal therapies were, however, more effective than this minimal therapy.

The conclusion of this study was that psychotherapy, in general, works, and its effects are not entirely due to nonspecific effects such as arousal of hope nor to spontaneous recovery. The general effectiveness of psychotherapy has been confirmed by a new statistical research technique, metaanalysis, in which the outcome from active psychotherapy is compared to the variation in a control treatment (Shapiro and Shapiro, 1982).

Page 663

Are some patients made worse by treatment? When critical attention first began to be paid to outcome studies, especially to those which reported no difference in average outcome between patients and waitinglist controls, it was noted that there was significantly greater variation of outcome among treated patients. It became apparent that some patients were actually being made worse by psychotherapy.

Any practising psychotherapist must recognize the truth of this observation—we do make some patients worse. A systematic attempt was made, therefore, to note the incidence of deterioration effects and also possible causes. Strupp *et al.* (1978) systematically reviewed the problem of negative effects. The best quantitative estimate of deterioration effects, both from dynamic and from behavioural psychotherapy, is 36 per cent. Possible sources of these negative effects include: poor preliminary assessment; personality factors in the patient, the therapist, or their interaction; inadequate training of therapists, leading to clumsy or rigid therapeutic techniques;

misguided or erroneous choice of therapy or of treatment goals. This is an area of current interest and importance: further investigation is necessary.

PULFRICH'S PENDULUM. This famous stereophenomenon, first described by Carl Pulfrich (18581927), is easily observed, by those with normal binocular vision, with the help of a pair of sunglasses and a length of string with a weight such as a teacup attached to one end. The string and weight are used to make a pendulum attached to a convenient point on the ceiling, and oscillating slowly from side to side. If the pendulum is viewed with the sunglasses covering one eye, the other eye remaining open, it will appear to move through an

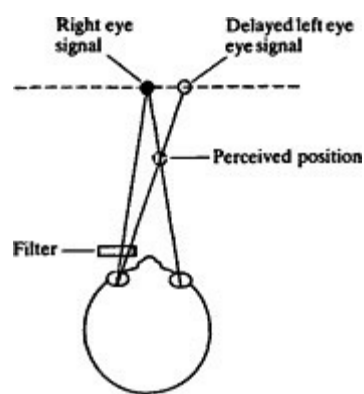

Fig. 1.

A plan view of an observer looking at a horizontally oscillated pendulum, the actual path of which is shown by the dotted line. When the observer's left eye is covered by a sunglass filter, the pendulum appears to move in depth along the trajectory represented by the solid line. The direction of movement is opposite if the right eye is covered.

elliptical path in depth (Fig. 1). The direction of movement in depth is clockwise (as if viewed from

above) when the sunglass filter is covering the left eye, and counterclockwise if the dark glass covers the right eye. The function of the sunglass is simply to reduce the amount of light reaching the eye, and any lightattenuating filter will serve just as well. The depth illusion applies not just to a pendulum but to any object in horizontal movement with respect to the eyes. In an ordinary television picture, for example, objects moving from left to right will appear displaced in front of the screen if the right eye is covered by a filter.

In his 1922 paper Pulfrich (who was blind in his left eye and never saw the phenomenon himself) describes previous observations of the effect by astronomers using stereocomparators. He attributes to Fertsch, an optical engineer with the Zeiss company in Jena, the now generally accepted 'delay line' explanation. Fertsch proposed that the filter causes a delay in the transmission of signals from the retina to the brain. Since the target is moving, a temporal delay corresponds to a spatial displacement: the covered eye is seeing the target with a delay in time, and thus at a spatially lagging point on its trajectory. The lag produces a stereoscopic disparity, and therefore a shift in depth (Fig. 2). Fertsch's hypothesis is now well established by direct electrical recording of the latency of the retinal response to light, and the geometrical reasoning can be verified by using a haploscopic display in which one eye's target is subjected to an actual delay. The cause of the delay is that the filter induces the covered eye to adapt to a reduced general level of illumination, which is a visual mechanism (like increasing photographic exposure time) for gaining sensitivity in dim light. The converse effect can be achieved by shining a bright pen torch into the corner of one eye: this eye now

Page 664

Fig. 2.

Fertsch's 'delay line' explanation of Pulfrich's effect. The signals from the covered eye are effectively delayed so that the eye signals an earlier point on the target's trajectory; the delay therefore produces a stereoscopic disparity, and the target is seen as shifted in depth.

adapts to a higher level of illumination and thus responds more quickly, with a consequent depth shift in the reverse direction to the normal Pulfrich effect (i.e. if the left eye illuminated depth shift is anticlockwise).

Technical interest in the phenomenon was rekindled by the finding that Pulfrich's effect can be observed with stroboscopically lit targets, and even when viewing an

'electronic snowstorm' on a detuned television set. In the latter case the snowstorm appears to rotate horizontally in depth when one eye is faltered. Since there is no real motion in the display, the delay line explanation needs to be supplemented by spatiotemporal averaging of target position.

A clinical use of Pulfrich's phenomenon has several times been suggested, on the basis of the finding that it may arise spontaneously, without the use of a filter, as a result of demyelinating disease of the optic nerve.

PURPOSE. We commonly explain what people (and perhaps animals) do by assuming they have some purpose in doing it, some idea in mind which guides their activity towards their goal in an intelligently flexible fashion.

We say, for instance: Why is Mary buying arsenic?—Maybe she intends to poison Martha, but more likely she needs it to get rid of the rats. Why did the chicken cross the road?—To get to the corn on the other side. What made Jill insult Joan?—I don't know, but she must have had some reason. As these examples suggest, we rarely use the word 'purpose' itself; perhaps this is why the Mock Turtle got the word wrong when assuring Alice that 'No wise fish would go anywhere without a porpoise. . . Why, if a fish came to *me*, and told me he was going a journey, I should say "With what porpoise?"' But we assume that we can explain or make sense of what people do by referring to their intentions, goals, aims, interests, ambitions, desires, wants, motives, needs—in a word, to their purposes.

Despite this universal acceptance of the concept of purpose in our everyday thinking about why people do what they do, it is not universally accepted by theoretical psychologists. On the contrary, throughout the history of psychology this concept has been, and remains, one of the most controversial of all. (It follows that the position argued in this article would not be endorsed by all current psychologists, although it is an increasingly accepted view.) People do not merely disagree about purpose, but get more than usually heated in discussing it, often ascribing gross irresponsibility of one sort or another to their opponents in debate.

Some psychologists refuse pointblank to admit the concept of purpose into their theories, regarding it as not merely unhelpful but positively mystifying. Others are content to use it as a convenient shorthand, but believe that purposive explanations of behaviour could in principle be replaced by complicated stimulus-response or neurophysiological explanations in which the concept of purpose would not appear. Yet others insist that psychology must give a central role to purpose, that action and experience cannot possibly be explained without it; usually, they add that what it is to be a *human* being cannot be understood without this notion, so that to reject it is to adopt an essentially dehumanizing image of mankind.

Theoretical resistance to purpose arises primarily from its close connection with the *mind-body* problem. It is difficult to understand how purposes can function as guiding factors in behaviour—for how can an idea affect bodily action? (There is no help in identifying the purpose with the actual goalstate, rather than with the subject's idea of the goal; for the goalstate is always in the future until the action has been completed, and is often not achieved at all. How can a not-yet-existent state, which may in fact never exist, cause anything to happen here and now?) The *behaviourists*, with the exception of *Tolman*, rejected purposive explanation, because they avoided all reference to *consciousness*, *subjectivity*, *ideas*, or *mind*. And neurophysiology, at least at first sight, seems to leave no place for purpose, since it deals with braincells and brain functions whose physical description does not involve reference to ideas.

However, with the work of *Kenneth Craik*, neurophysiology gained the concept of a cerebral model, or inner representation of the world.

Page 665

According to Craik, we possess physical mechanisms in the brain that function as inner models of the world—by which we perceive, think about, and act upon the environment. Explanations of psychological phenomena must refer to these models, since it is only via these internal representations that action and experience can take place. But inner models may sometimes be misleading: the fact that there are no unicorns does not prevent people from developing internal representations of such mythical beasts. Similarly, an inner model may represent a state of affairs that does not yet exist, or a plan of action that cannot be fully carried out; the person can nevertheless use this model to guide present behaviour in various ways. So there is no radical difficulty in understanding how it can be that a person acts with the purpose, or goal, of finding a unicorn—even though this purpose can never be achieved.

Cerebral models correspond to the *'schemas'* described by the psychologist F. C. *Bartlett*. They are essentially subjective, in that they constitute the psychological subject's view of the world—and of itself. This is why action and experience possess what *Brentano* and *phenomenologists* call *'intentionality'*. Many psychologists and philosophers have claimed that intentionality could not possibly be explained in terms of a physical system, so that physiology is in principle incapable of helping us understand how psychological phenomena arise. In any case since very little is known about the detailed physiological basis of cerebral models, neurophysiologists cannot yet offer precise explanations of specific psychological characteristics.

But the concept of internal representation has entered artificial intelligence, the science of writing computer programs which enable computers to do the sort of things that are done by human minds. Programs using different inner models of cubes, for instance, recognize (and misrecognize) cubes in different ways—and on different occasions. (See PATTERN RECOGNITION.) Each program has its own view of the world; and its behaviour (saying that *this* is a cube whereas *that* isn't) can be fully understood and explained only by reference to its inner schemata or models. Even though electronic engineers know precisely how the underlying mechanism works, it is the representational functions of the program which explain the 'psychological' characteristics of the programmed computer. Whether or not every aspect of human psychology could in principle be simulated on a computer is irrelevant here. The important point is that even though the computer's 'physiology' is fully understood, its 'psychology' can be explained only in terms of its subjective (internal) models of the world.

By analogy, then, even if neurophysiologists knew everything there is to know about the brain, *psychological* explanations would still be required to understand psychological phenomena. So psychology is not reducible to physiology, if by that it is meant the claim that with sufficient physiological knowledge we could stop talking about purposes, ideas, beliefs, mistakes, and the like. (See REDUCTIONISM IN PSYCHOLOGY.) Psychology is reducible to physiology only in the quite different sense that psychological features like purposes are generated by cerebral mechanisms, rather than being mysteriously inexplicable features outside the scope of science. A faith in the second kind of reducibility need not entail a faith in the first kind. It follows that the concepts in terms of which we express everything specifically *human* about human beings would still be needed, even if we understood in detail how purposes are embodied in brain mechanisms.

PYTHAGORAS (c.570 c.500 BC). Born in Samos, he founded a school at Croton in Magna Graecia, which combined asceticism, strict traditional rules of conduct and taboos (such as smoothing out the imprint of the body upon leaving the bed, and not eating beans), and an emphasis on reason and mathematics. Although Plato wrote a book on Pythagoras (lost in antiquity), all that has come down to us are a few doctrines, including that of the transmigration of souls (see METEMPSYCHOSIS); a list of ethical rules; and some mathematics, including his famous theorem (which has Babylonian origins), and especially number theory, which, so far as is known, he founded. See also PRESOCRATIC PHILOSOPHERS.

Page 666

Q

QUALIA. This Latin plural term (of which the singular is *quale*) has come into philosophical use by analogy with the term *quanta* (singular *quantum*). A *quantum* is an amount: to specify a *quantum*

involves reference to an amount of energy, mass, momentum, or whatever. The notion of a *quale*, by contrast, is, as the name implies, a qualitative rather than a quantitative one. To specify a *quale* is to say what something is *like*; and an irreducible reference to the phenomenological character of our experience, to the way in which things appear to the conscious subject, may be involved here. Examples of *qualia* are the smell of freshly ground coffee or the taste of pineapple; such experiences have a distinctive phenomenological character which we have all experienced but which, it seems, is very difficult to describe. An investigation of the nature, phenomenology, and possible causation of *qualia* has become an important concern of recent philosophy of mind. According to reductionists, *qualia* can be fully explained in terms of the neurophysiological events in the brain and its interactions with the environment. According to the view known as epiphenomenalism, *qualia* are causally dependent, or 'supervenient', on brain events, but cannot straightforwardly be identified with such events. According to dualism, *qualia* are independent of physics, and belong in the essentially autonomous, nonphysical realm of the mind. See further under QUALITIES; and MIND

BODY PROBLEM: PHILOSOPHICAL THEORIES.

J. G. C.

QUALITIES. The universe, as described by modern science, is conceived largely in quantitative terms. Mass, energy, velocity, length, breadth, and height are all expressible as mathematical quantities or amounts—as answers to the question *Quantum?* or 'How much?' But it is striking that most of the ordinary ways in which we describe our environment are not quantitative but qualitative: the descriptions involved answer the question *Quale?*, 'What is it like?' Such* *qualia*, or qualities, include redness, softness, sweetness, rankness, shrillness (of the five types of so-called 'sensible qualities' of sight, touch, taste, smell, and hearing, respectively). There is a longstanding philosophical debate about whether such qualities really inhere in objects or whether they are simply subjective effects in the mind of the observer.

John*Locke systematized (though he did not invent) a distinction between primary and secondary qualities. Primary qualities (roughly corresponding to the scientifically measurable *quanta* mentioned above) include shape, magnitude, and number, and are supposed to inhere in objects, so that our ideas of size, etc., actually resemble genuine features of the objects in question. But secondary qualities, such as redness, sweetness, etc., are rather different: our ideas of them do not, according to Locke, directly resemble anything in the object themselves, but are merely the result of the way objects affect our senses by means of their primary qualities.

Some philosophers have been suspicious of the primary/secondary distinction, pointing out that our attributions of colour, no less than our attributions of size, are a function of perfectly straightforward and objective rules of language, so that it is as correct to say that the sun is 'really' yellow as it is to say that it is 'really' spherical.

But there remains a special subjective or phenomenological character to our sensation of qualities like yellowness which seems to depend in part on the particular sensory apparatus with which our species is equipped—and it is not the same for all individuals. Thus it is possible to imagine that

aliens equipped with different kinds of organs would perceive light of a certain wavelength in radically different ways from us, to the point where the human notion of 'yellowness' would be inaccessible to them. This line of thought lends support to the idea that there is indeed something 'subjective' about sensory qualities such as redness and sweetness; the notions of squareness or sphericity, by contrast, do not seem similarly tied to the particular sensory 'mode' in terms of which they are experienced.

Apart from questions of subjectivity, there is a problem about whether *qualia* such as redness or sweetness can usefully figure in scientific explanations. Robert Boyle, writing in the 1650s, pointed out that if you want to know why snow dazzles the eyes it is no help to be told that it has the 'quality of whiteness'. Similar charges of explanatory vacuity were levelled against the scholastic theory that bodies fall because of an inherent quality of *gravitas* or heaviness. It was for this kind of reason that we find*Descartes insisting that scientific explanations should invoke 'nothing apart from that which the geometers call quantity, and take as the object of their demonstrations, i.e. that to which every kind of division, shape and motion is applicable' (*Principles of Philosophy*, 1644). Nevertheless, while this quantitative approach has undoubtedly been fruitful for physics, its application to psychology is more controversial. Sensible qualities are, after all, an inescapable part of the psychological landscape; any understanding of

$$R = k + n \log S \quad (1)$$

$$\text{Log } R = \log k + n \log S \quad (2)$$

$$R = kS^n$$

Page 667

our mental life must, it seems, include some account of *what it is like* for us to see colours, smell smells, and so on.

J. G. C.

QUANTIFYING JUDGEMENTS. Human judgement is so fallible that, in assessing magnitudes, objective physical measures need to be used wherever they are available. There are cases, however, where physical measures are not available: some magnitudes lack them. The loudness of noises, for example, cannot be measured directly in physical units because loudness is a subjective quantity which depends on the ear and the brain. A noise is likely to sound less loud to a partially deaf person than to a person with normal hearing. Similarly, the likeableness of people cannot be measured directly. In these and comparable cases it is necessary to resort to quantitative subjective judgements.

Theoretical issues. *Two kinds of stimulus magnitude.* It is important to distinguish between stimulus magnitudes with familiar physical units and those without (Poulton, 1981). Lengths, weights, and durations can be measured in physical units learned at school. In judging differences in magnitude or ratios between different magnitudes measured in familiar units, observers have merely to perform the appropriate arithmetical operations. Such judged differences and ratios are thus related by the rules of arithmetic, and the average of the findings of, say, several people in a group will be a reasonably

accurate one.

Here we will consider only stimulus magnitudes which observers are unable to measure in familiar physical units and for which they have to develop and use their own, subjective units. Such units of discriminability do not have, at the sensory threshold, an obvious zero from which absolute magnitudes can be judged; and therefore they cannot be used to judge ratios of magnitude. Even so, they can be used to judge differences between magnitudes, because where two magnitudes are the same size the difference between them is zero.

Two kinds of quantitative judgement. There are two ways of quantifying subjective judgements. One method uses a restricted range of responses with specified upper and lower limits: category ratings are the most frequently used examples. In contrast, the other method uses direct numerical magnitude judgements, which can provide the judge with a potentially infinite range of numbers.

Category ratings *characteristically* give a logarithmic relation between stimulus magnitude and subjective magnitude: where R is the response, S is the stimulus, and k and n are constants. By contrast, direct numerical magnitude judgements characteristically give a loglog relation (Stevens, 1975):

Taking antilogs, Equation (2) becomes a power function:

where n is the exponent.

S. S.*Stevens (190673) was the main protagonist of direct numerical magnitude judgements. Most technologists or others who need to quantify subjective judgements use category ratings, on the other hand, because their restricted range makes judging easier and provides less variable averages.

Logarithmic response bias. There has been controversy over whether Equation (1) or Equation (2) better represents the observers' perceptions of magnitude. It is now tacitly accepted that Equation (1) is correct. Stevens's Equation (2) incorporates a logarithmic response bias which occurs when observers use for responses a range of numbers containing a change in the number of allowed digits. After responding with numbers up to 10, observers have two alternative ways of proceeding.

They can continue 11, 12, 13, 14 . . ., using numbers linearly. Or they can go more logarithmic and continue 20, 30, 40 The average of a group of observers is likely to be a compromise between a pure linear and a pure logarithmic use of numbers, but closer to logarithmic.

Once Stevens had obtained his loglog relation, he instructed his student observers to use for responses a scale of numbers calibrated in ratios, like a slide rule. But this ensures that a loglog relation will be found, because it changes the R on the left side of Equation (1) to the $\log R$ on the left side of Equation (2).

There are two main lines of evidence that support the linear relation of Equation (1). In providing the first, Poulton (1986) asked separate groups of uninitiated observers to judge the difference between the loudnesses of two noises. The less intense noise he called 1.0. The observers were told to

respond with a higher number that represented the loudness of the more intense noise. When the medians of the very first judgements were numbers less than 10, they were linear in decibels.

The medians of the very first judgements showed a logarithmic response bias only when they were greater than 10, and so median responses were taken from a range of responses that contained both singledigit and twodigit numbers. A logarithmic response bias was found, also, when observers made a series of judgements of different loudnesses; but this was because the logarithmic response bias from using a range of responses which contained both onedigit and twodigit numbers transferred to the responses using only single digits.

Judged differences and ratios of magnitude have the same underlying relation. The second main line of evidence comes from several comparable investigations using different stimulus dimensions, which are summarized by Birnbaum (1980). In an

Page 668

investigation of the likeableness of people, described by single adjectives, Hagerty and Birnbaum (1978) compared judgements of differences, (AB), with judgements of ratios, A/B . The median difference judgements (of their 23 undergraduates) showed a linear relation to the stimulus magnitudes, following Equation (1). The median ratio judgements showed a logarithmic relation, following Equation (2).

Yet the rank orders of the sizes of the median difference judgements can be compared with the rank order of the sizes of the median ratio judgements, using Kruskal and Carmone's computer program Monanova. This program maximizes the fit of all the rank orders to the linear model, without changing the orders. When this is done, the two rank orders are found to fit almost exactly the same subtractive model. This should not happen if the difference and ratio judgements represent genuine differences in perception because, for example, (73) is greater than (41), yet $7/3$ is less than $4/1$. Clearly the subjects' difference and ratio judgements are simply two ways of describing the same perceptual relation between the stimuli of a pair.

Judged ratios of magnitude are simply judged differences with a logarithmic response bias. In the Hagerty and Birnbaum investigation, the relation perceived and judged must be a difference, not a ratio, because there are no familiar physical units of likeableness. The experimental subjects could use only their own improvised subjective units of discriminability. But these have no zero corresponding to a sensory threshold, which would have enabled ratios to be perceived and judged. When they were instructed to judge ratios, they were given a scale described in ratios; but it turned out that they could not perceive and judge the ratios.

However, they could use their subjective units of discriminability to judge the differences, because differences become zero when the two members are equal. Thus, differences were judged, but by using a scale of ratios.

In confirmation of this, Hagerty and Birnbaum presented adjectives representing pairs of people. The

undergraduates were instructed to judge the ratios of the two differences in likeableness, $(AB)/CD$. Both differences having obvious zeros, the undergraduates could judge their ratio. For the differences (AB) in the numerator, the median judgements changed from positive to negative as A changed from being more likeable than B to being less likeable than B . This indicates that the median of the subjects perceived the difference in likeableness between A and B . For the ratios, reducing the size of the difference (CD) in the denominator magnifies the median differences (AB) in the numerator. This indicates that the median of the subjects judged the ratio of the perceived differences.

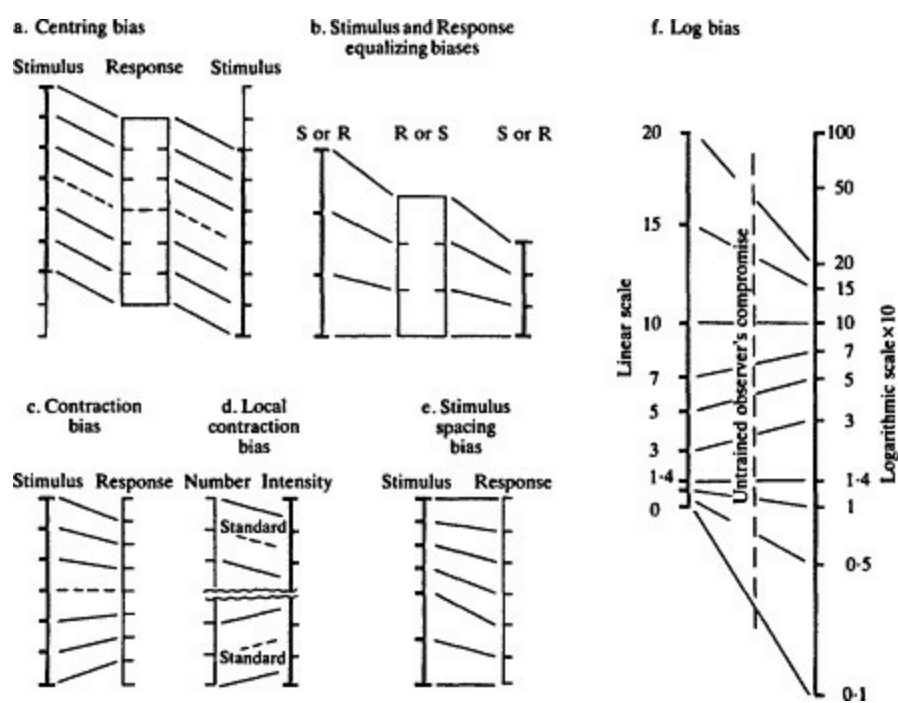

Since the ratios of the differences in likeableness bear the appropriate arithmetic relation to the magnitudes of the differences, the Monanova program cannot fit a simple model to all the medians taken together. To produce a simple acceptable linear fit, the ratios have to be excluded. The medians for each size of difference in the denominator have to be fitted separately. For the same reason, when all the medians are taken together, a nonmetric scaling program cannot fit a simple multiplicative relation either.

The important point is that it is the *differences* in likeableness that are perceived and their *ratios* that are judged, not vice versa. There is no corresponding condition where ratios are perceived and their differences are judged. In a crucial control condition, the undergraduates were instructed to judge the differences of the ratios, A/B C/D , and their median judgements showed a linear relation to the stimulus magnitudes. When subjected to the Monanova program, these median judgements fit almost exactly the same subtractive model as do the median judgements of a *differences of differences* condition (AB) (CD) . Thus, the subjects must have judged the differences of the differences, not the differences of the *ratios* as they were instructed to do.

Theoretical conclusions. The general rule is that in dealing with stimulus magnitudes that do not have familiar physical units, people perceive only differences in magnitude. People can judge the ratios of the perceived *differences*, because they can use their improvised units of discriminability. But they cannot perceive the *ratios* of the magnitudes directly, because this requires an obvious zero at the sensory threshold, which units of discriminability do not have.

By contrast, in dealing with stimulus magnitudes that do have familiar physical units, observers can calculate both differences and ratios. The differences and ratios are related by the rules of arithmetic. Thus it is not possible to tell whether the observers actually perceive the differences and ratios, or simply calculate them. Presumably they perceive differences as they do in dealing with stimulus magnitudes that do not have familiar physical units. But they may or may not perceive ratios as well.

Avoiding biases. Biases found in quantifying judgements are illustrated in Fig. 1. The biases are considerably larger when stimulus magnitudes cannot be judged directly in familiar physical units. The centring bias, a , and the stimulus spacing and stimulus frequency biases, e , are most often recognized in judgements using category ratings. The logarithmic response bias, f , and the stimulus and response range equalizing bias, b , occur most frequently in direct numerical magnitude judgements (see below). The contraction bias, c , and transfer bias (not shown) occur with all kinds of quantitative judgements. The local contraction bias, d , is seldom reported.

Page 669

Fig. 1.

Biases in quantitative judgements. S = stimulus. R = response. (Poulton, 1979.)

of responses. This centres their range of response ratings on the mid point of the range of stimuli, as is illustrated in Fig. 1a. Thus, in judging a series of road vehicle or aircraft noises, the just acceptable noise level in the centre of the rating scale is found to lie close to the middle of the range of noises—at whatever intensity level that happens to be. This means that in a quiet residential area the loudest noises will continue to be judged too loud, however much they are reduced in intensity.

In designing an investigation, this bias is avoided by presenting a range of stimuli with an unbiased mid point which corresponds to the centre of the rating scale. The unbiased mid point can be determined by presenting separate groups of people with ranges of stimuli that bias the centre of the rating scale in one direction. Other groups of people are presented with ranges which bias the centre of the rating scale in the opposite direction. The stimulus range with the unbiased mid point can then be determined, by interpolation.

The centring bias affects most kinds of judgement. In judging how hard up they are, people are likely to judge their present income against what they are used to spending, or what their neighbours spend. The relatively unstressful events in a relaxed period of people's lives are likely to appear at the time almost as stressful to them as the most stressful events in a stressful period of their lives.

Stimulus spacing and stimulus frequency biases. The stimulus spacing and stimulus frequency biases are produced by using all parts of the response scale about equally often. In the stimulus spacing bias, people judge a set of stimuli to be more equally spaced subjectively than they really are, as is

illustrated in Fig. 1e. The stimulus frequency bias can be treated as a special case of the stimulus spacing bias. The observers behave as if all the stimuli were equally probable. When one stimulus is presented more frequently than the others, the observers treat the more frequent stimuli as if they had almost, though not exactly, the same magnitude. Thus three identical stimuli one quarter of the way from the top of the stimulus range are treated as three closely spaced stimuli of slightly different size, as is illustrated on the left of Fig. 1e. This bias increases the amount of the observers' response range that is allocated to the identical stimuli. In designing an investigation, the *stimulus spacing* bias is avoided by spacing the stimuli at subjectively equal intervals. The *stimulus frequency* bias is avoided by presenting all the stimuli equally often.

The stimulus spacing bias may influence the choice of the candidate for a job. There may be a few very good candidates who are all close together in order of merit, like the stimuli at the top on the left of Fig. 1e. Yet, owing to the stimulus spacing bias, all the candidates are judged to be about equally spaced. As a result, the candidate who is only marginally the best may be selected, whereas if all the very good candidates were known to be almost equally good, the choice between them Page 670 could be made in part on other criteria that are important.

The stimulus frequency bias may influence the interpretation of a situation or object represented as a branching tree, which is sometimes used to help make decisions, or to find faults in equipment. People assume that all the branches represent equal frequencies or probabilities and so are equally important, whereas some branches may be much more important than others.

Logarithmic response bias. The logarithmic response bias is the cause of the theoretical controversy discussed above. The bias is avoided by taking two precautions: (i) Do not provide for responses a range of numbers which includes a change in the number of digits; (ii) Do not instruct the judges to use a scale of numbers calibrated in ratios.

Stimulus and response range equalizing bias. When judged magnitudes are plotted on the ordinate of a graph against physical magnitudes on the abscissa, smaller stimulus ranges give steeper slopes. People start their judgements with what they believe to be a sensible range of responses. They distribute these responses over the range of stimuli presented to them. With a smaller range of stimuli, the responses are spaced more closely, as is illustrated on the right of Fig. 1b. Thus the slope is steeper. This bias is usually unavoidable.

Contraction bias. People underestimate large sizes and differences, and they overestimate small sizes and differences. Once they know the range of responses that is available, they select a response that lies too close to the middle of the range, as is illustrated in Fig. 1c. The figure shows that the range of responses is contracted when compared with the range of stimuli. Hence the name 'contraction bias'. Stevens (1975) calls it the regression effect.

The contraction bias can be counterbalanced by reversing stimuli and responses. The dimension previously used for the stimuli is now used for the responses, and so has the contracted range. Averaging the results of the two investigations should counterbalance the contractions.

The contraction bias occurs in every kind of judgement. In giving people references, exceptional people do not usually receive as good references as they should do.

Dreadful people do not usually receive as bad references as they should do. At universities, the bias is likely to result in too many students being awarded second or third class degrees, while too few students are awarded first classes or failed. Small risks are usually overestimated, whereas large risks are underestimated. When respondents specify the range of confidence within which a statement is judged to lie, the extent of the range is likely to be underestimated at both ends, as in Fig. 1c.

Transfer bias: the influence of a condition on the performance of subsequent conditions. Transfer biases are likely to occur in any investigation where people perform more than one condition, especially if they are free to choose their strategies. Transfer biases are particularly common and powerful when uninitiated people have to judge several magnitudes in turn. Once a person uses a particular range of numbers in direct magnitude estimation, he or she is likely to use a similar range in subsequent investigations. If the instructions mention a range of possible numbers or ratios, they are likely to influence the numerical magnitude judgements of uninitiated people. Transfer bias occurs both between successive judgements within an investigation and between successive investigations.

Investigators who use balanced Latin square designs assume that transfer is symmetric; but it may be asymmetric. The effect of performing Condition *A* on the subsequent performance of Condition *B* may be different from the effect of performing Condition *B* on Condition *A*. If so, comparing the average of the two *A* conditions with the average of the two *B* conditions does not remove the transfer bias.

Worse still, adding conditions *C* and *D* to the Latin square may reverse the differences found between conditions *A* and *B*. This happens when conditions *C* and *D*

require a new strategy. The strategy may transfer to conditions *A* and *B*, and change the way in which the observers approach the task (Poulton, 1982). Transfer bias can be avoided for certain only by using separate groups of uninitiated people for each investigation or judgement.

RAMON Y CAJAL, SANTIAGO (18521934). Spanish neuroanatomist, born at Petilla, Navarra, in the Pyrenees. He studied medicine, and after army service in Cuba he returned to Spain to teach, becoming professor of anatomy at Valencia (1883), of histology at Barcelona (1887), and of histology and pathological anatomy at Madrid (18921922). Cajal improved Camillo*Golgi's method for staining nervous tissue with silver and undertook a systematic study of the microscopic structure of the brain. He established that adjacent nervecells did not join each other however close their fibres might be and suggested that nerve impulses passed from the axon of one neurone to the dendrite of the next, and not in the opposite direction (see BRAIN DEVELOPMENT; NERVOUS SYSTEM). In 1906 he shared a Nobel prize with Golgi for their work on the structure of nervous tissue.

REACTION TIMES. Like all other animals, humans can only *experience* the immediate past. Many scores of milliseconds must pass before any change in the world can be registered by a sense organ or interpreted by a brain. This perpetual lag behind the world, measured from the moments at which changes actually occur and the moments at which we can apprehend them, has become known as 'reaction time'.

Philosophies that attributed human consciousness to incorporeal entities whose rates of apprehension were infinitely fast ('the speed of thought') delayed recognition of this simple fact until very late in human history. In 1799, Nevil Maskelyne, then British Astronomer Royal, sacked his assistant Kinnebrooke because their timings of stellar transits always disagreed. Friedrich Bessel (17841846), a more considering scientist, noted that discrepancies between measurements made by individual astronomers were widespread and substantial. For the first time someone saw the necessity of calibrating human observers, as well as the equipment that they used.

Each astronomer, thenceforth, determined his personal, characteristic lag and used it as a corrective constant in his work.

By 1858*Helmholtz had recognized a further implication of this lag, seeing that one factor limiting human reaction time must be the speed with which electrical impulses travel along nerve fibres. To measure this speed he asked a human observer to bite on a contact switch as soon as he felt an electric shock, which might be delivered either to his foot or to his face. Responses to foot shocks were slower. Assuming that this difference occurred because impulses from the foot have further to travel before they reach the brain, Helmholtz measured the difference to obtain the first estimate for the velocity of transmission of nerve impulses. The phrase 'swift as thought' took on a potentially exact, if rather humble, value.

Helmholtz's brilliant insight, that measurements of human reaction times may be used to make deductions about the nature of otherwise unobservable neural processes, provided impetus for a next step. In 1868, F. C. Donders, a Dutch ophthalmologist, reasoned that a human must recognize a new stimulus before he can begin to organize a response to it. As we shall see, this is not quite true. However, Donders argued that since a stimulus must be recognized before a response to it can be chosen and executed, lags for these two processes must seem to give overall observed reaction times. By appropriate techniques reaction times may therefore be decomposed to give independent estimates for times taken to recognize signals and for times required to choose responses to them.

To obtain such estimates Donders required his observers to carry out each of three different tasks. In the ' *a*' task (simple reaction time task) they always had to make the same response as fast as possible every time a single signal occurred. In the ' *b*' task (choice reaction task) any one of five different signals might occur in unpredictable order and the observer made a different response to each. In the ' *c*' task (Go/No Go task) any one of the same five stimuli might occur, unpredictably, but the observer responded only to occurrences of one of them and ignored the others. Donders argued that differences in observed reaction times ' *c*' ' *a*' would provide estimates of how much longer a person needed in order to distinguish among five different signals than to make a response without having to discriminate which signal had occurred. Similarly, the difference ' *b*' ' *c*' would give an estimate of how long an observer needed to select among five different responses, rather than merely to always choose whether or not to make a particular response, after making the same discrimination. Donders's experiment gave him estimates for perceptual discrimination times (less than 50 milliseconds) which were far shorter than his estimates for response selection times (over 150 milliseconds), and he began to hope that his technique would allow

Page 672

independent estimates for other, more complex 'unobservable internal mental processes'.

Donders's results were reasonable in principle, but the logic of his experiment was flawed in two ways: first, in his ' *c*' task his observer never had to discriminate each of five signals from all of four others, as in the ' *b*' task. In the ' *c*' task the observer merely had to discriminate one 'Go' signal from all of another set of four 'No Go'

signals. There was thus no requirement to discriminate any 'No Go' signal from any other 'No Go' signal. Thus the ' *b* ' task involved both a more complex perceptual discrimination and a more complex response choice than the ' *c* ' task, and the ' *b* ' *c* ' estimate for discrimination time confounded these factors.

A more interesting weakness of Donders's experiment was that, like all other successful animals, human beings overcome their temporal lag behind events in the external world by learning to predict what will happen next. When they can do this they can have reaction times of zero milliseconds, responding to events just as soon as they occur, or they can even take leaps into the future, gaining an edge over a rapidly changing environment, or over rapidly moving adversaries, by anticipating events which have not yet occurred. In Donders's 'a' task his observer could set himself, in advance, to identify the same, recurrent, signal on every trial, and on every trial he could also safely prepare to make the same response to it. Thus the neural processes timed in the 'a' task have much more to do with anticipation and expectancy than with the processes of discrimination and choice that underlie the ' *b* ' and ' *c* ' tasks, in which observers must always wait until after something happens before their sense organs and brains can begin to work out what has occurred.

It is now widely recognized that reactiontime measurements make little sense unless we bear in mind that, although all living things can *experience* only the past, animals like ourselves have gained our success in the world by continuously, and accurately, predicting the very immediate future. A good cricketer has to predict, before the ball leaves the bowler's hand, the precise point in space at which it will be intercepted by his bat. A squash player who could not anticipate would founder hopelessly behind the game. Reaction times do not provide us with measurements of the time necessary for sets of nerve impulses generated in the sense organs to activate those parts of the brain that, in turn, activate our muscles. They rather measure the duration of operation of processes of active, predictive control, by means of which we organize responses that anticipate, and preempt, very fast changes in the world.

This point was only very slowly recognized. In Leipzig, in 1879,*Wundt set up the first laboratory of experimental psychology. His research programme was largely concerned with criticisms and extensions of Donders's work. It is sad that his many years of heroically dull experimentation now merely provide a textbook moral that conscious introspection can tell us little about the nature of decisions that may take us less than a fifth of a second to make.

As is often the case in experimental psychology, unpretentious calibrational studies proved the most fruitful in the long run. In 1892, yon Merkle showed that an observer's reaction times increase regularly with the number of signals among which he has to discriminate, and with the number of responses among which he must, consequently, choose. In 1931 Henmon showed that as pairs of signals become more similar to each other, people take longer to discriminate between them.

Observations such as these are very simple, and unsurprising, but their consequences are not at all trivial. From experiments based on yon Merkle's results, Hick (1952) and, separately, Henmon (1952) developed models for human reaction times that were the first, and the most influential, demonstrations that the new sciences of*cybernetics and information theory, which had been

developed during the 1940s, have very fruitful applications as abstract descriptions of the way in which the human brain arrives at decisions. From data similar to those gathered by Henmon, later workers such as Audley (1961), Crossman (1956), Falmagne (1976), Laming (1969), Luce (1969), and Vickers (1978) have shown how reactiontime measurements may be incorporated into a new*psychophysics of signal detection (see BIT).

Nonspecialists may capture something of the importance of this endeavour if they reflect that human experimental psychologists can only measure two things about human performance: how accurately people do things and how long they take to do them. Metrics and models that allow us to discuss speed and errors as complementary indices are basic tools of research.

P. R.

REALISM as a philosophical term generally refers to the doctrine that objects exist independently of sensory experience. The essential problem of*perception is to account for how we experience things which exist in the time and space of the real world. 'Naive' or 'direct' realism suggests that we experience objects as they are by a kind of direct awareness comparable with intuitive understanding of mathematics. This is very different from theories which suppose that perceptions are hypotheses (perhaps essentially like predictive scientific hypotheses) about, or 'about the nature of', or 'descriptive of' physical reality. Realism may be contrasted with*idealism.

REASONING: DEVELOPMENT IN CHILDREN. It is commonly claimed that, until the age of 6 or 7, children are very limited in their capacity for deductive reasoning. This claim is made largely on the basis of research carried out within two main traditions: that based on the thinking of Jean*Piaget in Geneva, and that based on the thinking of Clark*Hull in the United States.

The theories of Piaget and of Hull are in most

Page 673

respects opposed, and their conceptions of the nature of inference are very different. It is all the more striking that their work has led to agreement about young.

children's lack of competence; and indeed this agreement has seemed to many to be conclusive. More recent research, however, makes it necessary to reopen the debate.

Piaget's claims may best be illustrated by his studies of 'class inclusion'. These have demonstrated that, if young children are shown a group of, say, six flowers, comprising four red ones and two yellow ones, and are then asked whether there are more red flowers or more flowers, they are likely to answer: 'More red ones.'

And they will probably justify the answer by pointing out that there are 'only two yellow ones'.

Piaget's explanation is that at this stage a child's mind is lacking in a certain kind of flexibility, a kind crucial for reasoning. Piaget points out that the child who replies

'more red flowers' will normally have no difficulty in recognizing that if you take away the yellow flowers the red ones will be left; and further that if you take away all the flowers none will be left. To reach these conclusions, however, children need only think of the class and the subclasses successively. What they cannot do, according to Piaget, is think of them *simultaneously* (as they must, of course, if they are to reason as to the relations between them); for when they 'centre' on the whole class they mentally lose the subdivisions, and when they centre on the subdivisions they mentally lose the totality. So the seemingly simple comparison of whole with part is impossible for them. They have no mental structure representing a hierarchy of classes, with some included in others and these again included in still broader groupings, this being of course precisely the kind of structure with which logicians have traditionally been much concerned.

The deficiency in thought that is manifested by young children in the class inclusion task is held by Piaget to be quite general. Until it is overcome children's thinking is said to consist largely of a succession of separate 'moments', poorly coordinated with one another, so that the current one is too dominant. According to this argument, young children are not good at seeing their own momentary 'point of view' as one of a set of possible points of view coordinated into a single coherent system within which reasoning as to relationships can freely take place.

Piaget claims that the process of overcoming this deficiency is one of building 'cognitive structures', for which the original 'buildingblocks' are overt actions—acts of combining, ordering, etc., carried out on the real world. According to him, such actions, once they have been internalized (so that they can be performed 'in the mind') and organized into systems, are the very stuff of reasoning. It is then interesting to find that, in the other major tradition within which experimental studies of children's reasoning have been carried out—namely, the*behaviourist tradition, as exemplified in the thinking of Clark Hull—there appears the same emphasis on actions that are initially overt and subsequently internalized. Beyond this, however, the theories of Hull and Piaget have little in common.

For Hull and his followers, the essence of reasoning lies in putting together two 'behaviour segments' in some novel way, never actually performed before, so as to reach a goal. For instance, one 'behaviour segment' might consist in pressing a button, which act would release a marble from a little slot; a second might consist in putting a marble in a hole, which act would open a little door and allow access to a toy. An act of inference would consist in combining these (separately learned) acts in order to get the toy. Such an inference would obviously have the form: if *A* leads to *B* and if *B* leads to *C*, then *A* leads to *C*.

Work by Kendler and Kendler (1967) has shown that young children who have learned these separate 'behaviour segments' do not readily integrate or combine them.

So these investigators, like Piaget, conclude that children under the age of 7 are very limited in their capacity for inference.

There is now reason to think, however, that this conclusion needs to be modified. Simon Hewson has shown that if the apparatus and the procedure used by the Kendlers are changed in certain ways that do not alter the basic structure of the problem, then 5yearold children can perform as well as did the

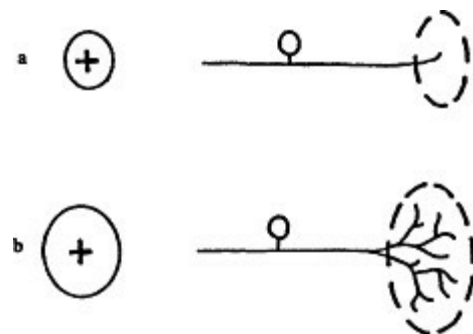

college students in the original studies.

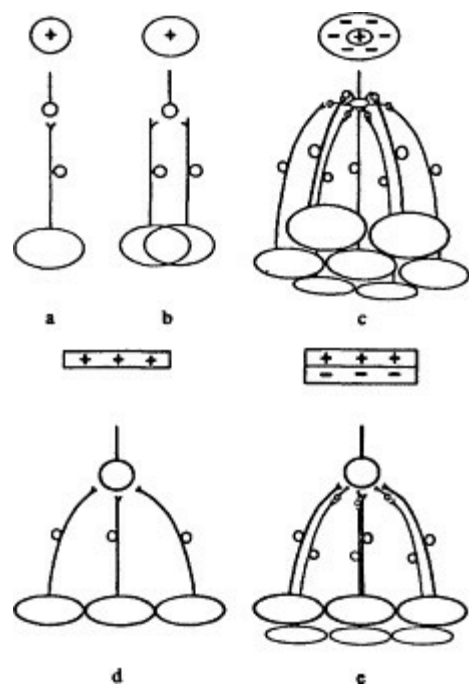

Hewson replaced the buttonpressing mechanism in the first 'segment' by a drawer which the child could open. Also he played a 'swapping game' with the children to help them to understand the functional equivalence of different marbles as means of opening the little door (so that they would realize there had been nothing special or

'magic' about the marble used in their original learning of the second 'segment'). These two modifications produced a jump in the 5yearold success rates from 30 per cent to 90 per cent.

It seems then that, whatever was the nature of the children's difficulty with the original task, it did not consist in a radical inability to make the inferential link. The conclusion that there is no such radical inability is supported by Peter Bryant (1974). Bryant argues that, in their perception of the world, young children continually make comparisons which depend on reasoning in the form: if $A = B$ and if $B = C$ then $A = C$. Thus they combine two separate pieces of information to reach an inferred conclusion.

Hewson's demonstration that the difficulty of the Kendlers' task can be greatly altered by inessential modifications has its parallel in studies of class inclusion. These have established that very slight changes in Piaget's class inclusion task can enable many young children to *perform* it successfully (see, for instance, McGarrigle, Grieve, and Hughes, 1978). It now appears that much of the difficulty with this and other similar Piagetian tasks lies in the fact that children are powerfully

Page 674

influenced by context, so that they do not interpret the experimenter's words alone with the strictness and rigour which—by adult standards—a reasoning task demands. It should also be noted that evidence obtained from observation rather than experiment suggests the presence of considerable reasoning skills in children as young as 3 or 4. An example is provided by a comment from a 4yearold who was listening to the story of Cinderella and looking at a picture of Cinderella marrying the prince. In the picture the prince looked effeminate, and the child thought it was a picture of two women. He called out, 'But how can it be (that they are getting married)? You have to have a man too!' He appears to have been using two premisses:

1. If there is a wedding there must be a man.
2. There is no man.

And he concludes validly:

So there is no wedding.

The general conclusion which we are now justified in drawing seems to be that young children have a considerable capacity for reasoning deductively about topics related to ongoing activities in which they are spontaneously engaged. What is hard for them is to accept verbal premisses which are 'set' for them by someone else in the absence of a meaningful, supportive context. Young children do not readily constrain their thinking in this way. Crosscultural studies (for instance, Cole et al., 1971) indicate that the same tends to be true of unsophisticated, illiterate adults.

With increasing age, and especially with the advent of literacy, people tend to become better able to turn their minds deliberately to a reasoning task and respect its constraints. But at all ages this kind of rigorous, disciplined inference is difficult for the human mind (see Henle, 1962).

RECEPTIVE FIELD. This term is widely used in sensory neurobiology. It refers to the 'region' from which a particular sensory neurone can be activated. The sensory nerve fibres concerned with cutaneous sensation provide a simple illustration of the concept (Fig. 1). A nerve fibre mediating, for example, touch sensation terminates in one or more processes in a restricted area of the skin.

Fig. 1.

Receptive fields of cutaneous afferents. a. Receptor is single terminal at the end of a cutaneous afferent. b. Receptors occur at the ends of all the terminals of an afferent which branches extensively in the skin.

Fig. 2.

This illustrates the way in which neurone complex receptive fields may be produced by convergence of the inputs from a number of afferents on to a secondorder (or thirdorder) neurone. a. Simple onetoone relay of input from afferent fibre to secondorder sensory

neurone. b. Convergence of two inputs on to one secondorder neurone, resulting in the secondorder neurone having a larger receptive field than either of the afferents. c. Formation of a 'concentric receptive field' with inhibitory region surrounding the excitatory zone. d. Organization of inputs to produce an oblong receptive field best activated by a bar, as in the visual cortex. e. Similar situation to d but with additional inhibitory side band to enhance the selectivity of the cell to the orientation of the bar.

(For further details, see VISUAL SYSTEM: ORGANIZATION.)

$S \rightarrow x \rightarrow R$

Page 675

These terminal processes together with any ancillary structures are the receptors relating to the nerve fibre in question. Touching the skin distorts these receptors, which depolarize and initiate an action potential discharge in the nerve fibre. The region of the skin surface which when touched results in activation of these receptors is known as the 'receptive field' of the nerve fibre. Taking this example further, individual nerve fibres are generally sensitive to one modality of sensation. Their receptive fields thus may be said to exhibit modality specificity and, in the case illustrated, this specificity is to mechanical distortion of the skin.

Receptive fields at higher levels in the nervous system can be much more complex (Fig. 2). Here the inputs relayed from a number of receptors may converge on to a single neurone. Moreover, these inputs may be organized to form a specific spatial pattern and some may relay via inhibitory interneurons, thus forming inhibitory zones in the receptive field. Furthermore, because of widespread interconnections in the brain, some higherorder sensory neurones may be slightly influenced by a wide variety of inputs in addition to the main input. At this level it can be difficult to decide where the receptive field boundaries are.

REDUCTIONISM IN PSYCHOLOGY—Luria's Philosophy. For a very long time reductionism remained the generally accepted philosophical aim of the natural sciences as well as of psychology. It was supposed that the basic goal of science is to reduce complex phenomena to separate simple parts, and that such reduction provides significant explanations of phenomena.

Reductionism had its origin in the middle of the nineteenth century, and in biology it was closely associated with Rudolf Virchow's cellular anatomy and pathology, which supposed that the organism is a complex of organs—and the organs a complex of cells. So to explain basic laws of the living organism we have to study as carefully as possible the features of separate cells.

The same principle of reductionism was seen in psychology. It was supposed that the basic goal of the behavioural sciences is to reduce the whole wealth of human behaviour to associations of separate elementary events. This was the aim of *Pavlovian* physiology and also the direction of *behaviourism*, which tried to reduce behaviour to the simple laws of conditioning.

Although the philosophy of reductionism was accepted as a general principle in the natural *sciences* and psychology, there are grounds to suppose it may be false.

To study a phenomenon, or an event, and to explain it, one has to preserve all its basic features: one must be able to describe their rules and their mechanisms without the loss of any individual characteristics. It can easily be seen that reductionism may very soon conflict with this goal. One can reduce water (H O) into H and O, 2

but—as is well known—H (hydrogen) burns and O (oxygen) is necessary for burning; whereas water (H O) has neither the first nor the second quality. This is why the 2

outstanding Soviet psychologist Leo *Vygotsky* stated that reduction can only be done up to certain limits. In order not to lose the basic features of water, one must split it into *units* (H O), not into *elements* (H and O). The same is true for the psychological analysis of human conscious behaviour.

2

Although this may seem obvious, psychology as a science followed, for many decades, a different view. During the period of associationist psychology, it was supposed that all forms of mental processes could be reduced to simple sensations (or ideas) and their associations. Even after *Gestalt* psychology had made its wellknown criticisms of the associationist point of view, the basic tenets of reductionism did not change: the only difference was that the Gestalt group of psychologists continued their attempts to reduce complex mental phenomena to physical or quasiphysical Gestalts, which were larger elements than single sensations or associations. It remained evident that the wealth and diversity of mental events was being lost through expression in the too generalized terms of Gestalt psychology, just as it had been in the former associationist theory. This situation remained unchanged in the twentieth century, when attempts were made to reduce complex forms of man's conscious behaviour to conditioned reflexes (see *CONDITIONING*), or to overgeneralized laws of conditioning.

Of course, human behaviour can be reduced to reflexes and their combinations; and general rules of conditioning are often supposed to be the most elementary rules for establishing new forms of connection. But it is evident as well that a reduction of human conscious behaviour to these 'elements' does not preserve the whole wealth of conscious behaviour. This means that the procedure of such kinds of reductionism is futile; and that real 'units' of conscious behaviour have to be found, which can preserve all the richness of the behaviour while at the same time pointing out models for it which can be the subject of an accurate study. Now we come to the basic question: what can serve as a real *model* of human conscious behaviour, as the 'unit' which includes all its essential qualities?

Vygotsky supposed that higher mental processes are of a social origin; and that the basic unit of human conscious behaviour is not to be found in unconditional or conditional reflexes (the latter being rather general physiological 'elements', not psychological 'units' *which* preserve all the essential features of conscious actions). He suggested that the simplest form of such behaviour can be found in tool or signusing, where a tool (or a sign) can be used to reach a certain goal. Instead of the elementary scheme of

,

→

where S stands for stimulus or situation, x for means (tool or sign), and R for reaction. Some decades later this scheme was improved, and a new component—that of feedback (see CYBERNETICS)—was added. This provides the formula

, essential for a selfregulating system.

Tiffs assumption changed significantly the general philosophy of reductionism. New components were added. Instead of attempting to reduce complex psychological phenomena to biological (or physiological) 'elements', a new method was proposed—to step outside the organism itself and to try to find the basic units of human conscious behaviour in the relation of the subject with the social environment, treating these *relations as* an essential feature of human mental processes.

Such an attempt radically altered the classical attitude of reductionist philosophy. The goal of psychology became not to try to explain the essence of complex phenomena by reducing them to elementary parts, but rather to find *new relations* in which the organism is involved. This became the ultimate goal of science. The more of these essential relations that can be found, the closer we come to the whole wealth of the phenomenon, and to its explanation. The *explanation of the phenomenon is supposed to lie not in its reduction to single elements but rather in its inclusion in a rich net of essential relations*.

This attitude has basic significance for every science, and for psychology especially. It is the way Marx calls 'ascending to the concrete', as opposed to the classical way of 'ascending to the abstract', based on singling out definite features and progressing to more and more general categories, such as 'dog' (opposed to 'cat')

'something' (as opposed to 'nothing'). Such a way of 'ascending to abstractness', a kind of inverted reductionism, inevitably leads to an overgeneralized nullity, in which the whole richness of concrete events is lost. The way of 'ascending to the concrete', i.e. the inclusion of the event in a rich net of relations, preserves the whole complexity of events, while at the same time revealing new and essential relations and thus providing the most important steps to the discovery of the *essence* of the phenomenon or the event, as opposed to its scientific explanation.

It may be supposed that such a method can serve as an alternative to dry reductionism, and that it can open new and productive ways for the scientific analysis of human conscious behaviour.

REFLEX ACTION. Reflexes are the automatic reactions of the nervous system to stimuli impinging on the body or arising within it. They are more easily described than further defined. The knee jerk (one of the 'tendon jerks') is a familiar instance. The tendon below the kneecap is struck sharply with a rubber hammer and the muscles of the kneecap in the thigh are caused to give a brief twitchlike contraction which extends the knee joint and causes a little kick of the foot. The latency, the time between the blow and the first sign of muscular contraction, is about a fiftieth of a second, not much longer than is required for nerve impulses to travel from the sense endings excited by the blow to the central nervous system (here the spinal cord) and back down to the muscle.

The word 'reflex' comes from the idea that nerve impulses are 'reflected' in the central nervous system.*Descartes instances the constriction of the pupil when a light is shone in the eye. In the eighteenth century, Robert Whytt and Stephen Hales showed that the integrity of the central nervous system is, indeed, essential for 'reflection'

to occur. In the next century the subject was greatly clarified by the discovery of*Magendie and*Bell that the nervous system uses separate*channels (nerve fibres) for input and output so that 'reflection' must occur centrally. With minor exceptions ('axon reflexes') the dorsal spinal nerve roots are exclusively sensory and the ventral roots exclusively motor in function. Detailed knowledge of the connections between the sensory and motor nerves in the grey matter of the spinal cord dates only from 1951, when Eccles obtained records from a microelectrode inside a motor nerve cell—the first time this had been achieved with any central neurone.

The tendon jerk is the simplest and fastest mammalian reflex known and its neuronal mechanism (although not its function in everyday life) is still the best understood.

Endless other reflexes exist of greater complexity and longer latency. Commonly instanced are responses to injury or irritation: sneezing and coughing, the withdrawal of a foot in a frog or quadruped, the scratching of a dog. There are very many reflexes concerned in the vital functions: blood pressure is reflexly affected by pressure receptors in the walls of the aorta, breathing by reflexes from stretch receptors in the diaphragm, and so forth. Reflexes from receptors in the muscles of the limbs and trunk (of which the knee jerk is one) are a large class, of still controversial function in the control of bodily movement.

Although the experimental investigation of reflexes in animals is traditionally carried out on the spinal cord after severing it from the brain, or on the lower parts of the nervous axis after removing the cerebral hemispheres (decerebrate preparation), there are many reflexes whose pathway is through the cerebral cortex. The involuntary

blink to a threatening gesture is one. And the elaborate learned responses called 'conditioned reflexes'

(see CONDITIONING) are cortical or usually so.

C. S.*Sherrington, to whom we owe much of our knowledge of reflex action, regarded the reflex as the unit of nervous action and suspected that complex sequential acts, such as walking, were in the nature of chain reflexes, in which one element reflexly caused the next: in walking, for example, the movement of the leg forward excited receptors in the leg which reflexly caused it to move back again, and so on. There is now evidence that the nervous mechanism for performing such acts as walking or breathing, exists in the central nervous system and can function, after a fashion, without reflex inputs; but that, normally, reflexes modify and regulate these actions and adapt them to changing circumstances.

The point at which an animal's responses to stimuli cease to be regarded as reflex and are called deliberate or voluntary, or by some similar term, is illdefined. A mild cough can be suppressed by an effort of will during a concert; but such coughing would be regarded as reflex. A similar suppression of the urge to pass water is more easily achieved and passing water is normally to be considered a deliberate act; the underlying reflex element is dominant only in infancy or when selfcontrol is impaired.

REFRACTORY PERIOD OF NERVE. Nerves conduct information from the senses, and send commands to muscles, by trains of electrical spikes—the 'action potentials'. For sensory nerves, the stronger the stimulation the higher the frequency of spikes; but this never exceeds about 800 spikes/seconds, for following a spike there is a short period of inactivity—the 'refractory period'—which sets an absolute limit to the maximum frequency of spikes. This limits the amount of information that can be transmitted down a single nerve fibre. This is far lower than electronic*channels—which, no doubt, is a reason for the large number of fibres in nerves and the rich parallel processing of the nervous system. See NERVOUS SYSTEM.

REID, THOMAS (171096). Scottish philosopher, born at Strachan Manse, Kincardineshire. He succeeded Adam Smith as professor of moral philosophy at Glasgow (176480). He reacted sharply to the scepticism of David*Hume's *Treatise of Human Nature* (1739), and defended intuitive common

sense knowledge and belief. His principal work is *Inquiry into the Human Mind on the Principles of Common Sense* (1764); also important are his essays on the *Intellectual Powers* (1785) and *Active Powers* (1788) of man.

Reid was influential in developing*faculty psychology, which supposed that human abilities can be considered in separate units, probably localized in specific brain regions. This has a basis of*phrenology—which on the whole had unfortunate consequences for nineteenth-century neurology.

There is a strong orthodox theological streak in Reid, who argued that our perception of the existence of external objects is given directly though with help from God, whereas sensation, as the raw data of experience, is given directly by physical objects. Reid's distinction between sensation and perception is still frequently used (though with God left out); but recent accounts of perception tend to blur this distinction, as sensation can be affected by processes of object perception, and it is far from clear that sensations are given at all directly by neurally peripheral or simple physiological processes (see PERCEPTION).

REINFORCER. See CONDITIONING.

RELIGION. John Macmurray used to say that the obvious difference between science on the one hand and art and religion on the other is that science is intellectual, while art and religion are peculiarly bound up with the emotional side of human life. Failure to make this distinction has led to much confusion. Some have simply dropped religion as no longer worthy of a thinking man's attention. Others, in extreme contrast, have turned a blind eye on contemporary doubts, and entrenched themselves in traditional dogma. But the twentieth century has been essentially the age of the halfbeliever—the person who is not without intuitions about the meaning of life, but is baffled by the dead weight of theology which has been accumulated.

The so-called five proofs of God's existence have never carried as much conviction as the personal encounters with God which religious people have claimed to have.

'Dieu d'Abraham, Dieu d'Isaac, Dieu de Jacob, non des philosophes et des savants.' So said*Pascal. And it is significant that all the great religions do appear to stem from some shattering personal experience. The Buddha achieved enlightenment as he sat in meditation beneath the Bodhi tree. As a result, he believed that he had found the cure for all human sufferings and dissatisfactions. The Old Testament prophets had experiences which, they alleged, told them profoundly important things about God—even suggesting that what passes for religion can be a bar to finding Him. There is always this gap between the religious founder and what the faith has

Page 678
become. We see it in Jesus's denunciation of the religion of *his* day, in contrast with his own sense of intimate closeness to the Father. One cannot read the Upanishads, the main source of Hindu doctrine, without feeling the writer's sense of union between the self and the Holy Power. And it was alone in the desert that Muhammad received his call to preach. True, these key figures quickly gathered round them a band of disciples; and other elements, such as a sense of common purpose and a sense of fellowship, accrued. Religion ministers to the group mind as well as to the individual. For all that,

what has been said about literature may equally be said about religion in its essence: 'The best in each kind comes first, comes suddenly, and never comes again.'

Is it the *same* basic experience that all religions are seeking to interpret? Making every allowance for the divergencies of time and place, it would seem a strong possibility. A study of so-called primitive people may offer useful clues. Their world is alive and shot through with elemental unseen power. This power is thought to take possession of certain of their chieftains, priests, and medicine men. One group of special interest are the shamans. In Siberia an aspiring shaman has to pass many hours in a cabin of snow, contemplating his own skeleton. He ends, we are told, by obtaining the 'flash' or 'illumination'—'a mysterious light that the shaman suddenly feels in the interior of his head'. He is now able to discern things hidden from other human beings.

Is the experience of conversion, as we know it in the West, so very different? Problems of language make it hard to judge. Here is a witness, quoted by Rudolf Otto:

'The more I seek words to express this intimate intercourse, the more I feel the impossibility of describing it by any of the usual images.' However, William*James analysed it as consisting of two elements—an uneasiness and its solution. Carl*Sung said that 'it gives a human being that sense of wholeness, which he had as a child, but loses when he leaves his parents'. And its common characteristic is a sense of something not earned, or even asked for—a sense of something 'given'. This led men naturally to infer a Giver; and therefore the postulation of a 'Someone', not ourselves, wholly other, out there in the void, may be directly connected with the origin of religion.

The human race, on the whole, has found no difficulty in filling that void with an endless variety of deities. Considering that no one could really have supposed that they had been *seen* by anybody, it is amazing the number of forms these gods have taken—from Rongo, the Polynesian god of agriculture, to Shiva, the Hindu lord of the dance, and from the Zeus of Greek mythology to the Jehovah of Michelangelo. From earliest times man has sought to establish some sort of working relationship with these powers that be—the enlistment of their aid against the evil all round him. The many and bloody sacrifices, which the Hebrew prophets denounced, were believed to open up communication between the sacred and the profane, and the idea of sacrifice has not yet ceased to be an important element in religion. (See BLOOD

MYTHS.) Men have also believed that 'mercy and *not* sacrifice' was what was required: that personal values count, when it comes to being right with God. Religion has always been closely linked with morality—even though it has given rise to some curious anomalies. Today the questions are still being asked. Is celibacy, or virginity, really demanded of us, if we are to be numbered among the saints? Are there absolute standards of conduct, applicable at all times and in all places? Or is everything relative?

As to our ultimate chances and the possibility of judgement after death, these remain beyond our logical apprehension. But Jung has suggested that our unconscious, which is free from the categories of space and time, may be the part of our makeup which 'knows' about these matters. Responses are set up in the unconscious by the use of certain symbols. Rituals give a sense of 'timeless moments',

and myths of flight and ascension suggest escape from one mode of being to another. The rites of spring around the world celebrate the rhythm of rebirth. Jung has furthermore maintained that the crisis of the West is in part due to the fact that the Christian myths and symbols are no longer lived by. They have become fossilized and irrelevant to most of the population. To some extent this must be true of Eastern religions as well—

despite all their genuine holy men and all their various techniques for quieting the mind. A recent traveller to Bodhi Gaya, where the Buddha was enlightened, was disheartened to see so many Buddhists, in his opinion, missing the point. If the truth lies within the self, why so much noisy ceremonial?

What then of the future? The twentieth century has certainly been a crisis for mankind. The sheer achievement of science has caused modern man to claim that 'what no God did for his worshippers in thousands of years, he has by his own efforts succeeded in bringing about'. For authentic existence from now on, so the existentialists say, we shall have to face up to the absence of God. Nobody can give us directions. We are alone in the cosmos. But the history of religions shows that they have an uncanny capacity for revival, even when they have seemed to be most dead.

Hinduism was at a low ebb at the time of the establishment of the British Raj, and it was thought that the educated Indian would soon reject it. But far from rejecting it, he has done much to reinstate it. Its strength lies in the recognition of different levels of spiritual development, and it has a special attraction for men alienated from the religion of their own society. One of the great texts of the Upanishads is: 'God does not proclaim Himself. He is everybody's secret.' An old prophecy says that after 2,500 years Buddhism will either fade away or enjoy a renaissance. It does not involve belief in God, over which many Westerners today have intellectual difficulties, and is undogmatic and

Page 679

experimental. One day a Zen master may deliver a sermon. Another day, if a bird begins to sing, the master will say nothing, and everyone will listen to the bird. Islam has been steadily increasing in influence and numbers, till there are over 817,065,200 Muslims at the latest count. In Christendom, the Roman Catholic Church is by far the largest, with 872,104,700 members. Its discipline is stricter than that of the Protestant Churches, and its appeal lies in its unbroken tradition. Protestants, by comparison, have broadened their outlook, yet they continue to preach to an anxiety-ridden world that 'sin' means separation from the ground of one's being, and that, as a matter of urgency, wholeness must be restored.

It is hard to be objective where religion is concerned. Objectivity suggests lukewarmness. It is easy for the agnostic to be objective, for there is nothing much at stake for him. It is very difficult for the man who claims that he has been vouchsafed a vision of the truth. 'Woe *is* me! for I am undone . . . for mine eyes have seen the King, the Lord of hosts.'

REMEMBERING. If one asks teachers, students, or the proverbial man or woman in the street for the best available techniques for remembering something, the answers will be quite varied. However, one recurrent theme is sure to be: 'Repeat it!' A psychologist is likely to comment: 'Yes, but . . . repetition by itself, mere repetition, does not help.' Yet the history of experimental investigations of memory is to a large extent concerned with mere repetition. In fact, the father of the experimental psychology of memory, Hermann Ebbinghaus, started his investigations in Germany in the last quarter of the nineteenth century by focusing almost exclusively on the effect of repetition. How many repetitions did it take to learn a list of words (or nonsense syllables)? How many trials were saved in relearning some list as a function of its prior repetition?

Both the common lore about repetition and the influence of Ebbinghaus dictated a preoccupation with the effect of repeated rehearsals. After all, it is well known that repeating a telephone number between looking it up and dialling it protects it from disappearance. And handsome, negatively accelerated learning curves resulted from numerous experiments that studied the effect of repetition on retention. But repetitive activities do not lead to effortless retrieval. Actually, when we try to remember an address, a name, the title of a book, or the plot of a play, we seem to engage in rather complicated search operations. The success of these operations depends not so much on how often we have repeated the required information in the past as on the proper embedding (the organization) of the target information within the larger flux of our knowledges and memories. When shopping for the weekend meals, we might retrieve the meats to be bought as a single memorial 'chunk', and liquid refreshments in another. Or another shopper might organize a mental shopping list by remembering what to buy in terms of what is where in the local supermarket.

Both of these schemas are kinds of organizations of the to be remembered things, and both require effort. Trying to recall the plot of a play, the rememberer might first recall vaguely the gist ('It was about a family who were always arguing') and then more and more details within coherent subdivisions ('Yes, there was the unhappy daughter and her pitiful suitor').

The notion that organization and structure are essential for memory retrieval is not novel.

Extensive mnemonic techniques date at least to ancient Greece, where orators constructed complex spatial and temporal schemata as an aid in rehearsing and properly presenting their speeches (see Yates, 1966). In modern times the associationism of British empiricism and German experimentalism was seriously questioned during the first half of the twentieth century by the Gestalt psychologists in general and by the British psychologist F. C. Bartlett in particular. Today we know in some detail what it is that repetition makes possible, what it is that is needed in addition to *mere* repetition.

A set of objects, events, or mental representations is said to be organized when consistent relations among the members of the set can be identified and specified. The result of such organization is called a structure. Structures may exist among events in the world as well as among mental events. A special kind of structure is the schema which is a mental structure, specifically an organized representation of a body of knowledge. Thus, schemata determine the expectations people have about events to be encountered, and about the spatial and temporal structure of those events.

The organization of to be remembered material takes time and conscious capacity. If we are told to remember a luncheon appointment while reading a book or watching our favourite television programme, conscious capacity is taken up by these primary activities and little organizational action will result. In order to remember the luncheon appointment we need to retrieve other plans (schemata) about the specific day and 'fit in' the appointment. For example, we need to store such things as

'After the dentist, go to work, but go to the luncheon an hour later'. In the temporal organization of that day's plan, dentist, work, and luncheon will form an appropriate mental schema. And thinking about these plans (repeating them) will make their proper retrieval on the appointed day more likely. But again it is not mere repetition

Page 680

that provides a better schema, rather it is the anchoring of the relevant events within better, richer, and more accessible events that provides the more effective schema.

Thus, each repetition provides an opportunity to relate the target event (the luncheon) to other events and thoughts. We may store the fact that our best friend will be at the luncheon, that it is held at a favourite restaurant, etc. etc. Each of these additions produces a more elaborate structure, and the more elaborate the retrieval opportunities for a target event the more likely it is that it will be recalled. Repetition provides opportunities for the organization of the to be remembered events.

While it is the case that most events are stored in longterm memory in complex, multistructured forms, certain frequently used structures can be identified. First there is the categorical or subordinate kind of structure in which a list of instances is stored under a general concept or label. To recall all the animals we know requires the use of such subordinate structures within a hierarchy of categories. Typically we gain access to some general animal category and then generate its subcategories such as domestic animals and catlike animals. Second there are coordinate structures of a few, usually less than five, events or things that are related to one another.

Spatial structures, such as the directions of the compass, are one good example; another is the set of things called a tablesetting. Whereas in the categorical structure the higherorder label or node retrieves the lower instances, in the coordinate structure the members of the set act as retrieval points for one another. The third kind of structure is a serial or proordinate structure in which a string of events is organized, usually in a temporal or spatial form. An excellent example is the way we retrieve the alphabet, another is the structure that represents the route we take to work from home. Parts of the serial string act as retrieval cues for subsequent things or events.

These idealized structures usually interact within any complex memorial event. More important, they are incorporated within the more general spatiotemporal schemata mentioned earlier. Thus the understanding of a conversation involves the kinds of expectation inherent in our schemata for social conversations, story schemata tell us to look for crucial aspects and themes of a story, restaurants require that we have the proper schema for ordering from menus, talking to waiters, and so forth. The episodes of our daily lives are organized within such schemata, which in turn incorporate the three kinds of structures described above.

Up to now the description of memory systems has focused on the recall of information. Another important kind of memory feat involves the recognition of previously encountered events. We are able to determine that people, rooms, foods, tunes are events that we have previously met, seen, tasted, heard. Not only do we know that we have encountered them before but we usually also know who or what they are. Conversely we sometimes know only that the event is familiar without knowing exactly who that person is, where we have seen that room before, what kind of food it is, what the name of a tune is. It is the latter phenomenon that has generally been studied by psychologists under the rubric of recognition.

The recognition of prior occurrence is a twostage process involving two distinct mechanisms. One of them is a judgement of familiarity, the other a retrieval process essentially identical to that discussed for the recall of information. The judgement of familiarity is an automatic process, requiring no conscious effort and occurring as an immediate response to the event. However, the familiarity of information available of the event may be inadequate to make a confident judgement of prior occurrence. In that case a search process queries the longterm memory system whether the event in question is in fact retrievable. If such an attempt is successful then the event is considered to be 'old', i.e. having been previously encountered. Thus, recognition involves a judgement of familiarity which is supplemented by a retrieval attempt. For example, we meet someone who looks vaguely familiar, but the definite judgement that we 'know' that person is not made until we can recapture the place or context where we have previously encountered him or her.

The process of judging familiarity brings us back to the problem of repetition, because mere repetition does affect familiarity. The more frequently an event has been observed the more likely it is to be recognized on the basis of familiarity alone. Thus, repetition does have a function, but not for the retrieval of information. Repetition affects the process of integrating the representation of an event; it establishes its familiarity independent of its context or its relations to other mental contents.

Finally, errors of memory can obviously be of two kinds, retrieval errors and, less frequently, errors

of familiarity judgements. Given the structural, schematic organization of memory storage, it is obvious that some events that 'fit' into the appropriate schema are likely to be retrieved even though they were not originally encountered. One might remember having witnessed an argument in a play because the structure of the play is stored under some general schema of 'family conflict', or one might 'recall' having seen a particular red armchair before, because it was stored as 'striking looking furniture'. Thus, errors of memory are often even more instructive about the nature of mental structure than the normal recovery of information. See also DÉJÀ VU.

REPRESSION, a key concept of*psychoanalysis, is a defence mechanism that ensures that what is unacceptable to the conscious mind, and would if recalled arouse anxiety, is prevented from entering into it. Akin to denial, which tends to refer to current events, it was invoked to account for a patient's failure to recall, in the course of*free association, events of significance in the past. Painful memories, being kept out of consciousness by repression, achieve 'psychic autonomy' and become fixed.

Derivatives of what has been repressed may evade the censorship and enter into consciousness in a disguised form as strange or seemingly irrational thoughts. Or they may be recalled in dreams or in other states, e.g. those due to alcohol or drugs, or hypnosis, with what*Freud described as 'the undiminished vividness of recent events'.

The method of psychoanalysis creates conditions for the undoing of repression, i.e. the making conscious what has been repressed. Painful experiences when so recalled are ranged alongside other related experiences which perhaps contradict it; they then undergo correction by means of other ideas.

RESPONSIBILITY AND MENTAL STATES. In ordinary discourse some people are spoken of as 'not responsible' for acts or omissions, but there are several uses of the term 'responsible'. For

example, not only people but things or events also are spoken of as 'responsible' for occurrences or nonoccurrences, when all that is meant is that they had a part in the physical causation of them. Again, people are said to be 'responsible' for other people—such as their children—or for organizations, in the sense that they are morally or legally culpable if the latter misbehave. In the sense, however, with which we here are concerned, 'responsible'

means 'to some extent culpable (either morally or in law, according to the context) for *one's own* acts or omissions'. The ascription of responsibility in this sense depends on what we believe to have been the person's mental state at or before the time of the act or omission. 'Premeditation' usually makes an objectionable act seem more culpable. If the actor foresaw a real possibility of his causing harm—for example by his way of driving—his act or omission will be called 'reckless', and blamed accordingly. If he did not foresee it, but we think that he should have, he may be called 'negligent', and blamed accordingly—usually less than for

'recklessness'. The law, too, makes distinctions of this sort, although with more subtlety (for example, civil law takes into account 'contributory negligence' by the person harmed).

More often it is the actor's state of mind at the time of the act—or more precisely what it is believed to have been—that determines the degree to which he is regarded as blameworthy. If the act seems to have been quite accidental—if for instance he knocks over a child whom he did not see in his path—he is not blamed, unless we think that he should have been aware of this as a real possibility. Again, if his physical movements that did the harm were of a kind which are, not willed, then he is not blamed: examples are the movements of a sleepwalker, or of a man who is sneezing. This excuse is called '*automatism' by English lawyers. Criminal courts usually demand medical evidence before accepting it, since it is usually based on abnormal cerebral conditions, such as an epileptic fit, or a hypoglycaemic state (which may occur in diabetics).

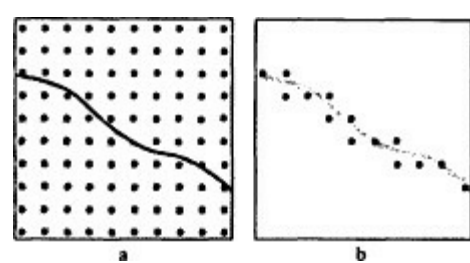

In certain situations, however, lawyers—and ordinary people—regard intentional actions as excused. Violence may be excused by the belief that one is about to be killed by the other person and that there is no alternative (such as escape). 'Necessity' is an excuse in the US Model Penal Code, although English judicial decisions are hostile to it. 'Duress'—acting under threats of death to oneself or one's family—is sometimes accepted. About 'superior orders' there is even more disagreement.

An official executioner who carries out a lawful sentence of death is not legally culpable, but is morally condemned by many people for accepting the task. Carrying out an order which one knows to be unlawful usually incurs moral—and sometimes legal blame, unless one does so in the knowledge that one would suffer death or a severe penalty for disobedience.

Even uncoerced intentional acts, however, may be excused, or at least mitigated, by other explanations. Provocation, if sufficient, is accepted by English law as lessening culpability rather than excusing the act completely, although courts are sometimes persuaded by it not to penalize the convicted person. Less transient mental states may also mitigate or even excuse. An example is an abnormal inability to control desires or impulses, especially if given a psychiatric label such as

'*psychopathic'. Other mental states, such as depression, frequently persuade courts to forgo penalties, and, if a hospital or clinic is willing to accept the sufferer, to entrust him to psychiatric care and treatment. The extent to which such states protect the sufferer against moral censure varies with the circumstances and the viewpoint of the censurer. The English Homicide Act of 1957 (following Scots common law) allows a person charged with murder (but paradoxically not attempted murder) to offer a plea of '*diminished responsibility': if successful this reduces the crime to manslaughter, and allows the judge freedom to impose a less severe sentence than life imprisonment. (The Infanticide Act of 1938 allows a somewhat similar plea of 'disturbed balance of mind' to a mother who kills a baby to whom she has given birth within the previous twelve months.)

Some kinds and degrees of mental disorder are regarded as excusing offenders completely. English law recognizes an 'insanity defence'. To qualify, the offender must, at the time of his act or

Page 682

omission, have been suffering from a 'disease of the mind' (in more modern language, 'mental disorder') such that he did not 'know the nature and quality' of the act, or alternatively know that it was 'wrong' (which is now interpreted in England as meaning 'against the law'). A third qualifying possibility is that he was suffering from a*delusion which, if true, would have legally justified what he did: for example a deluded belief that his life was threatened. In other commonlaw countries which have adopted and adapted this defence the exact definitions of the sufficient conditions vary, so that, for instance, 'wrong' can mean 'morally wrong'. In countries which follow the Code Napoléon the rule is simpler: no crime has been committed if the accused was suffering from *démence* at the time; but *démence*—or its equivalent—

is defined very restrictively in practice. Most such countries also recognize 'partial insanity' or its equivalent as grounds for reducing the severity of the penalty;

definitions of states which amount to this vary greatly.

Moral or political convictions are often regarded—especially by those who share them—as excusing behaviour which would normally be condemned, such as assassinations, violent demonstrations or even genocide. Few legal codes allow for such a defence, although it has been proposed, for example by Moran (1981).

RETINA. The screen at the back of the eye on which*retinal images are projected. The word derives from the medieval Latin *rete*, meaning 'net'. In human and many other eyes there are closely packed 'rod' light receptors which signal levels of brightness (giving*scotopic vision), and considerably fewer 'cones' which allow colours to be identified: photopic vision. Photopic vision occurs only in fairly bright light. The evidence suggests that mammals have very little colour vision, and that most almost certainly have none— except for primates including man. In the human eye there are about 100 million rods and about 5 million cones. Curiously, they lie at the back of the retina, so light has to pass through the vascular system, a mesh of nerve fibres and three layers of cellbodies, before it reaches the lightsensitive cells. It is possible to see the arterial system in another person's eye with an ophthalmoscope. It is also possible to see one's own retina by holding a torch bulb close to the closed eye and wagging it about—a tree of blood vessels becomes visible as their shadow image moves across the underlying receptors. The central, foveal region of best vision can be seen in one's own eye by wagging, in front of the pupil, a piece of cardboard containing a small hole, and looking at a blank screen—a faint pattern of nerve fibres (the blood vessels do not cover the fovea but pass round it) are revealed.

RETINAL IMAGES, STABILIZATION OF. The eye is continually moving—even when a person tries to fixate a wellmarked point as steadily as he can. The small residual movements of the eyeball cause irregular oscillations of the retinal image across the*retina and fluctuations in the light falling on retinal receptors near to boundaries (Fig. 1). W. H. Marshall and S. A. Talbot in the early 1940s worked out a detailed theory of the visual process based on the hypothesis that the receptors respond primarily to *fluctuations* of illumination and little, or not at all, to steady illumination—as indicated in the 1920s by the neurophysiological experiments of E.

D.*Adrian and R. Matthews, and of H. K. Hartline and R. Granit and their coworkers. According to this theory, the retinalimage movements are essential to vision.

An opposed view was that the eye movements were an unavoidable imperfection of the neural control of the eye muscles and that the retinalimage movements effectively blurred the boundaries, causing a loss of visual acuity—so that vision would be better if the retinalimage movements were stopped.

The crucial experiment to decide between these views is to make the eye movements control the movements of a target so that its image remains on the same part of the retina even when the eye

moves, i.e. to produce a stabilized retinal image. The simplest way to do this is to attach the target (and a lens which focuses it) on to a tightly fitting contact lens (Fig. 2). The whole system then moves with the eye and the retinal image is fixed on the retina. A more elaborate apparatus (Fig. 3) enables a wider range of targets to be used. The target is in the projection system P. The beam from P is reflected from the mirror M, which is attached to a contact lens worn by the subject. It enters the eye after passing through the telescope T. When the eye rotates through an angle θ , the beam from Fig. 1.

- regular array of retinal receptors. b. Receptors that receive
- fluctuating signals when boundary is given a small oscillation.

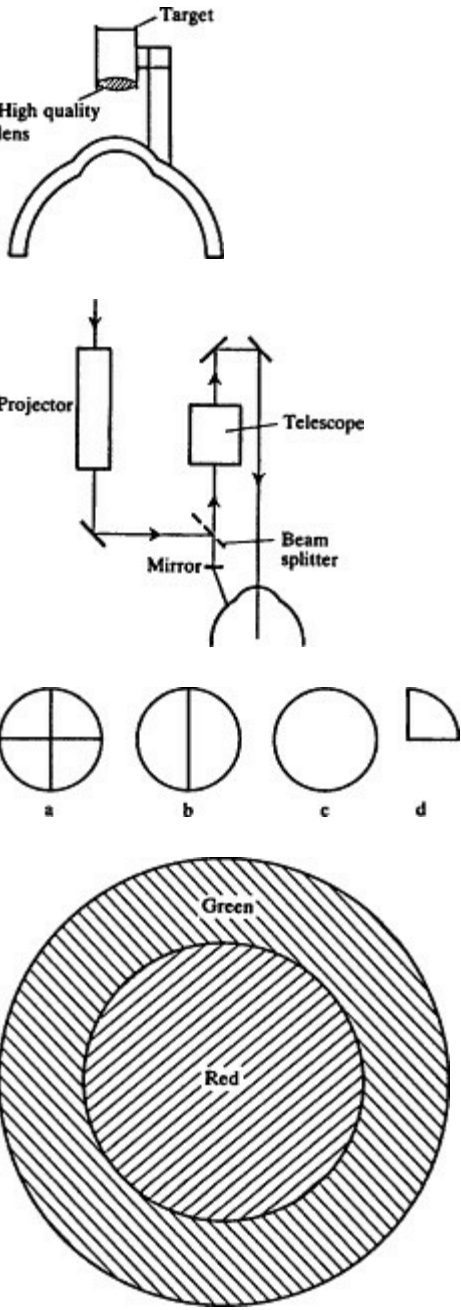

Fig. 2.

Direct attachment apparatus with
external contact lens mounted on a stalk.

Fig. 3.

Telescopic system involving a mirror
that is caused to rotate by the eye.

the mirror M rotates through an angle 2θ . If the telescope T has an angular magnification of $\frac{1}{2}$, the beam which enters the eye rotates through θ and its image falls on the same part of the retina even when the eye moves.

When a person views a stabilized image, the structure of the target fades out in two or three seconds and the field appears dark grey or black. If the target has no sharp boundaries between areas of high contrast, the field remains black so long as stabilization is maintained. Thus the retinal image movements are essential to normal vision, as was suggested by Marshall and Talbot.

If the target does contain sharp boundaries between areas of strong contrast, it reappears intermittently. These reappearances are usually hazy and sometimes fragmentary. There has been some controversy whether these reappearances are due to imperfect stabilization or to a weak visual signal which remains even when the image is stationary on the retina. Sharp afterimages may be imprinted when a target with sharp boundaries is illuminated with a brief, but strong, flash of light. These afterimages, which are certainly stationary on the retina, exhibit the same hazy, fragmentary, and intermittent reappearances. This strengthens the view that a weak secondary signal remains even when the retinal image is accurately stabilized.

When a target consists of a line pattern (Fig. 4a),

Fig. 4.

a. Target. b, c, d. Fragments seen at different
times when the retinal image is stabilized.

fragmentation of the stabilized image is observed (Fig. 4b, c, d). Fragmentation is not purely random, but the factors which determine what part of a pattern is seen at a given moment are not understood. Pattern units which are seen—or not seen—as a whole can be identified. The circle is one such unit and a complete circle may be seen even when the target is an incomplete circle. Fragmentation supports the ideas of those who have postulated the existence of pattern units (including the Gestalt school) but does not support any previously proposed scheme in detail. It seems probable that the human visual cortex contains cells which respond to particular pattern elements. The signals which reach these cells when the image is stabilized are very weak and difficult to distinguish from a background discharge of 'noise'.

From time to time the signal in one cell is recognized as greater than the noise, and the corresponding pattern element is 'seen'. Only very rarely do sufficient of these cells have signals above threshold simultaneously so that the whole target is seen.

Suppose that a target consists of a red centre surrounded by a green annulus (Fig. 5), with the outer boundary unstabilized and the inner boundary stabilized. Then the whole field appears green. The signals from the outer boundary give information that immediately within this boundary the field is green. Little or no information is received from the inner boundary, so the logical

Fig. 5.

Target with inner boundary stabilized,

outer boundary unstabilized.

Page 684

deduction is that the whole field is green. The target is 'completed', as happens in normal vision with a target which extends over the blind spot.

A more subtle example of the same process is obtained when a subject views a stabilized image of a large circle—15in (38cm) or more—divided by a diameter into two parts, light and dark. The boundary may fade first in the outer region while it is still seen in the central region. The available information cannot then logically be reconciled, because it is possible to go from a light to a dark region without crossing any perceived boundary. In this situation, the brain struggles to reconcile the irreconcilable. Various shapes of hazy boundaries appear briefly. Finally the whole field goes grey—and a 'logical', but useless, picture is obtained.

If eye movements operate in the way indicated by the experiments we have described, then the main visual information accepted by the visual system comes from receptors near to boundaries between strong contrasts of illumination or of colour—if there are any such boundaries. This may account for the extent to which an artist can convey both form and sensuous feeling by means of a drawing in which just a few lines indicate the boundaries (see ART AND VISUAL ABSTRACTION).

An animal, in order to survive in a natural situation, needs to keep in mind prominent features of the area in which it is placed and to give instant attention to any movement in the visual field which may reveal predator or prey. The visual receptors that respond mainly to *changes* of illumination filter the visual information so as to retain the permanent background but to give great prominence to any change, even in the periphery of the field. There is thus an inbuilt bias in favour of the information which is most important for survival.

See VISUAL SYSTEM: ORGANIZATION.

RETINEX THEORY AND COLOUR CONSTANCY. As we view an object from different distances, at different angles, and in different illuminations, there occur vast changes in the physical image on our retina; but our sensations prove much more stable than would be expected from our changeful retinal image. One of the several 'constancies' that characterize our sensory experience is colour constancy. Just as our visual system is built to tell us about the permanent size of objects rather than about the everfluctuating size of our*retinal image, so too it is built to tell us about the permanent colours of objects rather than about the spectral composition of the light falling on a local area of retina. The spectral composition of the light, that is, the relative proportions of the different wavelengths it contains, will depend on two factors: (i) the spectral reflectance of the object, its tendency to reflect some wavelengths more than others, and (ii) the spectral composition of the illuminant, the relative proportions of different wavelengths in the light that falls on the object. When we pass from, say, tungsten illumination, which is rich in long wavelengths, to the bluet environment of daylight, our perception of an object's colour remains dependent on the object's spectral reflectance, and we are aware of little change. To achieve this constancy, the visual system must be taking into account not merely the local absorptions in the three classes of cone cell (see COLOUR

VLSION: EYE MECHANISMS) but also the pattern of absorptions in other parts of the visual field. For the *local* absorptions can depend only on the local spectral flux; and the latter, being dependent on factors (i) and (ii) above, will vary greatly as the illumination changes.

A particularly impressive and instructive demonstration of colour constancy has been provided by Edwin Land. He performed an experiment in which a single mixture of red, green, and blue light produced many different colour sensations. Observers reported white, pink, green, red, brown, yellow, purple, blue, and black sensations from identical mixtures of red, green, and blue lights. The experiment used a large, complex display that Land called a 'colour Mondrian'. The display had approximately 100 different matt papers arranged arbitrarily so that each colour was surrounded by several others. The display was illuminated with three projectors, each with a different broadband interference filter. One filter transmitted longwave, or reddish light; one transmitted middlewave, or greenish light; and one transmitted shortwave, or bluish light. Each projector had an independent brightness control. The observers picked an image segment—say a white paper—and the experimenter measured the amounts of red, green, and blue light coming from the white paper. Then the observers picked a second paper—say a red one—and the experimenter measured the amounts of red, green, and blue coming to each observer's eye from the red paper. The measurements showed that roughly the same amount of red light and much less green and blue light are reflected from a red paper. The experimenter then changed the illumination so that the red light from the red paper was exactly equal to the red light from the white paper. This was a small change. The experimenter then substantially increased the brightness of the other two projectors so that exactly the same amounts of green and blue light came from the red paper as had previously come from the white paper. When all three projectors were turned on together, each observer reported the sensation red despite the fact that the physical properties of the light from that image segment were the same as that from the white with

the previous illumination. In this manner, Land went from paper to paper and showed that nearly the full gamut of colour sensations can be produced from a single mixture of red, green, and blue light.

Page 685

This experiment led Land to propose that the information from the longwave receptors is intercompared to compute a biological analogue of reflectance from the longwave light across the entire image. Similarly, the information from the middlewave receptors is intercompared to form the biological analogue of middlewave reflectance, and shortwave information for shortwave reflectance. The information from each of the sets of receptor mechanisms generates a separate lightness image; the comparison of three lightnesses is the determinant of colour. In Land's theory, which he called the retinex theory, these three lightnesses provide the coordinates of a threedimensional space. Whereas a colour space based on the absolute absorptions in the three classes of receptor will predict only whether or not two physical stimuli will match, a space based on the three lightnesses of retinex theory will predict how colours actually look. For, between them, the three lightnesses give the reflectance of the object in different parts of the spectrum—in other words, its spectral reflectance.

The formation of lightnesses and their comparison could occur in the retina or in the cortex. Land coined the word retinex—a combination of retina and cortex—to designate the mechanism that generates independent long, middle, and shortwave lightness images. This system independence does not require that the retinal receptors with the same spectral sensitivity are directly connected to each other. Instead it argues that the retinalcortical structure acts in total, as if all the colour mechanisms of the same sensitivity form independent lightness images.

McCann, McKee, and Taylor described a series of quantitative experiments that were patterned after Land's. In these experiments they measured the sensations of each area in a 'Mondrian' using a series of different illuminants. In each situation they measured the sensation by matching each area in the display to a Munsell book of colours in constant illumination. Secondly, they tested how well the sensations correlated with the reflectance of the papers as measured with spectrophotometers.

They showed that there was an excellent correlation between sensation and reflectance measured with light meters that had the same spectral sensitivity as the three human cone pigments. (This correlation was particularly good when the reflectance numbers were scaled by Glasser's Munsell lightness function.) Land and McCann proposed a lightness model that is based on the comparison of receptormechanism responses from all parts of the image. This lightness model does not use local averages or global averages, but rather comparisons that are based on the relationships of image segments. Local relationships are calculated by the visual system using the ratio of energies at nearby points, and this information is propagated to other parts of the image by multiplying ratios to form products. These products propagate relationships across the entire image. The mean of many different products is used as the prediction of lightness.

McCann, McKee, and Taylor showed that the ratioproduct lightness model combined with retinex colourmechanism independence accurately predicted the colour sensation reported by the observer in

the 'colour Mondrian' experiments.

The rods provide an opportunity to study sets of receptors forming an image in terms of lightness. With the appropriate lowintensity light source it is possible to see, below cone threshold, that the rods interact to form a lightness image—just as above cone threshold, lightness of an image segment is dependent on the relationship of objects in all parts of the image. With a lowintensity light that is very rich in longwave light, it is possible to see a wide variety of colour sensations from rod and longwave cone interactions. Colour is determined by the lightness of the image generated by the rods and the lightness generated by the longwave colour mechanism.

In summary, Land's retinex theory proposed that colour is determined by three lightnesses— each computed from comparisons using intensity information from the entire image. Each lightness is computed independently using intensity information from each spectral region. The Land and McCann lightness model uses the multiplication of ratios to form products that relate each image segment to each of the others. The mean of many different normalized products is used to predict lightness. Quantitative tests have shown that retinex colourmechanism independence and the ratioproduct lightness model can predict colour sensations in experiments with unknown changes in the spectral distribution of the illumination.

RIBOT, THÉODULE (18391916). French psychologist who did much to advance the subject in both its experimental and its clinical aspects. In 1885, he was made responsible for a course of experimental psychology at the Sorbonne and was later given a chair of experimental and comparative psychology at the Collège de France. His bestknown work is *Les Maladies de la mémoire* (1884),

translated as *Diseases of Memory* (1885), in which he put forward a theory of the progressive loss of memory brought about by brain disease along the evolutionary lines adumbrated by Hughlings*Jackson.

O.L.Z.

RIVERS, WILLIAM HALSE RIVERS (18641922). British physiologist, psychologist, and ethnologist, born in Luton, Kent. After qualifying in medicine, he was appointed to a lectureship in experimental psychology and the physiology of the senses at Cambridge, but his interests moved increasingly towards ethnology, partly because of the celebrated expedition to the Torres Straits in 1899 in which he took part, along with his fellow psychologists C. S.*Myers and William*McDougall, and the anthropologists C. G. Seligman and A. C. Haddon. As an experimental psychologist to the expedition, Rivers was particularly active in measuring sensory thresholds and visual illusions in what was probably the first crosscultural study ever carried out.

Notwithstanding his concern with anthropology, Rivers never wholly forsook his physiological interests, collaborating with the neurologist Henry*Head in an important study of the changes in tactile sensation resulting from the severance of a cutaneous nerve, Head himself being the subject. Their findings led them to the theory that there are two forms of cutaneous sensation, one relatively crude ('protopathic') and the other highly discriminative ('epicritic'). Although raising much interest at the time, this theory has since been wholly discarded.

At the outbreak of the First World War, Rivers's interests were largely centred on medical psychology, and he did important work in the treatment of war neuroses, then known as shellshock. Among his patients was the writer Siegfried Sassoon, who has painted an unforgettable portrait of Rivers in *The Complete Memoirs of George Sherston* (1937). After the war, Rivers wrote widely on issues in medical psychology and, though he remained eclectic in his views, his ideas were evidently much influenced by Freud.

Rivers, who died relatively young, was elected a Fellow of the Royal Society in 1908, and was for many years a Fellow of St John's College, Cambridge. His books included *Kinship and Social Organization* (1914), *The History of Melanesian Society* (1914), *Instinct and the Unconscious* (1920), and *Conflict and Dream* (1923).

RORSCHACH, HERMANN (18841922). Swiss psychiatrist, born at Zurich, who devised the famous standardized inkblots (made by placing a blob of ink on paper, then folding the paper to produce symmetrical patterns) that have been widely used as an 'openended' test for personality traits and disorders. The Rorschach test has, however, turned out to be extremely difficult to validate objectively, and its success depends very much on the intuitive grasp of the psychologist who interprets the patient's responses or comments. (See PROJECTIVE TECHNIQUES.)

ROUSSEAU, JEANJACQUES (1712-1788). Born in Geneva, his mother dying at his birth and his father deserting him when he was 10 years old, he was brought up by relations and had no formal education, except for reading Plutarch's *Lives* and Calvinist sermons. He had an extraordinarily ramshackle early life, taking up with an illiterate maidservant by whom he had five children—whom he committed to the foundling hospital even though he became famous for defending the natural goodness of man while blaming institutionalized life for the ills of the world. His *Confessions* (1781-82) are noted for their frankness. He died insane; and indeed his sanity throughout his life has been questioned in spite of his remarkable achievements and literary fame. See also ROUSSEAU AND EDUCATION.

Grimsley, R. (1973). *The Philosophy of Rousseau*. London.

ROUSSEAU AND EDUCATION. In *Émile* (1762) Rousseau presented a view of childhood and human nature which continues to inform educational thinking. In contrast to the Christian doctrine of original sin, he asserted that human nature was essentially good. He argued that it was the institutions of society which corrupted man. He reacted against the coercive nature of the authoritarian society of his time. 'From the beginning', he writes, 'to the end of life civilized man is a slave. At birth he is sewn up in swaddling bands, and at death nailed down in a coffin.' At a time when many children could not be expected to live for long, he argued powerfully that such life as they did have should be enjoyed. The memory of his own unhappy childhood made him acutely aware of the needs of children and insistent on their right to happiness. He argued for the transformation of childrearing: mothers were to breastfeed their own children, infants were to wear loose clothing and generally to enjoy freedom of movement and a closeness to nature. He viewed the child as a child and not as an inadequate adult, believing that it had the potential within itself to develop almost unlimited talents.

This kind of optimism is central to Rousseau's view of human nature and to his revolutionary ideas about society and education. The role of the teacher was not to restrain or to indoctrinate but so to arrange the child's environment that it could learn for itself. He attacked the education of his time on the grounds of its 'verbalism';

rote learning and textbooks were anathema to him. It was from things that they could actually experience that children best learned. His attitude was not antirational: 'I am far from thinking that children have no kind of reasoning. On the contrary, I notice that Page 687

they think very well on everything which bears on their present and obvious interest.' From observation and his intuitive sympathy for children he was led to conceive of stages in their development towards adulthood, a notion which Jean Piaget, another Genevan, later developed more scientifically.

Rousseau did not question contemporary faculty psychology (the theory that various capacities—moral, aesthetic, reasoning—exist discretely in the human brain and develop separately), but his developmental view led him to recognize that children need to be childish and adolescents

adolescent. He notes that the adolescent becomes ever more curious about the world, and eager for knowledge, but stresses that this knowledge must be his own, based on his own experience. Even at this stage he is sceptical of the educative value of books, except for *Robinson Crusoe*, which showed a man learning from nature and hard necessity. Rousseau understood adolescence, the moods and instability associated with the urgency of sexual development. His views about sex education are still pertinent: 'If your pupil cannot be kept ignorant of sex differences up to 16 make sure he learns about them before 10.' This strength of Rousseau's, his trust in an intuitive understanding of the nature and needs of children, remains a positive stimulus to educational thought and practice. His belief in the essential goodness of human nature may be a myth but it is a more sustaining one than its converse. There are also dangers: a distrust of accumulated human knowledge, an antiintellectualism that can lead to the worship of unreason, an overreliance on feeling as a sufficient basis for sane human action. His profound distrust of institutions, however, has proved well justified: we are still struggling to make schools good places for children to learn in. (See EDUCATION: THEORY AND PRACTICE for a discussion of the influence of his views.) C. H.

RUMI, JALALUDDIN (Jalaluddin Muhammad Ibn Bahauddin Walad alKhatibi alBakri alBalkhi, 1207-73). One of the greatest Sufis and a major Persian poet and thinker. Born of a royal and caliphal line of distinguished scholars in Balkh (present-day Afghanistan), he taught and died in Iconium (Konya, today Asiatic Turkey). His penname (literally 'of Rome' or 'the (eastern) Roman') was chosen, by poetic substitution cipher, because it represented both the town of his adoption and the Perso-Arabic word *Nur* ('light'). He acknowledges the Sufi masters Attar and Sanai as his 'two eyes', and they are undoubtedly his spiritual precursors. His major work is the *Mathnawii Maanawi* (Poem of Inner Meaning), which was something like forty years in the writing. His theme as a guide to mystical experience is that man in the ordinary state is cut off ('veiled') from higher perceptions by lower, usually emotional, stimuli. This state is often found in both the learned and the emotionalist: addiction to vice or to imagined virtue are both forms of idolatry, which cause 'veiling'. Teaching people to hate evil and covet sanctity is training in hatred and covetousness more than an approach to

goodness or holiness. Bad things cannot be avoided, nor good ones approached, he insists, by such crude and ignorant methods. The following major themes give an idea of his teaching.

Conventional religious systems are secondary, imitative, and limited: 'Do not attach yourself to the brick of the wall—seek instead the eternal original.' *A teacher is essential:* 'Water needs a medium between it and the fire, if it is to heat correctly.' *Laymen cannot evaluate mystical masters:* ' "This ruin may seem a prosperous place to you: for me, the better place is on the King's wrist," said the Hawk. Some owls cried, "He is lying to steal our home!" ' *Sufi knowledge involves escaping from familiar dimensions:* 'You belong to the world of dimension: but you come from nondimension. Close the first "shop", open the second.' *Knowledge of Objective Truth (God) is developed through love and selfknowledge:* 'Ultimate Truth is reached by Love, that special love of which worldly love is a crude analogue: HE is within you!'

RUSSELL, BERTRAND ARTHUR WILLIAM (third Earl Russell, 1872-1970). By general consent the most distinguished philosopher of the twentieth century, Bertrand Russell made fundamental contributions to logic, and influenced equally academic and popular philosophy, as also appreciation of psychological issues and social questions. Starting from a broadly*idealist

Page 688

philosophical position (*The Problems of Philosophy*, 1912), he became a thoroughgoing empiricist, after the manner of John*Locke, in later books such as *Human Knowledge: its scope and limits* (1948). His work on the place of the individual in society included the first of the BBC Reith lectures, *Authority and the Individual* (1949).

Russell also wrote on the philosophy of physics (*The A. B. C. of Relativity*, 1935; 1958). His main works on the basis of logic and mathematics are *The Principles of Mathematics* (1903) and, with A. N.*Whitehead, *Principia Mathematica* (1910-13), which attempts to derive mathematics from logic and to resolve Frege's contradictions by means of the celebrated Theory of Types, or Theory of Classes. Among his most important philosophical contributions is his theory of descriptions, given in an article in the philosophical journal *Mind* (1905), 'On denoting'. This distinguished between the logical and grammatical subject of propositions, and developed a theory of meaning which was able

to avoid the hitherto widespread view that the grammatical subjects of all meaningful propositions must refer to objects which in some sense exist. This is fundamental for an account of language that does not populate the world with a bizarre zoo of entities, such as glass mountains, female Popes, and all else that we can speak about, whether true or false.

Russell attempted to base physics on sensory—perceptual—experience. For him**sensedata* (such as sensations of red, hard, extension, and so on) are the basis of all knowledge of the world and the ultimate justification and test for all empirical statements. It is perhaps unfortunate that he did not consider phenomena of perception in any detail; for if he had, he would surely have concluded that much that we experience perceptually is not given at all directly by the senses of the eyes, the ears, and touch, but is rather itself created, much as we create explanatory concepts.

Russell will be remembered not only for his own outstanding philosophical achievements but also for the crucially important personal encouragement that he gave to his student Ludwig*Witto genstein, who might very well have abandoned philosophy had not Russell seen the importance of the *Tractatus LogicoPhilosophicus*, which appeared in 1922 and for which Russell wrote a highly significant introduction. In later life Russell gradually withdrew from his logical studies, and then from his philosophical work, towards political concerns and, especially, dedication to the cause of nuclear disarmament.

Bertrand Russell revelled in and inspired controversy: his *Autobiography* (3 vols., 19679) has the frankness one should expect from a man exulting in all aspects of life and intellect, while totally free of humbug. In spite of his unorthodox views and behaviour he received the highest honours: Fellowship of the Royal Society (1908) and the Order of Merit (1949).

Russell's main works include *An Essay on the Foundations of Geometry* (1897); *The Principles of Mathematics* (1903); 'On denoting', *Mind*, n.s. xiv (1905), 47993; with A. N. Whitehead, *Principia Mathematica* (vol. i, 1910; 2nd edn., 1935); 'Knowledge by acquaintance and knowledge by description', *Proceedings of the Aristotelian Society*, n.s. xi (191011), 10828; *The Problems of Philosophy* (1912); *Our Knowledge of the External World* (1914); *The Analysis of Mind* (1921); *The Analysis of Matter* (1927); *An Outline of Philosophy* (1927); *An Inquiry into Meaning and Truth* (1940); *The History of Western Philosophy* (1946); *Human Knowledge* (1948); *My Philosophical Development* (1959).

RUSSELL'S PHILOSOPHY OF MIND: DUALISM. When Russell wrote about the mind, his gaze was also fixed on the physical world beyond it, because he wanted to explain how minds can acquire knowledge of what lies outside them. This gave his philosophy of mind an outwardfacing character. He was especially interested in what happens at the point of contact between mind and matter when knowledge is acquired. What he says about the mind's output is less detailed except when the output is language and the language expresses knowledge or belief about the physical world. Emotions, intentions, and actions are treated in a more perfunctory way.

He shared Hume's view that psychology is the central science, because all the data of physics and physiology are somehow passed into the mind and one of psychology's tasks is to explain how this is done. However, he did not share Hume's tendency to scepticism about the physical world. He believed that science gives us a rich and extensive knowledge of what lies outside minds and that a philosophy of mind which denies, belittles, or jeopardizes that knowledge is unacceptable.

His main contribution to the subject was *The Analysis of Mind*, which he published in 1921. The theory that he there proposes about what happens at the point of contact between mind and matter is not one that appeals to common sense. Common sense might endorse the theory that there is a mysterious interaction between two irreducibly different kinds of things, the mental and the physical (dualism). But the theory proposed in *The Analysis of Mind* is that at the point of contact there occur events which are in themselves neither mental nor physical, but which are the basic components out of which we construct both the mental and the physical world (neutral monism). This is the kind of conclusion that could be reached only at

Page 689

the end of a long philosophical investigation. So perhaps the best way to explain it is to describe its development out of the dualism which Russell espoused first.

The leading idea in his early, dualistic philosophy of mind is that all knowledge is based on acquaintance. In his philosophical classic *The Problems of Philosophy* (1912) he defines acquaintance as the mind's relation with those objects that directly confront it. He explains that the kind of confrontation that he means occurs in senseperception, introspection, and certain kinds of memory. Senseperception gives us our knowledge of the external world, and the crucial question is whether the direct objects of perceptual acquaintance lie outside the mind. His answer is that they do. However, he does not think that they are the physical objects which the unphilosophical take themselves to perceive. They are sensedata, external to the mind, unlike mental images, but phenomenal, unlike physical objects. Their intermediate status is hard to formulate, and his specification of examples, such things as patches of colour and sounds, does not make it much easier to understand.

The construction of the physical world out of such components does not belong to the philosophy of mind. But the difficult task of specifying the components themselves does belong to it. There was also another difficulty that faced Russell at this point. Sensedata, which are by definition appearances presented to minds, do not provide a sufficient basis for constructing the physical world, in which

much of what goes on is never presented to any mind. So he had to enrich the basis with unsensed appearances (sensibilia). He could then treat a physical event as a centre from which lines of appearances radiate outwards in physical space and only a small proportion of these appearances would be presented to minds and so become sensedata. The introduction of unsensed appearances put a constraint on his philosophy of mind: it had to explain the difference between mere sensibilia and sensedata.

At first the distinction did not give him any difficulty. A sensedatum was simply distinguished by the fact that it was presented to a mind, or, to put this the other way round, by the fact that a mind was acquainted with it. But later, when this reliance on the mind as the subject of acquaintance (ego) began to strike him as illegitimate, he had to explain the difference between unsensed and sensed appearances in another way.

He finally gave up the ego in 1921, when he was converted to neutral monism, which constructs the mental world out of the very same components as the physical world and, therefore, cannot admit the ego. The construction of the physical world out of these components—the other side of neutral monism—was developed by him eight years earlier in *Our Knowledge of the External World*, and it did not produce a crisis in his philosophy of mind, as the abandonment of the ego did.

Russell's dualism lasted just so long as he refused to construct the mental world out of the same components as the physical world. In that period the main lines of his philosophy of mind were very simple. Acquaintance was a relation connecting the ego with its objects. At that time his main adversary was idealism, which in its extreme form maintains that we never make any contact with anything outside our own minds. Acquaintance seemed to offer a way of escape from this restriction. It was a relation, and he conceded to the idealists that it was a mental relation. But he rejected their inference that, therefore, its objects must be mental too. His early theory of sensedata attempts to exploit the possibility that they are sometimes physical. However, the attempt would succeed only if he could give an acceptable account of sensedata, which would not only show that they are the same kind of thing as unsensed appearances but also explain what distinguishes them from unsensed appearances.

If he could do these two things, he would have a realist theory of knowledge and a realist theory of meaning, and he would have thrown off the cramping restrictions of idealism. For though sensedata would be the only physical objects of acquaintance, all our knowledge of the physical world could start from them and the meanings of all our descriptive words could be derived from them.

This ambitious enterprise ran into two difficulties, one on each of its two main fronts. His reaction was to give up the dualistic theory that mental and physical things are irreducibly different and to take up neutral monism, which reduces both to the same basis.

The first difficulty was that he could rely on acquaintance only so long as he believed that the mind was, or contained, an ego, or subject. In fact, even in 1912, he felt unsure about the ego. It was too vulnerable both to Hume's criticism, endorsed by William James, that introspection reveals no such thing, and to Kant's criticism, foreshadowed by Hume, that no empirical meaning can be attached to

the hypothesis that there is such a thing. So Russell gave up the ego, and then had to find another explanation of the awareness that distinguishes sensedata from mere sensibilia. The new explanation could not be that sensedata are related by acquaintance or by any other relation to an ego. It had to be that sensedata and other directly presented objects are related in certain ways to one another.

The second difficulty concerned the status of sensedata. How could they be the same kind of thing as unsensed appearances? If, as he believed, unsensed appearances exist as actual things at points in physical space, they are unequivocally physical, and the word 'appearance' merely alludes to the possibility that they might acquire a relation with a mind. Sensedata, on the other hand, could be physical only if they occurred in the nervous systems of percipients. Now there is no doubt that in his early philosophy of mind he did

Page 690

ascribe this kind of physical existence to them. But that left many mysteries unsolved. How exactly did the mental relation, acquaintance, manage to reach out to them?

And how exactly did they themselves manage to represent their causes outside the percipient's body, as he implied that they did, when he specified them as things like patches of colour and sounds?

The neutral monism which he adopted in 1921 was intended to answer these questions. (See following entry.) D. F. P.

RUSSELL'S PHILOSOPHY OF MIND: NEUTRAL MONISM. The philosophy of mind adopted by Russell in his middle period was neutral monism, which denies that there is any irreducible difference between the mental and the physical and tries to construct both the mental world and the physical world out of components which are in themselves neither mental nor physical but neutral. He adopted this theory because he believed that there was no other way of solving the problems that beset his earlier dualism (see previous entry). The book in which he developed the theory, *The Analysis of Mind* (1921), is an unusual one. The version of neutral monism defended in it is qualified in several ways and it is enriched with ideas drawn from his reading of contemporary works on behaviourism and depth psychology. The result is not entirely consistent, but it is interesting and vital especially where it is least consistent.

The aim of neutral monism is to show that the difference between the physical and the mental is not a difference of components but only a difference in the way in which the components are put together. An analogy can be found in the difference between the division of a country's population into groups living in different areas and its division into the categories used by taxcollectors. In both cases the same human material is used, and the difference lies in the method of selection. Similarly, according to neutral monism appearances are grouped in one way to form physical objects and in another way to form minds. In order to get a physical object, you take all the appearances that radiate outwards from its position in physical space. In order to get a mind, you take all the appearances that start from surrounding objects and converge on its position in physical space. The difference is based on the distinction between output and input. However, a physical object is not the separate source of its

output of appearances, but only the group of all the appearances sent out, and similarly a mind is not the separate recipient of its input of appearances, but only the group of all the appearances received.

This theory was devised to solve the problems of perception, and its generalization to cover not only sensations (received appearances) but also such things as beliefs and desires was bound to lead to difficulties. But first, did it solve the problems of perception?

There were two such problems which Russell's earlier dualism had failed to solve. First, he had to explain the difference between an unsensed appearance (sensibile) and a sensed appearance (sensedatum), and his earlier explanation was that a sensedatum is presented to a subject (ego) which is then acquainted with it. But when he ceased to believe in the ego, he was no longer in a position to appeal to its acts, and he could not even use the word 'sensedatum', because it implies that something is given to a recipient. So he used the words 'sensation' or 'sensum' instead, and he had to find some other distinguishing mark of sensa. Second, he had to show that sensa really are the same kind of thing as sensibilia, and, what is more, that they are both in themselves neither physical nor mental but neutral.

The neutral monist solution to the first of these two problems was that sensed appearances are distinguished from unsensed appearances by the fact that they are related to other appearances in ways in which unsensed appearances are not related to other appearances. For sensed appearances produce later memories, and at the time they produce beliefs with the help of memories of earlier appearances. These networks of relations cannot be found among unsensed appearances and so they can be taken as the distinguishing mark of sensed appearances. The difference becomes more striking when we add the behavioural effects of memory and belief and all the stratified processes of learning. The details are complicated, but the essential point is that the analysis of*consciousness does not rely on a relation between subject and object, but relies, instead, on distinctive relations between sensed appearances and other appearances.

At this point Russell qualifies his neutral monism. The theory in its pure form would claim that these distinctive relations provide the complete explanation of consciousness. But he avoids this extreme position. In fact, the philosophy of mind of anyone who adopted it would be like *Hamlet* without the Prince of Denmark.

More specifically, it would be vulnerable to two objections. Depth psychology shows that the distinctive relations are not always accompanied by consciousness, and common sense suggests that, conversely, consciousness is not always accompanied by the distinctive relations.

The neutral monist response to the second of the two problems amounted to little more than an assertion that sensed appearances really are the same kind of thing as unsensed appearances. But sensed appearances are sensations, and sensations are already mental and do not need any distinctive relations in order to make them constituents of minds; and so their basic neutrality is a pretence. Indeed, the only plausible theory that is at all like neutral monism is the theory that sensations are a special kind of physical occurrence in the nervous systems of observers. It is, therefore, not surprising to find Russell adopting this position in *An Outline* Page 691

of *Philosophy* (1927) and in *My Philosophical Development* (1959). However, this is not neutral monism but the kind of materialism that identifies the mental with the physical. In subsequent decades many philosophers have subscribed to this identification in the general form that covers everything mental. When Russell suggested the theory in the special case of sensations, he put them in the same category as unsensed appearances only by giving them a physical aspect as well as a mental aspect. In any case, unsensed appearances would have nothing to match the mental aspect of sensations, but only the possibility of becoming sensations. In general, Russell construed the world, in a way that was always*Leibnizian but never*idealist, as a constellation of radiating views each of them something like what would be recorded by a photographic plate at the appropriate point in physical space. But neutral monism is not the right metaphysic to accommodate this idea.

Outside the area of perception it is even harder for a neutral monist to demonstrate that the basis of the mental world is neutral. The two most difficult cases are beliefs and desires. Neither of them can be constructed entirely out of sensa, and Russell's strategy is to call in images. But are images really like sensa? Certainly most images are quite unlike what is recorded on a photographic plate, and the use of an image is often more like drawing a picture than looking at one. In any case, images at best could supply only the content of a belief, and there is also assent to the content. Since Russell was committed to avoiding acts of mind, he adopted*Hume's theory that assent is a feeling. However, such a feeling would be completely unlike a sensum and at this point neutral monism has been left far behind.

Quite apart from neutral monism, it is questionable whether Russell's analysis was on the right lines. Assent may not be an act of mind, but it is directed on to a content and this feature (*intentionality) is not easy to include in a theory that treats assent as a feeling. Intentionality is*Brentano's idea rather than Hume's, and*Wittgenstein put it at the centre of his philosophy of mind. When Russell gave up the ego and its acts, he ought to have retained the essential feature of its acts, intentionality.

In his analysis of desire, his rejection of intentionality is deliberately provocative. His main point, derived from depth psychology, is that people often do not know what they want. Now it is undeniable that people often do not know what they need. So he assimilates desires to needs, and defines desire as a feeling that starts a line of behaviour and defines satisfaction as another feeling that terminates it. The name of the initial feeling is 'discomfort' and the name of the terminal feeling is 'removal of discomfort' or 'pleasure'. However, he is inclined to define these feelings not by their introspectible qualities but by their places in the pattern of behaviour. In fact, his whole analysis is very behaviouristic. The object of a desire is whatever would cure the discomfort, and conscious desire is merely desire accompanied by a true belief about the cure. If this were correct, it would certainly explain why people do not always know what they want.

The three main theories of *The Analysis of Mind* have had very different fates. Its neutral monism, already heavily qualified, has not survived, and materialism is the only monistic theory that seems to have any hope of replacing it. Russell's rejection of intentionality appears to have been a mistake. On the other hand, his critique of the assumption that all the contents of a mind lie open to inspection has produced an enduring effect. This critique is a characteristic Russellian achievement. It uses ideas taken from behaviourism and depth psychology with panache, and it threatens to destroy the Humean

framework in which it is set.

RYLE, OILBERT (190076). British philosopher, commonly characterized as a leading member of the school of 'linguistic philosophy' which was prominent at Oxford in the years following the Second World War. This description of him is questionable, however. He regularly made clear to students that he had no wish to be the founder of any philosophical 'school', and philosophical terms such as 'materialism', 'idealism'—and even perhaps the expression 'linguistic philosophy' itself—were sometimes described by him, almost dismissively, as 'hustings' words.

A central part of his programme was to classify concepts according to their 'category' or 'logical type'. His most famous work, *The Concept of Mind* (1949), is an attempt to show that philosophers have misled themselves by assigning concepts which purport to refer to minds and mental qualities to the wrong category. (One assigns words to categories according to their 'logical behaviour'; thus 'know' does not behave like 'read'—at least in some respects—since one can read carefully or carelessly but one cannot know something carefully or carelessly; similarly one can do some reading for half an hour but one cannot 'do some knowing' for half an hour.)*Descartes, according to Ryle, had correctly recognized that men were different from machines but had mistakenly characterized the difference by suggesting that some human movements were the result of 'nonmaterial' or 'nonmechanical' causes. A second 'world' had therefore to be invented—a 'mental' world—to house such entities; it belonged in the same category as the 'physical' world but contained nonspatial and nonmechanical happenings. The postulation of such a 'world' is scathingly

Page 692

referred to by Ryle as 'the dogma of the Ghost in the Machine'. He is not saying that there is *no* such world, since this would be to repeat the same category mistake;

he is arguing that the counting of 'worlds' is misguided and that we are misleading ourselves if we raise questions couched in 'ghostinmachine' terms. He argues instead that many mentalistic words are dispositional in character: thus to describe a person as intelligent does not imply that occult events going on 'in the mind' are influencing other events going on 'in the body'; it indicates some of the things which he is disposed to do if particular circumstances arise. Other mentalistic words, such as 'solve', 'detect', and 'see', are 'achievement' words: that is to say, they are used when certain processes or activities have been brought to completion and do not relate to shadowy processes or activities going on 'somewhere else'.

In his later writings (see *Collected Papers*, 1971, and the posthumously published *On Thinking*, 1979) he argues that when a person is described as thinking (like Rodin's *Le Penseur*) it does not follow that there is a single activity, for example operating with words or symbols, that is invariably going on. Other published works include *Dilemmas* (1954) and *Plato's Progress* (1966).

Ryle's views have sometimes been described as 'behaviourist', and they do indeed have a certain amount in common with the radical*behaviourism of B. F. Skinner. In particular both thinkers are in agreement in their opposition to methodological' behaviourism: neither wishes to say that 'mental events' exist *alongside* 'physical events'

but are not suitable objects for scientific study. Skinner's attack on 'autonomous man', however, is less sophisticated than Ryle's attack on 'the Ghost in the Machine';

mentalconduct words, for Skinner, are 'perquisites of autonomous man' (*Beyond Freedom and Dignity*, 1972, p. 15), and the suggestion that such words are not all of the same logical type is not considered. In addition Skinner writes at times like a traditional determinist, whereas Ryle correctly recognizes that the question, 'Does this action merit praise or blame?' is of a different logical type from the question, 'What were this action's causal antecedents?' An extension of Skinner's position might be to say that for its own purposes a science of behaviour requires a language without the explanatory superstructures implied by disposition words, and that it is for this reason—not simply for doctrinaire behaviourist reasons—that mentalistic words should not figure in scientific reports on human and animal behaviour. Ryle, however, unlike Skinner, is concerned with the use of mentalistic words for workaday purposes; and, apart from his admonition to philosophers, he is not attempting to argue that our ways of talking require revision.

The final chapter of *The Concept of Mind* offers an account of the subjectmatter of psychology. Its main thesis is that psychology should not be regarded as though it were a kind of counterpart to Newtonian physics, concerned with 'mental' phenomena as opposed to 'physical' ones.

The Cartesian picture left no place for Mendel or Darwin. The twoworlds legend was also a twosciences legend, and the recognition that there are many sciences should remove the sting from the suggestion that 'psychology' is not the name of a single homogeneous theory. Few of the names of sciences do denote such unitary theories, or show any promise of doing so.

For those interested in psychology perhaps the most important message from Ryle's work is that insufficient attention to correct categorization can lead to false contrasts, to misleading analogies, and indeed to downright bad theorizing. It is a message which, up to now, not all practising psychologists have fully taken to heart.

S

SACCADES. Rapid movements, punctuated by brief fixations of the eyes, during searching eyemovements. The saccades (or saccadic flicks) of the eyes do not occur when a person is following a moving object with his eyes, or with eyemovements due to the head turning as an object is fixated. Thus, there are two kinds of eyemovements—'saccadic' and 'smooth'—given by different neural mechanisms. The world remains fixed only during saccadic movements, and not during smooth eyemovements; this is probably because the efferent commands to move the eyes for searching are cancelled against the movement signals from the retinas: when the eyemovement command and retinal movement signals are equal and opposite, the world remains stable (unlike a panning cine camera) but only while the eyes move saccadically.

The successive fixations between the saccadic jumps refresh the borders of retinal images, as the receptors adapt (fatigue) with constant stimulation, giving rise to afterimages. Visual acuity for resolving fine detail is, however, slightly impaired by the small saccadic movements, as is shown by a slightly improved acuity, for a second or so, in flash afterimages, which are 'photographed' fixed on the retinas, although they move.

The word 'saccade' derives from an old French word meaning the sudden flicks of a sail.

SADISM. Term first used by KrafftEbing to describe sexual pleasure gained by the infliction of pain or cruelty on others. He derived the word from the name of the Marquis de Sade. De Sade was condemned to death by the *parlement* at Aix-en-Provence for sexual vices, but had his sentence commuted by the king to imprisonment. While in the Bastille he wrote scandalous novels based on fact: *Justice* (1791), *La Philosophie dans le boudoir* (1793), *Juliette* (1797), and *Les Crimes de l'amour* (1800).

SANAI, HAKIM (Khwajah AbulMajd Majdud ibnAdam Sanai, c. 1046?1141). A native of Ghazna in present-day Afghanistan, he was a major Sufi teacher and author, acknowledged by Rumi as one of his inspirers. He wrote an enormous quantity of mystical verse, of which his *Hadiqa* (Walled Garden of Truth, 1131) is his masterwork and the first Persian mystical epic of Sufism. He taught that lust and greed, emotional excitement, stood between humankind and divine knowledge, which was the only true reality. Love and a social conscience are for him the foundation of religion; mankind is asleep, living in what is in fact a desolate world. Religion as commonly understood is only habit and ritual.

I. S.

Sanai, Hakim. *The Walled Garden of Truth* (trans. D. Pendlebury, 1976). New York.

SARTRE, JEANPAUL (1905-1980). Sartre's father, a naval officer, died two years after JeanPaul was born, whereupon he and his mother went to live with her parents. Sartre thus grew up under the supervision of his grandfather, Charles Schweitzer (uncle of Albert Schweitzer), who exercised a powerful and not altogether benign influence on the boy's development. He was sequestered at home,

and there encouraged in precocious literary aspirations until the age of 10, when he was sent to school, to enjoy for the first time the companionship of other children. Sartre's own account of his childhood in *Les Mots* (1964) is mostly negative, and his grandfather is subjected to extremely unfavourable criticism. In the course of his adolescence he studied at the prestigious École Normale Supérieure, met Simone de Beauvoir, qualified to become a *lycée* philosophy teacher, and did national service in the meteorological section of the Army. He nurtured strong literary ambitions and ideals, which came to fruition with the publication (1938) of his first novel, *La Nausée*, the first existentialist novel. In subsequent years he published several plays and novels, notably *Huts clos* and *L'âge de raison*, in which his philosophy is given concrete dramatic expression. This work was combined with more purely philosophical productions, dealing with the imagination, the emotions, and Husserl's notion of the transcendental ego; in this he was much influenced by the works of the German phenomenological school. These studies culminated in his most systematic and ambitious philosophical work, *L'être et le néant* (1943), which powerfully integrated his philosophical concerns and his controlling literary themes. In later years he became increasingly occupied with *political* matters, both practically and intellectually, thus attracting by his outspoken heterodoxy the obloquy of both Church and state.

The subtitle of *L'être et le néant* is 'an essay on phenomenological ontology', and this aptly describes the method and content of that difficult but rewarding book. For Sartre's aim is to give a systematic descriptive account of the fundamental categories into which reality divides—an architectonic of being—and of their interrelations, by means of a phenomenological enquiry into the structures that consciousness displays. This is Page 694

designed to elucidate the basic character of man's existence in the world, and so expose the underlying principles of his various modes of conduct. The startingpoint and pivot of the enquiry is, in the spirit of the phenomenological tradition, an insistence upon the constitutional intentionality of consciousness—its directedness on to outer objects—and from this Sartre's whole philosophy ultimately derives. It is first observed that consciousness is, of its very nature, consciousness *of* things other than itself. These things exist independently of consciousness, and are thus transcendent to consciousness, inasmuch as their being is never exhausted by their presentations to consciousness. The objects of consciousness comprise the realm of being Sartre calls the 'in-itself'.

The in-itself, for Sartre, is wholly outside of consciousness: intentional objects are not (as they were for Husserl) in any sense constituents of, or in, consciousness. But consciousness itself, by contrast, is a dependent entity in that it cannot be conceived to exist independently of the in-itself, since it is essentially intentional; it is therefore supported in its being, as Sartre puts it, by something other than itself. (His position is thus the reverse of idealism.) Indeed, consciousness just *consists* in the intentional positing of transcendent objects; it has no other being. Yet—and this is the crucial point—it does not thereby collapse into the in-itself: it remains distinct from its intentional objects, and in a special way. Consciousness is not distinct from its objects in the way the inkwell is distinct from the table, since the being of these things is independent and the relation in which they stand external. Rather, consciousness stands off from the in-itself as a kind of pure emptiness, whose concrete being, such as it is, is exhausted by the objects it cannot but intend. Sartre characterizes the structure of intentionality, and thereby of consciousness itself, by saying that the relation incorporates a kind of

negation: consciousness is at a distance from its objects by *not* being those objects, and at the same time what is intended constitutes all that is *positive* in the being of consciousness. Sartre is thus able to conclude that, in virtue of the structure of intentionality, the being of consciousness consists in its unalloyed negativity, i.e. its intrinsic nothingness. The directedness of consciousness is then not the directedness of any *thing*, since that would have to be an in-itself and hence an object for consciousness. So this evacuation of consciousness does not stop at ordinary objects of perception or memory; it includes one's character, past, body, and even one's ego, which for Sartre (unlike Husserl) is intelligible only as an object of consciousness, not as its immanent unifying and constitutive essence. In general, nothing that is an *object* of consciousness can be *within* consciousness. As a result of this nothingness, says Sartre, we are apt to apprehend small pockets of negativity in the world. This occurs in the attitude of questioning and is revealed in the experience of *lack*, which characterizes human reality; the phenomenon is most famously illustrated by the example of the expectant man apprehending the *absence* of Pierre in the café. Sartre's contention is that consciousness of negation, which is integral to human experience, is possible only on the ground of the nothingness of consciousness itself.

But consciousness is not only engaged in the world by virtue of its intentionality and correlative nothingness; it is further distinguished from the in-itself by possessing the characteristic of *selfconsciousness*. Consciousness is thus a being, as Sartre says, that exists for itself. The primary mode of selfconsciousness is what Sartre calls

'prereflective' selfconsciousness, i.e. the awareness of its own directedness on to transcendent beings. It is important to Sartre that the structure of this primitive selfconsciousness does not recapitulate within consciousness the intentional relation: there is not, between consciousness and itself, the kind of distance that separates consciousness from the in-itself. For if there were, consciousness, in taking itself as object, would be selftranscendent; which is impossible. Prereflective consciousness is what Sartre calls 'nonpositional' selfawareness. Indeed, if this selfconsciousness were positional there would be the threat of an infinite regress, since the positing consciousness must always be transparent to itself. Consciousness is, paradoxically enough, entirely coterminous with itself, yet at a kind of distance from itself: there is, in Sartre's phrase, an 'impalpable fissure' within consciousness. This characteristic of selfconsciousness implies that whatever is a property of consciousness is a conscious property of it. Sartre's thesis now is that the properties of consciousness which are thus revealed to consciousness are not tolerable to it, and that we seek, by a variety of stratagems, to conceal these properties from ourselves. (Some of these conditions of consciousness appear also on the reflective plane, which is to say the kind of selfconsciousness that is genuinely positional, as when we take up the stance of another with respect to our own being.) We can now formulate and locate Sartre's conception of freedom: freedom is precisely the nothingness of consciousness as it stands off from its objects. Specifically, one's character or past or body—what Sartre calls one's *facticity*—transcend one's consciousness of them, and are symmetrically transcended by consciousness.

Choice consists in exploiting this distance in the formation of projects: the for-itself has possibilities because it *is not* its facticity. Imagining and questioning and doubting thus become models of human freedom. But, according to Sartre, consciousness is appalled by its freedom; it is therefore appalled

at its own being, which is nothingness. The outcome is that consciousness tries to conceal its own nothingness from itself by denying its freedom: this is the condition of *bad faith*. Bad faith is, however, doomed to failure because of the principle that what is true of consciousness is consciously true of it: there is thus no escaping the anguish that is

Page 695

consciousness of freedom. Moreover, in so far as bad faith represents the aspiration of the for-itself to become an in-itself, it characterizes the attitude of *sincerity* as well as the attitude of refusing to acknowledge to oneself what in fact one is. In both cases bad faith consists in a denial of freedom, either by conceiving of one's choices as externally determined or by trying to collapse the transcendent for-itself into its facticity, as with sincerity. We refuse to acknowledge our actions as our own by trading upon our transcendence from them, or we represent them as inevitable by denying this transcendence. And behind this mode of conduct is the basic structure of intentionality, now taking facticity as object. Good faith would be an undistorted conception of the relation between free consciousness and all that one *is* in the way of body, character, actions, past, and so forth.

In addition to the in-itself and the for-itself, Sartre discloses, by attending to the structures of consciousness, a third category of being, namely 'being-for-others'. So far, consciousness has been characterized as a pure point of view on the world, rather than as an item within it; but the revealed existence of other consciousnesses alters this solipsistic picture radically. The body has hitherto been considered as *my* body, as it is lived by me; but it is also the medium through which I exist for the other, and the same is true of other facets of my facticity. According to Sartre, consciousness takes on the structure of being-for-the other—it becomes an object *in* the world—when it is subjected, via the body, to the *look* of the other. In experiencing the look I can establish a new relation to myself, as in the attitude of *shame*: I am ashamed of myself as I appear to the other, and my body mediates for me the formation of this attitude. (It is to be noted that, for Sartre, the primary mode of recognition of others is affective, not cognitive: it is not a relation of knowledge.) In being-for-others consciousness presents itself to itself as an object in the field of another subjectivity, and this on the prereflective plane. The fundamental character of interpersonal relations is thus a confrontation of freedoms, which Sartre sees as generating relations of *conflict*. As with bad faith, this arises from an inherently unstable oscillation between freedom and facticity. Thus, for Sartre, the basic modes of human relationship embody self-defeating projects. Love, he says, is the wish to possess the other's freedom, for the other to be freely enslaved; but this is not possible, so the project of love is futile. Similarly the conducts of *sadism* and *masochism* involve, in their different ways, the possession or appropriation of a freedom: but in the end the possession self-defeatingly implies an exercise of freedom. In sex, too, the aim is to induce the identification of the other with his or her body; but the being of the other, as an incarnated consciousness, cannot but transcend the facticity that invades the desiring consciousness.

What is not clear in all this is whether Sartre thinks that his bleak and pessimistic account of human relations is essential to them or whether, like bad faith, they are conditions of consciousness from which we might conceivably be liberated. It does not seem, at any rate, that they issue from the constitutive structure of consciousness as it relates to the subjectivity of others.

It is important to bear in mind, in coming to grips with *L'être et le néant*, that Sartre's philosophy

does not take the form of a series of unconnected but insightful commentaries on the human condition; it consists, rather, of a systematically articulated body of doctrine, ostensibly derived from certain basic tenets of phenomenological ontology, and is to be evaluated as such. In particular, one should be aware that familiar terms—'freedom', 'shame', 'nothingness', 'anguish', etc.—

are employed with a specific theoretical content which can only be grasped by coming at the work as an organized whole. Nor should such paradoxical-seeming dicta as 'the being of the for-itself is defined as being what it is not and not being what it is' be taken at face value, but should be construed as dramatic expressions of thoughts whose meaning, often relatively sober, can only be grasped in context.

Next to *L'être et le néant*, Sartre's main philosophical works are *La transcendance de l'ego* (1936); *L'imagination* (1936); *Esquisse d'une théorie des émotions* (1939); *La Critique de la raison dialectique* (1960). Arthur C. Danto, *Jean-Paul Sartre* (1975) contains a bibliography of English translations of Sartre's works.

C.M.

SCANNING. Used loosely, this word is sometimes used to describe the searching movements of the eyes, but a usefully restricted technical sense is conveying information by movement (as of the flying spot in a television camera and a corresponding electron beam in the receiver) down a single channel. The receptors of the eyes, the ears, and the skin are parallel channels and do not employ scanning in this technical sense. There is, however, a creature with a single channel scanning eye—a copepod, *Copilia quadrata*. See SACCADDES.

SCANNING OF THE BRAIN. SEE IMAGES OF THE BRAIN IN ACTION.

SCHEMAS. In walking down the street with a friend, one simultaneously engages in at least five movement processes: walking (including maintaining posture), breathing, talking, gesticulating, and scanning the shop windows and passersby. But each of these processes involves the cooperation of multiple processes: for example, stepping is determined *inter alia* by high-level route-selection processes ('turn left at the town hall'), visual*feedback about the location of obstacles, and tactile feedback from the soles of the feet. And each of these in turn requires activity in a neural network linking an array of receptors with an array of motor neurones.

These behaviours involve not only 'externally directed' movement, but also a variety of 'exploratory' movements that help update an 'internal model of the world' (Fraiberg, 1943). In a new situation, we can recognize that familiar things are in new relationships, and use our knowledge of those individual things and our perception of those relationships to guide our behaviour on that occasion. It thus seems reasonable to posit that the 'internal model of the world' must be built of units which correspond, roughly, to domains of interaction—a phrase carefully chosen to include objects in the usual sense, but to include many other things besides, from some attentionriveting detail of an object all the way up to some sophisticated domain of social or linguistic interaction for purposeful beings. We shall use the word

'schema' to correspond to the unit of knowledge—the internal representation of a domain of interaction—within the brain.

The intelligent organism does not so much respond to stimuli as select information that will help it achieve current goals—though a well designed or evolved system will certainly need to take appropriate account of unexpected changes in its environment. To a first approximation, then, planning is the process whereby the system combines an array of relevant knowledge, to determine a course of action suited to current goals. In its fullest subtlety, planning can involve the refinement of knowledge structures and goal structures, as well as action *per se*. While an animal may perceive many aspects of its environment, only a few of these can at any time become the primary locus of interaction.

In general, our thesis is that*perception of an object (at least at the preverbal level) involves gaining access to routines for interaction with it, but does not necessarily involve execution of even one of these subroutines. Our image for the control of the ensuing behaviour is contextdependent interpretation (in the sense described in PROGRAMS AND PLANNING), in that new inputs (such as coming upon an unexpected obstacle) can alter the elaboration of the highlevel structures into lowerlevel tests and actions which in turn call upon the interaction of motor and sensory systems. We study programs which are part of the internal state of the system prior to action, and which can flexibly guide that action in terms of internal goals or drives and external circumstances.

To better appreciate the intimate relation between perception and action, consider the *perceptual cycle* (Neisser, 1976). The subject actively explores the visual world—for example, by moving eyes, head, or body (or manipulating the environment). Exploration is directed by anticipatory schemas, which Neisser defines as plans for perceptual action as well as readiness for particular kinds of optical structure. The information thus picked up modifies the perceiver's anticipations of certain kinds of information which—thus modified—direct further exploration and become ready for more information. For example, to tell whether or not any coffee is left in a cup we may reach out and tilt the cup to make the interior visible, and keep tilting the cup further and further as we fail to see any coffee, until we either see the coffee at last or conclude that the cup is empty.

Head and Holmes (1911) were perhaps the first to study systematically patients' perceptions of the spatial aspects of their own bodies. They referred to the basis of this perception as the 'postural schema'. This integrated representation of prior movements was held to be updated by each change of position, and to provide a postural model into which all incoming sensations might be integrated. F.

C.*Bartlett (1932), who had been much influenced by H.*Head, introduced the term 'schema'

into the psychological literature in the sense of an active organization of past reactions, or of past experiences, which must always be supposed to be operating in any welladapted organic response. With this, the emphasis shifts from the postural frame to cognitive aspects as revealed in Bartlett's memory experiments.

Workers in*artificial intelligence organize their schemata for 'understanding', separating the problem of sensory representation from that of directing action (see Bobrow and Collins, 1975, for a sampling of approaches). Minsky (1975) has advanced his concept of 'frames' as a unification of these studies. Here, the stress on recognition of overall contexts which subsume the particularities of the current situation complements the schemaassemblage emphasis on the building up of a representation from familiar subparts.

Neisser (1976), influenced by Gibson, takes a holistic approach with little *concern* for mechanism and with the schema usually viewed as corresponding to a total situation rather than some localized element of it. He takes explicit account only of those actions which are directed to sampling sensory data. Neisser's use of schema seems to be that of Bartlett, augmented by the Gibsonian view of information pickup and the resultant stress on the perceptual cycle discussed above.

Another root of the use of 'schema' in current psychology is found in the work of Jean*Piaget. The Piagetian schema is the internal representation of some generalized class of situations, enabling the organism to act in a coordinated fashion over a whole range of analogous situations. Reviewing his approach to the genesis and development of knowledge, Piaget (1971) relates his schemas to the innate releasing mechanisms of the ethologists and thus, via Konrad Lorenz, to the schemata of*Kant in the *Critique of Pure Reason* (1787). Yet Oldfield and Zangwill (1942) assert that the HeadBartlett concept of schema has no connection with that of Kant!

The concept of schema has also developed a special meaning in the motor skills literature—for instance, in the work of R. A. Schmidt. Schmidt's schemas seem suited to the performance of a single motion in the laboratory or in sports (such as

Page 697

swinging a bat) rather than to a complex manipulation or to goaloriented performance in a dynamic environment. Each such schema is broken into two parts: The *recall schema* seems akin to feedforward (cf. Fig. 2 in FEEDBACK AND FEEDFORWARD), being responsible for the complete control of a rapid movement, even though environmental feedback may later signal errors. The *recognition schema* is responsible for the evaluation of responseproduced feedback that makes possible the generation of error information about the movement. It thus seems to combine online feedback and identification procedures which may operate even after a movement is completed to better tune the schema for its next activation.

SCHIZOPHRENIA. Towards the end of the nineteenth century Emil*Kraepelin suggested that most of the variegated forms of insanity familiar to his contemporaries were manifestations of two major disorders, which he named *dementia praecox* and manicdepressive insanity. His claim was based on a meticulous study of large numbers of patients followed for many years and it had a profound effect on the subsequent development of psychiatry. *Dementia praecox* was a progressive illness which started in adolescence or early adult life and followed an inexorable downhill course; recovery, if it occurred at all, was always incomplete. Manicdepressive insanity, on the other hand, was a phasic illness. Although in the course of a lifetime a patient might have several episodes, and spend many years in hospital, individual episodes always ended in recovery and full restoration of the previous personality. The term schizophrenia, meaning 'split mind', was coined by Eugen*Bleuler, the medical director of the Burgholzli Hospital in Zurich, during the period of ferment that followed this seminal innovation. Bleuler's schizophrenia was an expansion and elaboration of Kraepelin's *dementia praecox* and he believed that its protean manifestations were due to a 'splitting', or loss of coordination, between different psychic functions, particularly between the cognitive (intellectual) and conative (emotional) aspects of the personality. The monograph he published in 1911 was so influential that within a generation Kraepelin's original terminology was forgotten, and for the last

fifty years schizophrenia has been recognized throughout the world as the most important single cause of chronic psychiatric disability.

The subjective experiences and observable alterations in behaviour which characterize schizophrenia are both very variable; but there is a central core of symptoms which, though occasionally seen in the presence of brain disease of various kinds, are in practice highly specific. The subject ceases to experience his mental processes and his will as under his own control; he may insist that thoughts are being put into his mind or removed from it by some alien force, or suspect that he is being hypnotized. He hears voices telling him what to do, commenting on or repeating his thoughts, discussing him between themselves, or threatening to kill him. In the acute stages of the illness other*hallucinations and*delusions of varied kinds may be present. His thought processes also develop a characteristic vagueness and illogicality. At first he simply keeps wandering off the point, but in some chronic patients there eventually ceases to be any logical connection between one idea, or phrase, and the next; so their speech becomes almost incomprehensible. Although*intelligence and*memory remain relatively intact, the whole personality is affected by the illness.

Above all, the patient loses his vivacity and drive; he loses his interest in and capacity to respond emotionally to other people; and he becomes increasingly more apathetic, eccentric, and isolated.

Schizophrenia is a relatively common condition, affecting nearly 1 per cent of the population. Although its onset is usually in adolescence or early adult life, it may develop in childhood, or be delayed until middle age or even later. There is no good evidence that its incidence has changed in the past 150 years, and it occurs in much the same forms and with much the same frequency throughout the world, regardless of environmental differences or differences in language, creed, or social structure. Neither do wars nor other catastrophic events appear to influence its incidence. Although it is well established that some people may, even in the absence of treatment, have a single attack from which they recover completely and permanently, it is more common for a series of psychotic episodes to lead to some degree of lasting emotional impoverishment, even though the subject may still be capable of supporting himself and earning his living.

Of all mental illnesses schizophrenia is the most feared, and the most fascinating, and it is the model for the layman's concept of madness. It causes Page 698

great suffering, not only to the patients whose lives and personalities it slowly destroys but also to their families, and its high incidence and chronicity make it a greater burden on health services than any other single illness. The fears and frustrations it engenders are also a fertile breedingground for worthless treatments and fanciful theories of causation. In the last twenty years there have been claims that schizophrenia can be cured with novel forms of*psychotherapy, by special diets, and by massive doses of vitamin B. Others have asserted that it is not an illness at all. To R. D. Laing it is the only rational way of coming to terms with an insane world (see LAINO'S UNDERSTANDING OF INTERPERSONAL EXPERIENCE); to some sociologists it is merely a convenient label used by society for coping with troublesome deviants; to Thomas Szasz (*Schizophrenia. The Sacred symbol of psychiatry*, 1979) it simply 'does not exist'.

Despite much research, the cause or causes of schizophrenia remain elusive and no specific neuropathology has ever been identified. It is well established that the lateral ventricles of the brain are often modestly enlarged, but it is still unclear whether this is a direct manifestation of the disease process, or merely a predisposing factor. It has also been established, by postmortem studies, that the number of dopamine receptors in parts of the basal ganglia of the brain is increased in chronic schizophrenia, but again it is uncertain whether this is a fundamental abnormality or a secondary consequence of neuroleptic treatment. Psychological and psychophysiological researches have not been any more successful, though it is clear that the eye movements of schizophrenics are abnormal, and also that there is often a disturbance in the distribution of functions between the two cerebral hemispheres. There is also evidence to suggest that schizophrenics have difficulty processing incoming information, both auditory and visual; they find it hard to distinguish the relevant from the irrelevant, and their performance on a variety of perceptual and other psychological tests differs from that of other people. But the range of variation is wide and there is always a considerable overlap between them and normal people. There is no doubt, however, that schizophrenia is, at least in part, transmitted genetically. Several studies in Europe and North America have shown not only that the illness runs in families, and that the concordance rate is consistently higher in uniovular (identical) than in binovular (nonidentical) twins, but also that the offspring of schizophrenic parents have a high risk of developing the illness even if they are separated from them soon after birth and adopted by other people. The mode of transmission remains uncertain, but is probably polygenic, like height and hypertension. (See GENETICS OF BEHAVIOUR.) There is also no doubt that environmental factors are important. Uniovular twins, being derived from a single fertilized ovum, are genetically identical, but if one of the pair develops schizophrenia, there is less than a 50:50 chance that the other will do the same, and this fact alone is proof of the importance of environmental influences.

But we have little idea what these environmental factors are, or whether they act in childhood or shortly before the onset of the illness. In the 1900s there were claims that the childhood relationship between the patient and his mother, and emotional strains within the family as a whole, were the crucial factors—that some mothers or families were so pathological that they eventually drove their children into madness. However, the few established facts in this area are all capable of alternative explanations, and it is irresponsible and heartless to suggest to a distraught parent that she is responsible for her child's illness, when there is no real evidence to that effect. There is evidence, though, that the onset of the illness is often preceded by stressful events (like being called up for military service or spurned by a girlfriend) and also evidence that relapses are commoner in schizophrenics living with relatives who nag or criticize them than in those living in more tranquil settings. So it is clear that emotional or psychological factors must be involved, directly or indirectly, in causation.

Because so little is known about its aetiology, schizophrenia has to be defined, and diagnosed, largely on clinical grounds. In consequence, as with other diagnoses which cannot be confirmed by laboratory tests, usage of the term is liable to vary from place to place. Indeed, major international differences in usage were identified in the 1960s, American and Russian psychiatrists, in particular, using the term much more freely and loosely than psychiatrists elsewhere. (It was mainly in these same two countries, and this was probably no coincidence, that psychiatrists were accused of abusing

the diagnosis and labelling as schizophrenic people who were really perfectly sane, but who were a nuisance to their families or the state, and incarcerating them in hospitals to receive treatments they did not require.) In the last decade, the adoption of unambiguous operational definitions, at least for research purposes, has reduced the confusion; though the coexistence of several alternative ways of defining the term still means that a diagnosis of schizophrenia may have a somewhat different meaning in different centres.

In the past, most schizophrenics spent most of their lives in hospital, but since the 1950s the course of the illness has been greatly improved by the discovery of the tranquillizing effects of the phenothiazines. The efficacy of these and other neuroleptic drugs, both in controlling the acute illness and in reducing the risk of relapse, is well proved and almost certainly depends on the fact that they inhibit transmission in dopaminergic neurone systems in the brain. Unfortunately, because dopaminergic neurones (i.e. brain cells which use dopamine as their transmitter substance) are also involved in the extrapyramidal motor system, these drugs are all liable to produce

troublesome restlessness in the legs (akathisia), involuntary movements (tardive dyskinesia) and*Parkinsonism as side effects. (For a more detailed discussion, see SCHIZOPHRENIA: EVIDENCE FOR AN ORGANIC CAUSE.)

There have also been important social changes in the last thirty years which have probably contributed as much to the improved outlook as these neuroleptics. Partly as a result of legal changes embodied in the Mental Health Act of 1959, partly as a result of increased public tolerance, and partly because of the growing realization by psychiatrists themselves that life in the huge asylums (which they inherited from their Victorian predecessors) increased rather than reduced the disabilities of their patients, the last two decades have seen a substantial change in policy. Instead of being allowed, or compelled, to remain in hospital as long as their illness persisted, patients are now discharged as soon as possible, and if they relapse and have to be readmitted they are discharged again as soon as their acute symptoms are controlled. In this way the evils of 'institutionalization' are avoided, and many schizophrenics who in the past would have spent forty or fifty years in an asylum are now able to live useful and even happy lives. There are times, however, when contemporary enthusiasm for 'community care' (and for closing hospitals in order to save money) is taken too far and the emotional and practical burdens which a chronic schizophrenic may place on a family are too readily overlooked. There are still situations in which the most humane course is to provide the patient with asylum from a world he can no longer comprehend or cope with. (See ASYLUMS: ARE THEY REALLY NECESSARY?)

Wing, J. (ed.) (1975). *Schizophrenia from Within*. London.

SCHIZOPHRENIA: EVIDENCE FOR AN ORGANIC CAUSE. Important recent advances in the

understanding of the neural mechanisms involved in schizophrenia have come from discoveries of the mode of action of drugs used in its treatment. Chlorpromazine has been known as an antischizophrenic drug since the mid 1950s, but not until 1963 was there a good pharmacological explanation for its action. Measuring the rate of formation and metabolism of the neurotransmitter* dopamine, it was possible to suggest that this and other clinically effective drugs block dopamine receptors in the brain. Chemically related drugs that were not clinically effective did not have this property. This suggestion was later confirmed by direct measurement of the binding of drugs to dopamine receptors. The receptor blocking property is specific to dopamine receptors at low concentrations of the drug, since other neurotransmitter receptors are not powerfully blocked, and even closely related receptors (e.g. noradrenaline receptors) are not sensitive to the drug. In addition, the potency of these drugs as blockers of dopamine receptors closely parallels their clinical potency. Thus it seems that brain areas innervated by dopamine neurones are the main sites of the clinically effective actions of antipsychotic drugs. Of course, dopamine neurones, by means of their high degree of connectivity with other neural systems, are not the only ones involved in schizophrenia, but it does seem that they form an active link in the neural circuitry necessary for this condition.

The involvement of dopamine neurones is also suggested by evidence that two drugs which increase the release of brain dopamine, amphetamine and levodopa, may worsen schizophrenic symptoms; and that amphetamines may produce a condition, in previously healthy volunteers, that is indistinguishable from acute paranoid schizophrenia.

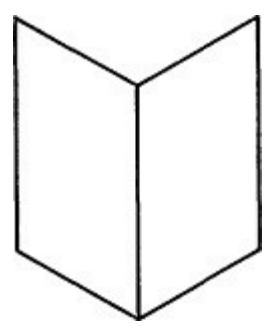

Although the pharmacological evidence for understanding schizophrenia in this way is encouraging, direct evidence from postmortem schizophrenic brain tissue is less so. The technical difficulties of studying transmitter chemistry in poorly preserved tissue are formidable and render interpretation of results very difficult. Most evidence has been unable to demonstrate clear abnormalities in dopaminergic function, partly because of the difficulty of excluding treatment-induced changes. However, some evidence does suggest that the amygdala (a phylogenetically ancient part of the brain buried deep in the temporal lobe) contains abnormal quantities of dopamine in schizophrenics. Since the amygdala is closely related to the temporal lobe cortex and the symptoms of temporal lobe epilepsy closely resemble some schizophrenic symptoms, this finding is of some interest.

The general problem of how to determine which of the many brain dopaminergic systems may be disturbed has been given a new perspective by recent neuropathological and brain scan techniques. These appear to show atrophic change in brainstem structures, in the periventricular system: the thalamus, basal forebrain, and temporal lobe (amygdala and hippocampal region). Further progress in understanding this condition will hardly be possible until there is a clearer understanding of precisely how these brain areas are connected, and how these connections underlie normal brain function.

O. T. P.

SCHOPENHAUER, ARTHUR (1788-1860). German philosopher, born at Danzig, now Gdansk. His father was a banker and his mother a novelist. He was educated at Göttingen and Berlin, where he became *privatdocent*. As a challenge, he held his lectures at the same time as*Hegel, but without success. He retired to Frankfurt-on-Main as a lonely and unloved bachelor, befriended only by his

poodle Atma, 'World Soul'. He was a personal and professional pessimist. He held a subjective idealism that the world is a personal fantasy, while will is primary as creating (subjective) reality. He is

Page 700

thus a kind of solipsist. His main book is *The World as Will and Idea* (1819).

SENSATIONALISM. See CONDILLAC, ÉTIENNE DE.

SENSATIONS. Traditionally*perceptions have been thought of as made of sensations: sensations such as colours, touches, smells, and sounds being accepted as

'bricks' of which perceptions are made. Hence the now somewhat outofdate term*'sensedata'. But now we generally think of physical*stimuli at the organs of sense (the eyes and ears, and so on) or the neural *signals* from the sense organs as the data of perception. This change of thinking is from regarding sensations such as colours as being in the world of external objects and detected by the senses, rather than as being generated by the brain, or produced in the mind. Sir Isaac*Newton contributed the important notion that light itself is not coloured, but that the sensations of colours are generated in us, according to what sort of light strikes the eyes.

Some regions of the brain have been identified as specially important for various sensations; but just how, or indeed why, certain brain activities in critical regions produce sensations remains mysterious. It is not even clear that sensations are necessary for perception, at least as perception is defined behaviourally by recognizing and handling objects. And as an object is differently identified, so sensations of colour or brightness may change. So perception is not simply built up of 'brick'like sensations, as sensation bricks are modified and even entirely created by what objects are (correctly or not) identified. Effects of perception on sensation were appreciated by Ernst*Mach, whose book translated as *The Analysis of the Sensations* (1897) remains interesting and important. Mach pointed out that the seen brightness of a surface may change, in ambiguous figures, when the surface 'flips' in depth though there is no change in the stimulus, as is seen in Fig. 1.

This effect appears dramatically with a card bent to this kind of shape. In general, when a region is accepted or is likely to be a shadow, it looks lighter than when seen as a surface. This shows that sensations such as brightness and colour are not

Fig. 1.

Mach figure.

simply given by stimulation of the eye, or the other sense organs, but may be drastically changed and enriched by 'higher level' perceptual processes. A most dramatic example of this is Edwin Land's demonstrations of a rich variety of colours given by only two colours, by combining a pair of otherwise identical photographs, one taken, for example, with a green filter and the other with a red filter, and projected with the same filters. This can be done even with one picture unfiltered (white) and the other with a red filter—when greens, blues, and many other colours are seen. Another dramatic example is the appearance of illusory surfaces and contours, which seem to be created perceptually, as postulated nearer masking objects, to account for surprising gaps when the gaps are likely object shapes. The best known examples are due to the Italian psychologist Gaetano Kanizsa (1979). (See ILLUSIONS.)

Because sensations are essentially private, we have no way of knowing how the world appears to other people. Thus, strictly speaking, we have no way of knowing whether their 'red' is our red—which may bother painters. At least for some colourblind people it may well be that sensations are individually different, and surely (if they are conscious) bats must have sensations very different from any of ours when detecting objects by sound-ranging. These issues are explored most imaginatively in philosophical papers collected by Hofstadter and Dennett (1981).

Having said that strictly speaking we cannot know another person's sensations, it may seem impossible to *measure* sensations. There have however been many attempts to relate stimuli to sensation in quantitative ways, following the pioneer work of *Fechner and *Weber. Fechner measured the smallest difference of stimulus intensities that could be discriminated, and with a mathematical treatment he tried to derive measures of sensations. This involved certain assumptions which are very difficult to justify, but the approach remains of great interest (see PSYCHOPHYSICS). Also interesting are attempts to 'scale' sensory dimensions. Thus, for example, if there were two lights one brighter than the other, how would one set the intensity of a third light to lie halfway between the other two? Or could a picture be said to be twice as beautiful as another? The American psychologist S. S. *Stevens spent many years trying to scale sensations and judgements of various kinds, and claimed that each psychological dimension obeys a power law, with an empirical component that differs for the various senses, or kinds of judgement being made. There are methodological difficulties in this, but again the attempts to measure aspects of mind are interesting. (See QUANTIFYING JUDGEMENTS.) A full discussion of many of these issues is given by Savage (1970).

Although sensation is ultimately mysterious, as *consciousness is mysterious, it is worth pointing out that much the same holds for *matter. If a

Page 701

physicist is asked, 'What is an electron made of?' he has no answer. Indeed he may say that it is nothing but a probability distribution, or some such. In any case he will not say that it is made of matter, for physics is concerned ultimately only with relations and not with substances. Perhaps this is so also for mind—perhaps there is no

'mind stuff'—and in any case sensations should not be thought of in such terms. The trouble is, though, the kinds of relations that have been found and that are so powerful in physics are exceedingly hard to discover or measure in psychology. Although the attempts to measure sensation are intriguing we cannot feel that they are satisfactory, so psychology remains apart from the physical sciences.

SENSEDATA. A philosophical term referring to the experience, of patches of red, heat, hardness, and so on, which have been supposed to be the data by which objects are known. This concept has given way, with increasing physiological knowledge, to the very different account that objects are signalled via patterns of received energy (*stimuli) and represented at the brain via the neural signals of action potentials. Where the *experience* or *consciousness* of sensations comes in—or what it *does*—is highly mysterious, for it no longer seems to be data. (See CONSCIOUSNESS; PERCEPTION; SENSATIONS.) **SENSORIMOTOR COORDINATION**. See SPATIAL COORDINATION OF THE SENSES.

SENSORY DEPRIVATION, EFFECTS OF. See ISOLATION EXPERIMENTS.

SET. In psychology, the intention to act in a particular way or to accept certain kinds of information. The term is linked to the concept of *attention, or attending to what may be needed in a given situation; for example, one has a set for laying the table for a meal. The set may be evoked by an external stimulus, or be selfinitiated.

SEX DIFFERENCES IN CHILDHOOD. Distinctively male and female development begins soon after conception, and the eventual degree of human sexual dimorphism exceeds that in many Primate species. The twentythird pair of chromosomes in females is XX, while in males it is XY. In the presence of the Y

chromosome, cell division of the zygote is accelerated, and the medulla of the initially bipotential embryonic gonad differentiates during the seventh week into a testis.

The secretion of androgenic hormones from the foetal testis organizes both the development of the genitalia and of the brain according to the male pattern. Female differentiation always occurs in the absence of the male hormones. Circulation of androgens *in utero* is known to increase the amount of aggressive behaviour and gross physical activity in Primates, and it is likely that these hormones predispose the human male to greater physical activity.

At birth, males are heavier and longer than females, and from the second month their calorie intake is greater; boys have a consistently higher basal metabolism than girls and greater vital capacity. However, in terms of bone age the newborn girl is equivalent to a four to six weeks old boy, and growth velocity in the boy lags about two years behind the girl. Puberty is attained roughly two and a half years later in males than in females. (See HUMAN GROWTH.) In addition to their relatively retarded postnatal physical development, males are characterized by a greater susceptibility to a variety of adverse conditions. They are more vulnerable to both postnatal and perinatal complications that can lead to death or longterm disability. In developing countries, where infant mortality rises at weaning due to intestinal complications, again it is the male who is more at risk. Throughout life, males remain more prone to a variety of diseases—respiratory, cardiac, infective, and neurological, as well as the sexlinked recessive disorders.

Thus cultural and social pressures that influence sextyped behaviours act on organisms which, biologically at least, are distinctively male or female. A crucial issue for psychologists is the extent to which these different biological substrata may predispose males and females to different abilities or behaviours. Male and female babies do behave differently—boys are more restless than girls. They are also treated differently by those who care for them; it is therefore difficult to disentangle the relative influences of socialization and biological predisposition. It is none the less illuminating to document cultural influences on behaviour and to speculate upon their possible effects on sex differences.

In the early months of life boys tend to be handled more than girls, but newborn girls are spoken to and smiled at more during feeding sessions. These differences in caregiving behaviour have been attributed to the babies' differential responsiveness, and it is important to stress that any adult/infant interaction is a two-way process, and depends on far more than the adult's perception of the infant's sex. A recent comprehensive review of parental behaviour in laboratory studies concludes that there is 'a remarkable degree of uniformity in the socialization of the two sexes'.

Page 702

Against this finding, though, stands evidence from observations of a more general nature. Consider, for example, a study of 96 middleclass homes—in the 48 boys'

rooms there were 375 vehicles, whereas in the 48 girls' rooms there were only 17; over half the girls possessed a baby doll, compared to just 3 of the boys. In general, the boys' rooms contained more educational materials and more sports equipment than the girls' rooms. The agents of socialization are, evidently, insidious.

Books and television are also factors which can strongly influence children's perceptions of sexappropriate behaviours. In a study of children's literature, it was found that most children's books were about boys, men, and male animals; in nearly onethird of the books which won literature prizes (over a fiveyear period) there were no women at all. Boys were portrayed as active and adventuresome, girls as passive and immobile. This highly exaggerated presentation of sexstereotypes is repeated in the medium of television, where females are very much in the minority. Males are portrayed as aggressive, constructive, and helpful; females as deferential and passive.

Despite the restricted range of female roles presented by the media, adults appear to tolerate a wider range of behaviour from girls than from boys—thus, whereas it is perfectly acceptable for a girl's behaviour to be tomboyish, a boy who engages in female typical behaviour would be labelled with the more pejorative term 'cissy'.

None the less, the preferred play activities of boys and girls are very different: boys play more outside, they are more physically active, and they play less with dolls.

Parents tend to allow boys of school age greater freedom to roam the local neighbourhood and are more likely to encourage girls to stay at home. Investigators who have observed young children in playgroups and nursery schools have found that boys initiate more aggression than girls (approximately twothirds of all aggressive acts are initiated by boys) and their aggressive encounters are more prolonged than those of girls. Even before they reach school age, girls tend to be more nurturant and protective than boys, and this is evident in their increased readiness to comfort a distressed child or to help a younger child in some activity.

The evidence for sex differences in cognitive abilities is equivocal, and this may be partly due to the fact that many tests are specifically designed to ensure that groups of males and females obtain the same mean score. There are, however, two types of tests in which boys do excel: mazes of the kind frequently seen in children's comics, and Koh's blocks (where a set of coloured blocks have to be assembled to match a pattern). Both these are tests of spatial ability and reflect boys' greater facility in understanding concepts of orientation and perceptual configuration. Girls tend to use verbal strategies for solving these types of problems— though this does not affect their accuracy, it slows down their performance relative to boys and accounts for their lower scores. More boys than girls have reading difficulties, and it has been thought that this is due to relatively poor language ability; it is now considered more likely that there is no sex difference in general language abilities, but that boys'

greater restlessness at school makes them more difficult to teach! In studies of arithmetical ability, boys have usually achieved slightly better scores than girls; however, it has recently been shown that girls perform better when the problems are phrased in terms of 'female' objects (such as dolls and clothes) than they do when the same arithmetical computations are phrased in terms of 'male' objects (such as rockets and cars).

It is known that in adult males the right hemisphere of the brain is specialized for visuospatial skills, whereas the left hemisphere is specialized for language skills. Thus, if a male adult sustains damage

to the left side of the brain his language ability will be impaired. In adult females there appears to be language representation in both hemispheres, and damage to the left hemisphere does not have such a profound effect as it does for the males. These sex differences in lateralization develop during childhood years, and the superior performance of boys on tests of visuospatial skills has been attributed to the earlier specialization of the right hemisphere for these abilities.

The fact that boys show a slight but consistent advantage in visuospatial abilities is insufficient to account for their vastly superior performance in science subjects during adolescence. It is well established that visuospatial ability is correlated with mathematical ability, and it would not be unexpected to find slightly more males than females preferring to study sciencebased subjects. There is now evidence that girls' reluctance to study science is due less to their lack of ability than to the fact that they perceive science subjects as 'masculine', and therefore inappropriate to them.

In conclusion, the following four statements summarize our understanding of psychological sex differences in childhood: (i) There are biological sex differences which predispose males and females to some behavioural differences. (ii) Caregivers respond differentially to males and to females, but these responses are to the child's behaviour rather than to his or her sex. (iii) There are sex differences in brain organization, but it is not established beyond doubt that these are related to sex differences in intellectual ability. (iv) Cultural influences act to persuade children to conform to sexstereotyped expectations.

The overwhelming importance of cultural influences in shaping sextyped behaviour is evidenced by data from studies of cultures where male and female sexroles are characterized quite differently from those in our own culture. The biological dichotomy of the sexes should not be seen as necessarily implying an equally rigid dichotomy of abilities and behaviour; it would none the less be unhelpful to deny that biological

differences will interact with environmental influences.

SEXUAL DEVELOPMENT. Human sexual development has been described as the last frontier of psychological knowledge. Until quite recently it has been a subject surrounded in myth. Popularized Freudian concepts of the repressed libidinous forces of the id have fuelled the kinds of fantasies that have discouraged serious research. Only the cumulative influence of*Freud (1905), Kinsey and his colleagues (1948, 1953), and Masters and Johnson (1966, 1970), in building up a coherent body of clinical, sociological, and scientific knowledge over the course of the larger part of a century, has at last established a climate of opinion in which sexual function and development have been widely

accepted in the scientific community as a proper area of systematic research.

Medical science has traditionally concentrated on the processes connected with birth and the diseases surrounding venery. It is the psychological and sociological sciences that have considered the totality of human sexual experience, and thereby established a core around which physiological and anatomical knowledge about sexual function can be set in its place. Such has been the development in recent years that the mainstream psychiatric view, expressed by MayerGross, Slater, and Roth in 1969—'. . . a sexual activity is usually regarded as perverse if it has no immediate connection with reproduction, and still more so if it tends to lead to a sexual activity which could replace reproduction'—is no longer supportable. Sexual activity is now seen as a multiply functional part of human potential, in which the intention to reproduce is one among a number of valid intentions, such as pleasure, or the deepening of a bonding relationship, which the sexual act may properly subserve.

As a body of knowledge becomes established, so its operational concepts become increasingly elaborated. What was previously selfevident becomes redefined. That the study of human sexual development has reached this phase is perhaps best exemplified by considering first the biological basis of sexual development and then its psychological basis. It will be seen that the psychological, especially in regard to the development of male and female identity, intrudes continuously upon the biological as the means of making sense of it.

The simple idea that male and female is an unvarying dichotomy, from which much else springs, has been observed by Haeberle (1978, to whose thoughtful writing this contributor is happy to acknowledge an especial debt) to be more complicated than the Latin root of sex (*secare*: to cut, divide, or separate) implies. At least seven different factors have to be taken into account.

In the first place is *chromosomal sex*. The male body cells contain one X and one Y chromosome, whereas female cells contain two X chromosomes. Recently other combinations have been recorded, at least one of which (XYY) may be linked to severe aggressive tendencies. Nevertheless, chromosomal sex appears to be the most basic distinction between male and female.

Secondly, there is *gonadal sex*. The male's testicles and the female's ovaries are their primary anatomical sexual characteristics, but in rare cases tissues of both may occur in the same body.

Thirdly, *hormonal sex*—the balance of the androgens and oestrogens—which starts sex differentiation in the second month of foetal life, and continues through puberty and adult sexual maturity to old age, affecting all stages of growth and differentiation, has a wide range of characteristics of its own. The balance considerably affects essential sexlinked physical features during maturation, such as body shape and hair distribution, as well as controlling the reproductive process.

Fourthly, the *anatomical structures of reproduction* in the male and female may be less than fully developed, giving rise to variations of sexual classification.

Fifthly, the *external sex organs* may in some instances be missing, malformed, or inappropriate to

chromosomal sex. Thus a child with the chromosomal structure of a male may be brought up as a female, the absence of a penis at birth giving rise to the assumption that a girl child has been delivered. There is evidence that the presence or absence of a penis is the most marked sign upon which sex is assigned to a child, with considerable social consequences.

Whether or not there is anatomical cause, a child of one sex may be reared as a child of the opposite sex, so that the *gender* or *social role* normally assigned to one sex is transferred, usually by parental influence. Instances are recorded in which early traumatic loss of the penis, through surgical accident for instance, have resulted in a child male by all usual tests being brought up as a female.

Finally, and in seventh place, but by no means least, the individual may assume a *gender identity* other than the gender role assigned during early development. In cases of transsexualism, for instance, the gender identity a person wishes to assume is the opposite of the gender role that has been assigned socially. Sex reassignment surgery may change the anatomical structures very successfully, creating a functioning penis or lubricating vagina, but the individual who encourages psychiatrist and surgeon to cooperate in such a process of elective change cannot change the chromosomal identity of their sex, which has usually been that of their gender role up to the point of reassignment surgery.

For the vast majority of individuals there is no conflict in any of these variables. The XY male has functional testicles, the appropriate hormonal

balance of androgen and pituitary hormones, adequate reproductive mechanisms, an apparent penis responsive to sexual stimulation, is raised as a male, and feels himself to be such as he moves through adolescence into adult life. *Per contra* the female. The complexity of that apparent normality, however, and its dependence upon hormone production at the critical time, masterminded, as it were, by the pituitary, is a cause for marvel as hormone assay methods become increasingly refined.

It should perhaps be recorded in passing that, embryologically, all human life is female. In the first month of uterine existence the embryo is sexually undifferentiated.

Towards the end of the second month testosterone in the potentially male embryo begins to circulate, which causes the gonads that would otherwise have grown into ovaries to become testicles, and the penis and scrotum to form from the tissue that in the woman remains the clitoris, vagina, and labia of the genital structures.

Given this physiochemical developmental process, which by birth is usually responsible for clearly differentiated male and female sexual organs as the *primary sexual characteristics*, two other stages of development can be observed.

Hormonal influences produce the *secondary sexual characteristics* of puberty, confirming the maleness or femaleness of the individual in varying degrees by varying emphasis on anatomical structures. Fifteen secondary sexual characteristics have been noted, ranging from differences between the sexes in body hair distribution, shape of breasts, and muscular size, to the carrying angle of the arm and leg, which in the male is straight and in the female forms an angle at the elbow and the

knee.

Finally, *tertiary sexual characteristics* are those gender role qualities of being masculine and feminine that cultural or subcultural conditioning emphasizes as appropriate to one sex or the other. It is clearly in the area of tertiary characteristics that there is most room for change, as the primary and secondary are physiologically determined whereas the tertiary are determined by sociopsychological forces. The feminist movement, which has arisen in part from the separation of the sexual and reproductive processes in consequence of reliable contraception, and advances in medical technology such as artificial insemination, is an excellent example of a social process that has a profound effect upon tertiary sexual characteristics.

Tertiary characteristics are of course, always influenced by the family subculture and the larger social context of an individual's growth. It might be assumed that the gender roles of men and women would change only slowly; or, conversely, be changed quickly only by violent or radical means, because of their very fundamental purpose in the identity-stabilizing process of the sequence of the generations. (The psychological theories of *transactional analysis*, as developed by Berne and his followers (e.g. Harris, 1970), describe especially the means by which the wisdom, or prejudices, of the generations is transmitted onwards and received.) The involvement of women in the combat forces of many countries is a particular example of a radical process shifting tertiary characteristics suddenly and widely.

As with the gradual and sequential development of the physical sexual characteristics, so the psychological and social tertiary characteristics are established over many years. In reviewing this process, Haeberle (1978) observes that '... the realization that adult human sexual behaviour results from a long, complex, and often hazardous development is relatively new'. While sex may be perfectly natural, it is clear that it is not always naturally perfect. The Freudian challenge of the early twentieth century begins this clarification.

In traditional psychoanalytic thinking, the three phases of early and infantile sexual development (oral, anal, and phallic) are more or less successfully passed through and repressed until, after the quiescent period before puberty, puberty itself provokes the awakening of early adolescent sexual urges, which may or may not attach themselves to appropriately mature heterosexual relationships and behaviours. This process of attachment depends upon whether early fixation at one of the infantile stages has taken place, or whether those erotic stages have been integrated; and also upon how the child's attachment to its parent of the opposite sex (the resolution of the so-called *Oedipus or *Electra complexes) has been managed.

Cultural variations in these processes, described by anthropologists from Margaret Mead onwards, suggested that the Freudian view was not universally appropriate.

In considering the tertiary aspects of sexual development, it is now widely accepted that cultural influences are both significant and variable. The work of Money at Johns Hopkins (Money and Green, 1969), as well as that of Kinsey, and Masters and Johnson, can be held to provide firm support for this view.

In the end, it is the sum of the biological processes and the development of gender role and identity, in whatever circumstances that takes place, that results in sexual orientation—whether this be heterosexual, homosexual, bisexual, or object-related as in fetishistic behaviours.

In a society that can reconsider longheld aversions to some sexual behaviours—such as admitting that homosexual behaviour can be the basis for both pleasure and longterm relationships—questions of what is normal or abnormal inevitably arise. Such questions have particular relevance for those concerned in an educative or clinical way with the developmental process. As the boundaries alter, so moral and ethical questioning properly arises too. In such circumstances, what are clearly in a developmental sense aberrant behaviours need specifying clearly. In the current state of knowledge it is possible to state without fear of informed

contradiction that sexual practices between adults and children (paedophilia) are harmful to the development of children; and that any sexual acts which seek to expose another person unwillingly to the demands of a close aggressor (rape) or more distant aggressor (the *frotteur* or the exhibitionist) do physical and/or psychological violence of a personally intrusive kind that a mature society finds reprehensible. The open sale of pornographic material might come under such a rubric. In addition there are clearly some sexual behaviours, such as the sadomasochistic, which, in their more extreme forms, contain elements of violence that would lead them to be considered symptomatic of a disturbed personality. However, the range of sexual behaviours which are now tolerated and openly advocated (see Comfort, 1974) includes mild degrees of fetishism and sadomasochism. The question of when the normal becomes the abnormal is difficult to resolve in principle, but in specific cases can reasonably easily be determined by a skilled enquiry into the total sexual value system of an individual or partnership. As clinical dependence upon alcohol is considerably distant from the majority of alcohol users, who have personality structures sufficiently robust to be able to enjoy its disinhibiting effects yet control the limits of the experience, so if a person's generally preferred sexual behaviours involve no compulsive quality, and if no manifest physical or psychological harm results to the individuals involved, then such behaviours should be classed as proper and within the realm of private and responsible action.

It is apparent from the above that in considering matters of human sexual development it is not possible to ignore the maturation, or regression, of the society in which the development takes place.

Since Freud drew attention to infantile sexual development, the broad acceptance of such development as natural and proper has become firmly established, even if all the psychoanalytical assumptions deriving from it are not so firmly accepted. Infant boys will have spontaneous erections, and infant girls the equivalent in vaginal lubrication. General body and specifically genital exploration and stimulation is now happily recognized as establishing later adult comfort with sexual matters. The untoward effects of inhibiting such exploration and its consequent discoveries are more strongly acknowledged than was even quite recently the case.

By and large the explorations of the child are sensually diffuse rather than erotically specific, though well before the onset of puberty both boys and girls may masturbate to some kind of orgasmic experience without there being, in the boy, any ejaculatory consequences. Masturbation is itself now

recognized as a valid sexual experience throughout the whole lifespan, and the nineteenth-century horrors with which it was invested are rapidly fading from popular culture. (It might be noted in passing that this statement refers to Western cultures, and even so would not be true of many countries of southern Europe where there is a specifically Catholic cultural tradition. In many Third World countries there are often still severe, and perhaps surgical, prohibitions against sexual activities that would be considered a natural part of the developmental process in most of northern Europe and North America).

Adolescence, started by the hormonal triggers that create the secondary sexual characteristics, is the beginning of sexual fertility. It carries the individual from childhood through to increasing separation from parents and emerging independence in the adult world. Adolescence is a period that is very variable from culture to culture, and where education is extensive it may be considerably prolonged. In the last hundred years or so in Britain, as the period of education has increased and the age of the onset of puberty has decreased, so the time between actual sexual fertility and the opportunity for independent existence in a continuing relationship of adult choice can become surprisingly long. Haeberle observes that there may now be as many as twenty years from the age of puberty to establishing full economic independence, while ten years is very common. In contrast, '... many of the great romances of the world celebrate the passionate loveaffairs of the young. ...

Margarethe was a teenager when she fell in love with Faust, Helen was only twelve when she left her husband Menelaus and followed Paris to Troy. Narcissus was sixteen when "many youths and maidens sought his love". Ganymede was even younger when Zeus made him his favourite.' The contentious age of Juliet is well known to generations of schoolchildren.

The prolonged changes of adolescence, which occur at different ages for different individuals, and may take one or several years, begin rather earlier for boys than girls. Heredity, diet, climate, and cultural and emotional influences may all be implicated in the start and duration of this period between the ninth and fourteenth years.

The development of adult sexual organs, fertility, the enlargement of breasts in the girl, and the obvious development of male and female body shapes in this period all serve to concentrate adolescent awareness on the increasing differentiation into men and women. The typical same-sex gang behaviour of the early teens begins to give way by the midteens to open sexual awareness of, and increasing interest in, members of the opposite sex. Boys' sexual interest appears to focus on overt sexual activity earlier than girls', a difference in sexual awareness and responsiveness that persists through early adult years. Men are at their most sexually active and interested in the late teens and through the twenties, whereas women's sexual responsiveness and interest appears to increase to a peak in the middle thirties. It is then capable of being sustained for the next thirty years or more, whereas male sexual responsiveness tends to decline from the late twenties onwards. There are of course wide individual variations in this overall

physically or sociopsychologically determined is not yet clear. The differences are, however, dearly observed. Changing social roles and expectations may have a particular effect on this tertiary aspect of male and female sexual development.

While the adolescent male is generally encouraged, in Western society, to view himself in a specifically and overt sexual way, the adolescent female is encouraged to be undemanding sexually but attractive socially. It is the adolescent boy's task to push at the boundaries of what sexual experimentation his adolescent girlfriend will permit, and it is her social task to set the limits. 'Nice girls say "No!"', while boys are not discouraged from sowing wild oats: which rather unfairly requires that there must be some girls who are not nice. These differentiated tasks, previously strongly reinforced by social conditioning and the necessity of avoiding unwanted pregnancy, are under attack by feminists and modern sexologists as potentially harmful to the female in limiting her awareness of her own sexuality, and harmful to the male in encouraging an achievement-oriented view of sex. Only time will demonstrate whether there is a fundamentally passive aspect of being female and an essentially aggressive aspect of being male, of which these different tasks of sexual development in adolescence are the consequence; or whether they are only the result of social value systems and will yield to new values in due course.

It is during adolescence that boys experience their first discharge of seminal fluid, either through masturbation or through spontaneous nocturnal emission. There is no parallel to this in the sexual development of adolescent girls: some girls may experience spontaneous orgasm during sleep, but such an event is very rare. Indeed many girls do not discover masturbation spontaneously at all, and in the absence of specific information about it from reading, or adults, or their peer group may not be conscious of overt sexual arousal, and may enter marriage and their first experience of coitus without being at all informed of their sexual responsiveness. Whereas at one time it was thought that this was a proper state for a young woman, it is now recognized that this not only lays responsibility on the man for the development of female sexuality—a burden for which men are developmentally not prepared—but denies the woman responsibility for the awareness and control of her own body and its responses. It remains the case, however, that many girls do not receive specific information even from their peer group, as evidenced by the lack of a slang word among girls for masturbation, in comparison with the extensive vocabulary that boys have for the same activity. Again this seems to be related to cultural conditioning, and we may expect the influence of such books as *Our Bodies, Ourselves*, and Dodson's *Liberating Masturbation*, as well as the female preorgasmic workshops that have begun to make their appearance quite extensively in the USA and to some extent in the UK (Hooper, 1980), to have a beneficial effect upon undue inhibition of sexual development. The modern trend of adolescent sex education is to make facts that were previously not known or not generally discussed much more widely available, and to stress responsible choice rather than avoidance in matters of personal sexual practice and experience. Kaplan (1979) and Cousins (1980) are excellent examples of this approach.

Homosexual fantasy and/or contact is not at all uncommon among boys and girls in adolescence. In the vast majority of cases it appears to be part of the transition from the sexually undifferentiated responses of childhood to increasingly articulated adult heterosexuality. Characteristically, in the adolescent homosexual phase, boys tend to be sexually attracted to (have crushes on) younger boys,

while girls have crushes on older girls. Overt physical contact may or may not be present in these adolescent phases. The presence or absence of overt physical or sexual contact appears to bear no relationship to subsequent adult homosexual or bisexual behaviours.

It is at present a matter of controversy as to whether adult homosexual behaviour should be regarded as normal or not. In statistical terms it is infrequent but not abnormal. The temper of the times suggests that to raise the question at all is to convey narrowminded prejudice or bigotry. However, Stoller (1976) has convincingly argued the case for considering adult sexual behaviours that are not heterosexual, and indeed some that are, as 'perversions'—in the technical sense that the biologically determined recipient of the sexual process must be the person of the opposite sex so that the survival demands of the species are met through mating and consequential reproduction. Acts that do not serve such a function should properly be considered as having had their focus turned away, and hence perverted, from the biological intent.

The range of heterosexual contacts during adolescence is very variable. It is however now thought that the large majority of couples will have experienced sexual intercourse prior to marriage. This is a significant shift in the sexual practices of the population in little more than a generation.

Adulthood is a period with its own characteristic phases that are only just beginning to receive detailed descriptive attention. In delineating the phases of adult life, Levinson (1978) has remarked that the period from early adulthood to the onset of old age—a span of about forty years—has been ignored as if it were a tranquil period. Clearly it isn't. It is the period sexually when the pleasures and difficulties of the marital and childbearing years subordinate sexual development into limited expectation and less discovery. It is also the period when sexual difficulties become manifest. The current tendency is to assume that sexual development will have taken place by the early adult years, but

Page 707

that sexual experience and discovery may lag considerably behind physical maturation.

The work of Masters and Johnson has made it quite clear that sexual activity can happily persist well into the seventh and eighth decades of life. The needs and urgencies of a couple may change, yet the reassurance and confirmation of existence that comes from the close physical intimacy of sexual contact can be pleasurable in itself to an advanced age and highly beneficial in the process of adjustment to increasing years. There is a growing though as yet limited professional interest in the relation between poor marital and sexual adjustment and a high incidence of demands for the resources of medicine by way of gynaecological distress, psychosomatic distress, and psychiatric breakdown, suggesting that much might be prevented by more successful adaptation earlier on.

In the male entering his fifties and sixties, the vasocongestive responses of sexual arousal become less, even in the presence of effective physical or psychological sexual stimulation. Erections become harder to establish. It is important at this stage for a couple to know from within their own experience that sexual involvement is not simply dependent upon the act of intercourse, but involves a wide range

of pleasurable behaviours of which coitus may be only one. Sexual desire may remain high in the absence of strong erectile response, and the male urgency to ejaculate upon sexual arousal correspondingly diminishes too. The lack of erection should not be taken as the sign of lack of sexual interest and desire for sexual expression of affection.

In the female some corresponding changes in the tissue of the vaginal barrel may occur after the menopause. Changing hormone supply may cause some thinning and drying of the walls of the vaginal barrel, the same occurring after surgical removal of the ovaries. Hormone replacement therapy has been advocated after such operations and after the menopause to counter the adverse effects of the absence of ovarian hormones, but it is not yet clear what the longterm effects of such replacement are. As in the male, however, the absence of one physical sexual response, vaginal lubrication, does not in later years necessarily indicate loss of sexual desire. As with all bodily functions, the rate of change varies enormously from individual to individual. There is some suggestion that the rate of loss of physical sexual function is less in those who have had a generally continuous and satisfying sexual life.

Quite clearly the doubts, urgencies, and discoveries of adolescent and young adult sexual development give place to sexual function coming more under the influence of increasing life stresses as the thirties and forties merge into the later adult years. In positive caring in relationships, however, sexual development subserves not only the continuation of the species but the most vital existential discovery—that physical encounter with a person of the opposite sex, and perhaps of the same sex too, sustains, supports, and heals in the individual life journey (Dominian, 1977).

SEXUAL PROBLEMS in marriage became a matter of particular clinical and popular interest with the publication in 1970 of Masters and Johnson's *Human Sexual Inadequacy*. This was an account of an elevenyear period of clinical work and research, conducted at the Reproductive Biology Research Foundation in St Louis, Missouri, involving the treatment of a group of sexual difficulties that Masters and Johnson classed together as sexual dysfunctions. Over the elevenyear period, 790

instances of sexual difficulty were seen, the majority (733) presenting in 510 marital partnerships where one or both of the partners were experiencing a sexual problem. The treatment of single individuals is referred to later.

This clinical work was itself based upon a research programme into the physiology of human sexual response that Masters and Johnson had started in 1954, and which they had published in 1966 as *Human Sexual Response*. Unlike Kinsey's pioneering work of twenty years previously, which had asked people in considerable detail what they did in their sexual lives, Masters and Johnson established laboratory conditions for observing how people reacted sexually in terms of their physiological mechanisms under specific conditions of stimulation. It was their avowed intention to make the field of sexual function academically and professionally respectable. There is now no

Page 708

doubt that they achieved this aim in a quite signal way, though probably with consequences for the effective use of the knowledge that they supplied which are not yet fully appreciated.

Until the appearance of their works, sexual problems had been seen clinically within the framework of psychopathology, and no distinction was made between difficulties of normal function and

variations of normal function. Freudian thinking generally underpinned this view, and there was overall pessimism about the possibility of help for specific sexual problems. Sexual difficulties were themselves seen as symptoms of deeper, underlying problems, and moreover clinicians generally had no clear diagnostic framework within which to consider sexual difficulties that might not be deeply rooted in psychopathology. The most optimistic views of treatment had been presented by Friedman in *Virgin Wives*, where he reported the work of Balint at the Tavistock Clinic in the mid 1950s. Balint had developed a form of brief psychotherapy, particularly for the disorder of vaginismus, which is a spasm contraction of the outer third of the vaginal barrel that effectively prevents intercourse by presenting such a constricted vaginal entrance that penetration by the male is not possible. Standard psychiatric texts of the 1960s and early 1970s, however, hardly touched sexual difficulties *per se*, beyond the blanket terms 'frigidity' in women and 'impotence' in men, and ' *ejaculatio praecox*' also for men who complained of too rapid an ejaculation. In any event, both 'frigidity' and 'impotence' had acquired considerable pejorative overtones in popular usage by the 1960s, and (as had previously happened with such terms as 'idiot' and 'imbecile') required redefinition for clinical usage for that reason if no other.

It was the particular achievement of Masters and Johnson to shift thinking about difficulties of sexual function from considerations of psychopathology to those of learning and the failure to establish effective learning, and it is in this context that sexual difficulties are now first regarded upon presentation at a clinic. It is only when they appear to be unresponsive to treatment based upon educative concepts that considerations of psychopathology and inner psychic conflict are introduced. It is moreover quite possible now to separate sexual difficulties from sexual perversions—which is not to say that the two might not coexist.

Masters and Johnson also made the startling observation, which had previously passed most clinicians by, that sex tends to happen between two people. They concluded therefore that it might be best to see a couple in therapy rather than the single individual, as the focus of treatment is most likely to be upon the couple's pattern of sexual communication—what exactly happens between them—and not so directly upon the specific presenting difficulty of function, which is seen as a consequence of, or as being maintained by, the limitations of the couple's communication. The logic of this observation was also carded through by observing that a male clinician can never fully understand the female sexual experience, nor a female clinician the male. In consequence it might be helpful to have both a male and a female therapist present. This creates the situation of cotherapy—the treatment of a couple by a couple in a therapeutic foursome.

In defining the group of difficulties with which they were concerned, Masters and Johnson also made it possible, as noted briefly above, to distinguish the sexual dysfunctions from the sexual deviations. The sexual dysfunctions are often experienced by the majority of individuals in a transitory fashion, becoming dysfunctions by their persistence or their adverse effect upon the sexual relationship. For instance, most men will experience difficulties of erectile function in their adult life, and most women may have intermittent difficulty establishing a climax, even when these functions are generally satisfactory for the individuals concerned.

The description of the sexual dysfunctions is, briefly, as follows. In the man, primary or secondary

impotence, premature ejaculation, and ejaculatory incompetence.

That is to say, men who fail to establish and/or maintain an erection of sufficient strength for effective vaginal insertion, either throughout the whole of their adult sexual experience (primary impotence) or temporarily (secondary impotence); and men who ejaculate too quickly for their own and their partner's satisfaction (premature ejaculation), or too slowly, or not at all (ejaculatory incompetence). In the woman, the dysfunctions were classified by Masters and Johnson as being primary orgasmic dysfunction or situational orgasmic dysfunction. The first specified a situation in which the woman had never been orgasmic by any means (intercourse, masturbation, or any other method) throughout the whole of her sexually mature life, while the second described the conditions under which a woman might be orgasmic by coitus but not by masturbation (masturbatory orgasmic dysfunction), by masturbation but not by coitus (coital orgasmic dysfunction), or only occasionally orgasmic and without any feeling of certainty or predictability (random orgasmic dysfunction). Additionally they considered problems of pain upon intercourse in both men and women (dyspareunia) and vaginismus in women. They made a particularly strong case for encouraging physicians to believe in and thoroughly investigate a statement of pain during sexual intercourse, and not simply to dismiss it as 'hysterical' or 'psychogenic' because it was related to the sexual act. They also considered problems of low sexual drive.

In their physiological studies, Masters and Johnson had observed the processes of sexual arousal, from original quiescence through arousal and climax to quiescence (resolution) again, in a total of 694 male and female volunteers in the age range 18 to 89. In doing so they had made it clear that the

Page 709

sexual physiology of men and women is essentially the same even though the specific sexual anatomy is markedly different—bearing in mind, in regard to this latter statement, that in the embryo eventual male and female both start out as female, and are only differentiated as a consequence of hormonal effects, from about the sixth week of intrauterine life, so that it is not until the third month of gestation that anatomical differences are apparent.

The first physiological change to arise as a consequence of effective physical or psychological sexual stimulation is that blood begins to flow more rapidly around the body as heart rate increases, so that specific tissues become engorged. This process, called vasocongestion, creates an erection in the male of which the exact equivalent in the female is vaginal lubrication. Both are the early signs of sexual arousal and/or interest. In the female, increasing vasocongestion in the tissues of the vaginal wall creates a type of sweating response on the surface of the walls of the vaginal barrel (the transudorific reaction) which accumulates to form the lubrication of sexual arousal. Masters and Johnson observed this process by the simple expedient of introducing a clear plastic dilator into the excited vagina, illuminating the interior, and filming the process. Not only did they thereby dismiss the assumption that vaginal lubrication came from the glands of Bartholin at the vaginal entrance, or that it was a product seeping through the neck of the womb, but they also observed the continuing process of arousal, which was that after lubrication had established itself the vaginal barrel lengthened and increased its diameter considerably, ballooning in its upper third. The vagina was thus seen to produce changes which were the effective analogue of the male erection. As the limp penis is

a potential erection, so the vagina in its unaroused state was seen to be potential space.

One immediate consequence of these observations of vaginal lubrication was that the processes of arousal in the woman began to be seen as equally important to those of the male, if the sexual act was to be mutually satisfying, and that it made as little sense to tell a sexually unresponsive woman to use a cream in order to make male insertion possible as to tell a man without an erection to tie a splint on his penis.

Apart from the vaginal and penile reactions of erection, other marked changes take place in the erectile tissues of the female sexual organs, including the clitoris, and in the breasts, which are all dependent upon vasocongestion. Not only is the sexual response of the body more widespread and complex in the female than in the male, but a wide variety of cultural influences make it possible for the female to value and enjoy the feelings of her body whereas the male is often taught to discount feelings of all kinds. Thus the woman may especially enjoy and value the experience and complexity of feelings in a sexual relationship, while the male may be more concerned with the performance of the act. Difficulties in a sexual relationship frequently arise from this difference, as the man's interest may centre more on achieving climax than upon the pleasure of the encounter. It is also the case that the complexity of the woman's sexual responses is more vulnerable to adverse social conditioning; this may teach her that sexual acts are connected with excretory acts and menstruation which, if they themselves are adversely loaded emotionally, may make it difficult for her to value her sexuality positively and enjoyably.

At a specific point in the process of sexual arousal, involuntary muscular responses are triggered which in the male result in ejaculation of seminal fluid, and in the female in the experience of orgasm. In the male the sites of sexual sensation and orgasm are essentially the same, occurring in both cases around the tip of the penis, the glans. In the female, however, there is relatively little specific sensation inside the vagina, where the muscular spasm of orgasm is experienced. The main site of sexual stimulation on the input side, for the majority of women, is the clitoris, and ineffective clitoral stimulation is one of the main contributors to orgasmic difficulties.

The separation of the clitoris and vagina in the sequence of sensory input and orgasmic experience has been a considerable theoretical dilemma in the development of Freudian thinking, giving rise to the now redundant clitoralvaginal transfer theory of adult female sexuality.

Their physiological observations led Masters and Johnson to conclude that the sexual response cycle of arousal and climax is a natural physiological property of the intact adult human being and responds predictably to adequate stimulation. However, it is also under the potentially inhibitory control of higher centres, and has the singular property for an autonomic process that its function can be effectively inhibited for the whole of a lifetime. It is therefore distinguished from other autonomic processes, such as respiration, heart rate, digestion, and so on. In consequence, Masters and Johnson's treatment procedures have been developed to aid the establishing of normal function. The goal of therapy is not to teach couples how to function sexually, but to help them discover how to stop stopping their natural functioning.

The therapy format which Masters and Johnson developed was a rapid, fourteenday programme of intensive, therapistguided development of effective sexual communication, using all senses but especially touch, the basic source of sexual pleasure. The early stages of treatment involve guided exercises (sensate focus) which the couple build up in discussion with the therapists and then undertake in the privacy of their own lives. Out of the shared experience of sexual responses occurring under the right conditions, specific techniques may become useful for specific difficulties. For instance, in the case of premature ejaculation, the woman in the partnership eventually becomes the therapeutic controller of the ejaculatory

Page 710

experience by applying a specific squeeze upon the glans penis just prior to an ejaculation provoked by masturbation, thus inhibiting the ejaculation and helping the man acquire the kind of reflex arc control that he acquired as a small boy in learning to control the passing of urine by discriminating internal signals.

Not only did Masters and Johnson's therapy proceed upon systematic lines, illuminated by a clear understanding of the expected physiological effects of an increasingly skilled sexual encounter between the couple in treatment, hence commending itself instantly to a planned therapeutic approach previously absent in this field; they also established treatment effects of a very high order. At best, 978 per cent of 186 premature ejaculators responded to treatment; at worst, 594 per cent of primary impotence cases recovered. Over all disorders, male and female, the initial successful outcome rate was 81.1 per cent, a figure of an extremely high order for any therapy. Fiveyear followup on 313 marital units showed a relapse rate of only 5.1 per cent. In consequence it can be claimed that Masters and Johnson developed not only a very systematic treatment procedure but also a highly effective one, for difficulties not previously responsive to treatment nor properly understood.

The publication of their treatment results in 1970 led to a considerable surge of popular and professional interest, occurring as it did at a time when reliable and readily available contraceptive measures in the USA and northern Europe had become established aspects of the sexual life of these cultures. With the separation of the act of intercourse from the act of reproduction, the increasingly discussed concept of sexforpleasure *for both partners*, responsibly undertaken, suddenly acquired an authoritative knowledge base. This reached an elegant if early apotheosis in Alex Comfort's *The Joy of Sex* in 1972. Clinics for the treatment of sexual difficulties sprang up throughout the United States, so that within five years of the publication of *Human Sexual Inadequacy* it was reliably rumoured that over 3,000 such clinics had established themselves.

This mushroom development sprang in part from a small amount of work which Masters and Johnson had done with single individuals, where, for 41 males, a female partner, called a 'surrogate', was made available by the therapists to cooperate in providing psychological and physical involvement during therapy. Masters and Johnson themselves abandoned this approach to therapy in view of the considerable administrative and ethical issues which their bold exploration of it raised. It led to a good deal of sexual 'therapeutic' licence in the States, a process eventually controlled by the development of a professional association for surrogate partners in sex therapy. Reputable schools of

practice did also develop using a much more physically involved approach by therapists than Masters and Johnson had advocated, Hartman and Fithian being one example and McIlvenna at the Institute for the Advanced Study of Human Sexuality another. Apart from a treatment series conducted by Dr Martin Cole at Birmingham, the use of surrogates in therapy has not become common in Britain. Therapy for women to explore their own sexuality has become so, however, and there are some accounts of this (e.g. Hooper, 1980), though no clinical trials in a formal sense.

Indeed, the whole field of sexual function therapy is notable for its enthusiasm rather than systematization, and it is often difficult to distinguish therapy from sexual enrichment work. Perhaps at times there may be no useful distinction to be drawn. Be that as it may, no systematic replication of Masters and Johnson's work has been attempted, and it is possible that such a task could not now be accomplished. Their work has itself dramatically altered the levels of information available in the population about sexual matters; their personal therapeutic effectiveness as the outstanding pioneer authorities in the field is an element that could not be replicated; the nature of their fourteenday, vacationbased therapy programme is not one that is easily recreated once a variety of more local centres becomes available; and their criteria for selecting couples for therapy has never been clearly stated.

Despite a flood of literature following their work, of which LoPiccolo and LoPiccolo (1978) is a good summary, the only two studies to have investigated components of their treatment procedures have originated in England, where J. Bancroft and his colleagues at Oxford and P. T. Brown on behalf of the National Marriage Guidance Council at Rugby considered the cotherapy situation, among other aspects, in clinical trials. In both these cases therapy was modified to weekly attendance procedures, and spread out over ten to twelve weeks instead of fourteen days. This is now the typical pattern for sexual function therapy in Britain, a development that has in part been systematized through the establishing of a multidisciplinary Association of Sexual and Marital Therapists in 1976.

Kaplan in the United States has been the strongest source of clinical thinking to integrate Masters and Johnson's work into the established psychological therapies, and she has been particularly concerned to distinguish disorders of sexual desire from the dysfunctions, as well as clarifying other aspects of the diagnostic statements of Masters and Johnson. Brown (1977) has summarized Masters and Johnson and Kaplan into a diagnostic schema which lists in a simple fashion the categories of the sexual dysfunctions, and makes it dear that they are now readily distinguishable from those difficulties of sexual expression which were once called 'perversions', then

'deviations', then 'variations', and most recently by the*behaviourists 'excesses', but which Stoller has argued should properly be called 'perversions'. Their characteristic, to distinguish them from the dysfunctions, is

Page 711

that they are not difficulties of sexual expression, but contain choices of sexual object other than the familiar acts associated with heterosexual arousal and response.

Treatment for sexual dysfunction, both for couples and individuals, is now available throughout the UK, though more so in some areas than others. Both the National Health Service and the National Marriage Guidance Council have developed specialist clinic facilities, and there is a limited private field. Therapy typically involves an exploration of not only what the problem is, but why in the particular partnership or individual it has arisen or been maintained; and this is followed, usually on a weekly basis, by guided exploration of effective sexual stimulation. Thus the couple and the individual are helped to become increasingly expert and effective in their own sexual wellbeing.

SHERINGTON, SIR CHARLES SCOTT (1857-1952). British physiologist, born in London and educated at Ipswich grammar school and at Cambridge; he qualified at St Thomas's Hospital in

London in 1885. As a physiologist he anticipated Pavlov in attempting to uncover the structure of the nervous system by looking at input and output. Moreover, his discoveries stand up better than Pavlov's because he worked mainly on a comparatively simple aspect of the nervous system, spinal reflexes, whereas Pavlov was attempting to investigate the workings of the brain using the same techniques. This work on nervous integration and brain functions resulted in a neuroanatomical theory of behaviour that prefigures ethological models and, unexpected as it may seem, converges with some basic teachings of phenomenological psychology. Yet his originality is not limited to his masterwork *The Integrative Action of the Nervous System* (1906, 2nd edn. 1948); it is equally patent in his two late works, *Man on his Nature* (1940; 2nd edn. 1952) and *The Endeavour of Jean Fernel* (1946), which deal with man's place in the world as a living being endowed with consciousness and reflective power, and involve fundamental issues in the fields of philosophy of science, ethics, and the theory of values. To complete the picture, one should remember the great physiologist's interest in the humanities and literature, as evidenced, among other things, by his publication in 1925 of *The Assaying of Brabantius, and other verse*.

Sherrington's career was exceptionally brilliant. He was Brown professor of physiology, London (1891), Fellow of the Royal Society (1893), Holt professor of physiology, Liverpool (1895), and in 1913 he became Waynflete professor of physiology at Oxford, a post he held until 1935. In 1932 he shared the Nobel prize for medicine with E. D. Adrian. His physiological investigations, which began with the study of nerve degeneration in the decerebrate dog (1884), developed into a manifold and steady production covering a great diversity of topics, ranging from anatomy to perceptual processes. However, the guideline in the vast majority of his works is analysis of the functional properties of the nervous system. Important discoveries within this framework are the reciprocal innervation of antagonistic muscles, decerebrate rigidity, and the basic features of peripheral reflexes. In addition to *The Integrative Action of the Nervous System*, he produced *Mammalian Physiology* (1919; rev. edn. 1929), *Reflex Activity in the Spinal Cord* (1932), and some 300 specialized articles. He opened an era of experimental research and theory by clarifying the functional relations between reflexes and behaviour patterns. This is one of the major objectives, if not the major one, of neurophysiology, comparative physiology, physiological psychology, and, most recently, neuroethology. It is therefore necessary to ask where exactly Sherrington's originality lies.

First, his experimental studies of reflexes on decerebrate animals allowed him to discover both the complexity of spinal reflexes and the control effected on them by superior (or 'higher') brain centres. This he could achieve by decerebrating the animal at the mesencephalic level, a technique which proved most appropriate and led him to clear evidence of integrative processes. Secondly, he was able to establish a now classical distinction between different categories of receptors—interoceptors, exteroceptors, and proprioceptors—according to the sites where they gather information as required by the organic processes actually in course. For the connections between neurones, the term synapses was introduced by Sherrington and Michael Foster in 1897.

These and other important contributions to the systematic and accurate knowledge of the anatomophysiological structures and functions of the

nervous system amounted progressively to a general interpretation of the organism's activity which is

present on every page of *The Integrative Action of the Nervous System* and is fully developed in the last two chapters of that work. Sherrington succeeds in explaining the emerging properties of behaviour patterns by referring to the *continuity* that exists between anatomophysiological substrates and overt behaviour, thus doing away at the outset with classical dualistic views.

Moreover, the question of internal causation of behaviour is viewed not in the form of extrinsic mechanical links between acts and supposedly corresponding internal organic events: it is systematically related, rather, to the structural constraints of the body as a spatiotemporal system within the process of evolution.

In brief, physicochemical changes inside the body and bodily changes at the behavioural level occur within subsystems included in overall organic activity. Continuity therefore implies integrative action, for causal factors to be at work between one level and the other in order to ensure survival. This comprehensive philosophy of the organism is exceptionally well outlined in the penultimate chapter of *The Integrative Action of the Nervous System*. After discussing the main features of the reflexarc, Sherrington goes on to describe the central nervous system as a synaptic network. He then turns to the analysis of receptive fields, contrasting the richness of the exteroceptive field with the relative poverty of the interoceptive one. This is apparently due to the fact that receptors of a special kind, the *distancereceptors*, initially appeared in relation to locomotion requirements, and are located for this reason in the leading segment of an animal. The distinctive functional advantage of the *distancereceptors* lies in their unique power of dissociating the stimulus from its physical source, thereby enabling the organism to develop around itself peculiar spacetime relations in perceptual activity. This may be observed in various degrees in vision, hearing, and smell, as well as in some less widespread mechanical and thermal receptors. The *distancereceptors* are said to be 'precurrent'—i.e. they can gather information about the animal's surroundings without requiring a direct physical contact between the source of a stimulus and the body surface. This important feature is not to be found in the proximal receptors, namely those of touch and taste.

The high survival value of precurrent responses is evident, since it allows for explorative appreciation of, for example, *potential* prey and predators. If food could be detected only by taste, or enemies only by mechanical contact, an organism would be unable to make any preparatory decision as to the positive or negative nature of any biologically important stimulus. In other words, the subjective spatiotemporal field would be practically nonexistent and the autonomy of the animal would be drastically limited (as is the case, to some extent, in so-called 'primitive' living forms). Clearly, the product of evolution we call the 'superior' animal is that type of organism which has evolved towards an increasing explorative autonomy, due to the potentialities of the *distancereceptors* and the corresponding development of a highly complicated brain capable of integrating a great diversity of sensory information. Considering the time sequences of behaviour patterns, anticipatory responses, which allow for an extension of subjective space and consequently for an increase in reactiontime and duration of response, have the fundamental function of preparing the responses of the immediate receptors, i.e. the reactions triggered by proximal stimuli in contact with the body.

Sherrington's account of these active relations established by the organism with its surroundings converges to a great extent with later ethological teaching, a fact which is still hardly recognized in

ethological circles. The expression 'consummatory reaction' appears in *The Integrative Action of the Nervous System* twelve years before Wallace Craig introduced the term 'consummatory act', to which ethologists refer as the first formulation of the concept. The main difference is that Sherrington's outline of the role of anatomical structures in exteroceptive communication emerged from his neurophysiological experiments, whereas the corresponding topic was developed in ethology on the basis of naturalistic descriptions of behaviour patterns in the social life of animals within the framework of phylogenic studies.

Finally, there exists a definite affinity between Sherrington's analysis of the precurrent receptive fields and the phenomenological descriptions of bodily subjectivity.

Phenomenological themes, such as the lived experience of bodiliness in the active constitution of a meaningful world, or even descriptive studies of animal subjectivity referring to the perception of bodily limits in the actualization of observable behaviour patterns, may conveniently be set against Sherrington's theory of the biological significance of the body's 'interface' as meetingpoint of exteroceptive and interoceptive experiences. His interpretation of the subjective field as a result of his experimental studies on reflex activity also laid the foundations of a physiologically inspired psychology which is in many interesting respects at variance with the Pavlovian model. In Sherrington's view, *behaviour* must be considered as that sector of overall biological activity which is initiated by the precurrent receptors and which ceases to exert itself as soon as the subsequent activity of nonprecurrent receptors comes into play. Concerning feeding behaviour, for instance, he writes: 'The morsel vanishes from an experience at the moment when our choice in regard to it becomes inoperative. The psyche does not persist into conditions which would render it ineffective.' In Pavlov's view, on the contrary, behavioural processes are conceived as events resulting from stimuli which impinge on the organism without any previous activity in the behavioural field. Whatever the case may be, the

Page 713

careful reader of Sherrington's writings will readily be convinced of the founding character of his contribution to the biology of behaviour.

SHOCK. This term is sometimes applied to an event of special force or significance that causes disruption or collapse of mental or physical functions or behaviour, and sometimes to the effects of such an event. After the impact, a usually shortlived attempt to restore the position is followed by reduction in activity and in responsiveness to the external world. After a serious accident, for instance, a person becomes apathetic and largely unresponsive to what goes on around him. He lacks initiative and is compliant, sometimes to a degree of childlike dependence on others. These effects

protect him from further stimulation. If he has suffered serious physical injury, and his state is one of surgical shock, he is pale, his skin is cold, and his peripheral pulses feeble. These effects reflect the shunting of blood from the skin to organs more essential for survival. The adaptiveness of the effects has not always been recognized: for instance, surgical shock used to be treated by warming the patient in an attempt to restore the circulation to the skin.

The term 'shellshock' was used in the First World War to describe a variety of bizarre hysterical symptoms which were attributed to the pressure effects of exploding shells. It was superseded in the Second World War by 'battle neurosis' or 'exhaustion', implying a psychological rather than a physical cause for the condition.

SHORTTERM MEMORY. *Memory for what happened an hour ago or a year ago fulfils an obvious function in our lives. However, our capacity to store information for periods measured in seconds is equally if not more important to our integrity as human beings. This capacity is referred to as shortterm memory (STM). *Descartes asserted, 'I think, therefore I am'. It is equally true to say 'I think, therefore I have shortterm memory'. Indeed any mental activity extended in time, including the production and comprehension of language, must involve STM. It is certainly fortunate that STM is robust and, unlike longterm memory, is seldom affected by old age, drugs, or brain damage.

The most familiar fact about STM is the *existence* of the so-called span of immediate memory. A rough definition of the span is that it is the longest sequence of items that can be reproduced correctly following a single presentation. However, the same individual may manage a sequence of seven items on one occasion and make a mistake with a sequence of only five items on another. Accordingly, the span is in fact defined as that length of sequence for which the chance of correct reproduction is fifty-fifty. The span has a number of interesting properties. Two are as follows. First, for items in random order, the span is about seven, plus or minus two. This is surprising in that the amount of information per item has little effect on the span. For example, the span for binary digits (0,1) is only slightly longer than for decimal digits (the digits 0 to 9), although the latter contains over three times as much information. Second, within wide limits, the span is almost unaffected by the rate at which items are presented, and is therefore relatively independent of the time elapsing between the presentation of an item and its recall. These two facts are nicely explained by the so-called slot theory. On this theory, the span reflects the capacity of an information store in the brain with about seven 'slots'. Each slot is capable of storing a single item or unit. Once the store is full, new items can only be stored by displacing existing items. Variation in the span is attributed on this theory to the fact that a unit can sometimes comprise more than one item. For example, two or more digits can sometimes be recoded as a familiar number which can then be stored as a unit.

Indeed, if an individual has an exceptional familiarity with numbers he may have a digit span of fifteen or more. However, recoding digits into familiar numbers cannot account for the digit span of eighty recently achieved by one individual after extensive practice, who reported using both recoding and a hierarchical grouping strategy.

At best, therefore, the slot theory describes the mechanism which *normally* determines the span.

Two other interesting facts force another qualification to the slot theory. The span is reduced if the items of the sequence sound similar. For example, the sequence B

V T G P is more difficult than the sequence S K L R N. If reproduction of the sequence involves retrieving the items from separate slots, why should this be so?

Similarly, the span is smaller for long words than for short words, which is puzzling if each word is a unit and occupies a separate slot. With visual presentation, both the effect of similarity of sound and of word length vanish if the subject is asked to count aloud during presentation of the sequence. (At the same time, the counting task somewhat reduces the span.) This suggests that normally there is subvocal rehearsal of earlier items during presentation of later items of the sequence and that such rehearsal contributes to the span as normally measured.

Since the slot theory postulates a special store for STM, by implication there must be a different store for longterm memory (LTM). Evidence for a twostore view of memory comes from memory pathology.*Amnesia due to brain damage can take one of two forms. In the common form, STM is intact but LTM, in the sense of the ability to form new permanent memories, is impaired. In a rare form, which has only been identified quite recently, the reverse is found, with LTM intact but Page 714

STM impaired. Clearly independent impairment of STM and LTM is highly consonant with the twostore theory. However, recent theory tends to postulate not one but several stores for the temporary storage of information. Indeed, evidence from the study of patients with impaired STM suggests that there are separate temporary stores for auditory speech sounds and for nonverbal sounds.

Other evidence has been interpreted as showing that there are also temporary stores associated with touch and vision, although information from the latter fades in less than a second. There is also the possibility that the brain has temporary stores concerned with making responses. In the case of speech, for example, such a store might hold in readiness the codes for articulating several words and would substantially assist the smooth production of speech. Accordingly, the span of immediate memory (and STM generally) may reflect the output of one or more temporary stores, depending on circumstances. The common characteristic of these postulated stores is that each is of limited capacity and new information displaces old information. The slot theory of the span therefore seems too simple, although the facts it explains need to be accommodated in more complex accounts of the mechanisms underlying STM. If shortterm memory depends on specialized stores holding information over short intervals of time, the question arises of how information reaches the store responsible for LTM. One possibility is that there is a process of information transfer from these stores to the LTM store. If so, this process is presumably successful for only a proportion of the information entering the temporary stores, since we forget more than we remember. A second possibility is that information enters the LTM store directly at the time of perception, although at a slower rate than it enters the temporary stores. On this hypothesis, STM as we observe it may depend both on information retrieved from temporary stores and on information retrieved from the LTM store. At present, there is

no decisive evidence favouring either possibility. Indeed, some theorists prefer to view memory as a single complex system. For example, the different properties of STM and LTM can be held to reflect, not the operation of different stores, but factors affecting the ease of retrieving stored information. This sort of theory is not implausible in view of the fact that problems associated with the retrieval of information from a storage system often imposes major constraints on efficiency. However, the detailed facts about STM do seem to favour the view that specialized temporary stores are involved. Ideally, there would be physiological evidence to show how many stores underlie memory, but at present the evidence is indirect and difficult to interpret.

SIGN STIMULUS. See ETHOLOGY.

SIZE CONSTANCY SCALING. See EMMERT'S LAW.

SIZEWEIGHT ILLUSION. Lifting weights was a favourite activity of experimental psychology in its early days; but now, although these experiments involve much of interest, they are unfashionable and are seldom even mentioned in textbooks. This may change, however, as manipulative skills in space at zero g give rise to new problems in relation to*perception (see SPACE PSYCHOLOGY). One of the most theoretically significant of perceptual*illusions, which also has practical importance, is the sizeweight illusion: when objects are lifted by the hand, a *larger* object feels and is judged to be *lighter* than a smaller object of the same scale weight. This makes a nice kitchen experiment, which can easily be carried out, with a pair of tins of different size, partly filled with sugar or salt (or lead or sand) to have the *same* scale weight. When lifted, a few inches from the table, the *larger* tin will feel *lighter* than the smaller tin—though they both have the same scale weight.

Ideally, the tins should be lifted by identical handles or wire loops, so that there are no significant touch signals from the different sizes of the tins—for the whole point is that sensory signals of weight are the same for both tins, though the smaller feels heavier. This illusion is interesting because it shows very clearly that the sensation of the weight—which one might think is directly and simply given from forces on the hand and arm—is markedly affected by the assumption of how heavy it 'should' be.

Further, it turns out that it is the *surprise* that the larger weight is not the heavier (as it would usually be) that produces the illusion. (Weight illusion also arises from the colours and shades of objects—darker objects being accepted as probably heavier than lighter ones.) Even the 'purest' sensory signals must be 'read' or interpreted according to general knowledge or assumptions in order to provide

information, sometimes fallible, about the objects handled. Thus, sensed weight is not given simply by skin and muscle receptors, but also from our knowledge that larger objects are usually heavier than smaller objects. Anticipated weight is important when lifting objects, since the muscle force must be set to give a reliable smooth lift and avoid injury. That we do not always correctly anticipate the force required is obvious from the familiar 'empty suitcase' effect: that is, when we pick up an empty suitcase assumed to be full, it flies up in the air! For, then our anticipation of its weight was wrong—which shows that we *do* anticipate weight before we lift things.

The sizeweight illusion is a large (up to about 30 per cent), stable, and repeatable effect, which offers an opportunity to challenge an assumption

Page 715

of*psychophysics—that our ability to discriminate between small differences depends, simply, on relative stimulus intensities. It is possible to test whether the*Weber

Fechner law depends (as is generally assumed) simply on the weight stimuli, or whether it is related also to our knowledge and assumptions of what objects are like.

We can test this by finding out whether it is more difficult to distinguish differences between weights of small objects than it is in the case of larger ones. It turns out that there is an effect of size, and so of *apparent* weight; but it is not merely a matter of an increase of the Weber fraction in proportion to apparent weight. Rather, weight discrimination is best—that is, the Weber fraction is smallest—when the density of the lifted weights is about 1, which is roughly the average density of objects. Both lower and higher densities give impaired weight discrimination.

Why should this be so? A possible reason is that the neural signals for weight are compared with expectations, and that the *signalled* and *anticipated* weights are *hulled*—as in delicate measuring instruments such as Wheatstone bridges. Cancelling of received input against anticipated values is useful as a way of gaining sensitivity over a wide range of input values, even when the components (whether electronic or those of the nervous system) have only small dynamic ranges. A*nulling arrangement gives high stability even if the components are liable to 'drift' or fatigue, as neurones are. That our weightsensing system is labile is obvious—for after carrying a heavy object even for a short time the arm, and even the whole body, feels light when it is released. And the arm may float up, almost out of control. This is the basis of the party 'levitation' trick: after someone's shoulders have been pushed down in the dark, that person may have the impression of rising towards the ceiling, for such is the lability of the nervous system.

SKILL, HUMAN. In everyday parlance, 'skill' is used to denote expertise developed in the course of training and experience. It includes not only trade and craft skills acquired by apprenticeship, but highgrade performance in many fields such as professional practice, the arts, games, and athletics.

The psychological study of skills came to the fore during the Second World War with the need to match the demands of new equipment such as radar, highspeed aircraft, and various sophisticated weapons to human capacities and limitations. More recently, the growth of sport as highly lucrative entertainment and as a medium of national pride and international diplomacy has raised competitive standards and led to studies of human performance at games and athletics in order to extract maximum physical and mental effectiveness.

The common feature running through all these types of skill is that the performer has to match the demands of a task to his capacities. He does this by applying some *method*, or, as it is often called, 'strategy' of performance. For example, a tradesman will select tools and manipulate them in ways which match his capacities for exerting force and exercising fine motor control to the requirements of the metal, wood, or other material he is using. Similarly, a barrister or negotiator will order the questions he asks in a manner which he judges will best enable his powers of persuasion to secure the outcome he desires. These strategies, it should be noted, are not typically concerned with single responses to stimuli, but with chains or programmes of action which look ahead from the situation that initiates them to a future goal or end result. Some strategies are more efficient than others, in that less capacity, time, or effort has to be deployed to obtain the results required. *Skill consists in choosing and carrying out strategies which are efficient.*

Almost every skilled performance involves the whole chain of central mechanisms lying between the sense organs and the effectors, but different types of skill can be distinguished according to the link in the chain where their main emphasis lies. For this purpose, the central mechanisms can be broadly divided into three functional parts: perception of objects or events; choice of responses to them; and execution of phased and coordinated action giving expression to the choice made. An example of perceptual skill is the ability of musicians to judge 'absolute pitch'. It depends upon the possession of a conceptual scale against which any note heard can be placed. The ability is sometimes claimed to be inborn, but studies have shown that it can be acquired, or at least greatly improved, with practice. Analogous skills occur in other occupations which require the making of fine discriminations, such as dyers distinguishing subtle shades of colour, steel furnacemen deciding when the colour of molten metal indicates that it is ready to pour, wool and other fibregraders assessing thickness by 'feel', cheesegraders judging softness by pressure, and wine or teatasters using a 'sensitive palate'.

Skills in making choices, or, as they are sometimes termed, 'decisional' skills, include the expertise shown in various intellectual pursuits, and also in games such as chess and cards. In all these cases, the perceptual data are usually clear and the precise manner of executing the actions required is unimportant: the essential for success is to decide upon the correct actions to take.

Examples of motor skills include sitting on a horse, riding a bicycle, or manipulating the

controls of a car. Their essential characteristics lie in motor coordination and timing. They have attracted somewhat less research than other types of skill, probably because the knacks involved are largely unconscious.

Industrial and athletic skills display the characteristics of all three types. Perceptual factors enter into trades and crafts in the assessment and judgement of materials, and in observing the effects of tools such as drills and lathecutters. In ball games they are concerned in the observation and assessment of the flight of the ball and of the moves made by other players. Motor skills are obviously involved in the fine manipulation of tools in trade and craft work, and in bowling, catching, or kicking and making strokes with bat, racquet, or club in various games. However, the core of all these skills, especially at higher levels of expertise, lies in processes of choice and decision. Thus highlevel skill in craft and trade work lies less in the ability to execute particular manual operations, such as shaping clay on a potter's wheel or cutting cleanly through a piece of metal with a hacksaw, than in deciding what shape is needed or exactly where the cut should be made. Similarly, highgrade athletic skill lies more in the strategy of the game than in the ability to make accurate individual strokes or in sheer muscular strength. Again, in music, the soloist's skill transcends the mere playing of the instrument to the interpretation of the score.

Strategies are developed and become more efficient in the course of practice, and it is these rather than basic capacities that are amenable to training. Four points should be noted.

1. For improvement to occur with practice, some knowledge of results achieved by previous action (*feedback) is required, and, broadly speaking, the more precise and direct this is the better. Early in practice feedback needs to be detailed, but when comprehension and action become organized into larger units the need for feedback within these is reduced. In extreme cases the units become 'automatic' in the sense that conscious attention to feedback no longer occurs and the performer has little awareness of what he is doing. When this stage is reached two results follow. First, because each decision covers a larger unit of performance, fewer need to be made, so that action becomes smoother and less hurried—the skilled performer 'seems to have all the time in the world'. Secondly, performance becomes highly efficient, but may also become rigid in the sense that it cannot be adjusted to meet changing circumstances. A highgrade yet versatile expertise involves a nice balance between such efficiency and flexibility.

2. Strategies and information acquired in training for one task may* *transfer* to others: for example, techniques learnt when mastering a foreign language can be applied again when studying another language. Such transfer usually results in the later task being mastered more easily than it would otherwise be, but occasionally the reverse is true: for instance, the coordination between tilt and movement needed to ride a bicycle leads to gross oversteering if applied when riding a tricycle, and must be inhibited before the tricycle can be ridden successfully.

3. Improvement with practice is typically rapid at first, then more gradual but continuing over long periods: for instance, the speed of some repetitive work in factories has been shown to rise with time

on the job over several years.

4. Once high levels of skill have been attained, they are usually well preserved over periods of many years. The fine edge of performance may be lost without continual practice, but can usually be regained relatively quickly.

Most discussions of skill have been concerned with men or women interacting with machines, tools, or other objects in their environment. It has recently been recognized that the concepts of skill can be applied also to the interaction of one human being with another. *Social skill* includes all the three types already distinguished. It includes perception of the needs and desires of others and of the effects upon others of one's own actions; decisions about how to react to the behaviour of, and communications from, others to achieve rapport and to influence them in ways desired; and on the motor side it includes the making of gestures, kissing, and modulations of the voice in expressing feelings such as sympathy. Social skill applies not only to relationships between individuals, but is essential for efficient leadership and communication in industry and other organizations, and is indeed necessary for living satisfactorily in any society.

SKILLS, MEMORY FOR. One apparently never forgets how to swim or ride a bicycle. Is this really the case? If it is, does it mean*memory for skills is in some fundamental way different from other kinds of memory?

What is the evidence? The fact that one does not immediately fall off a bicycle when remounting after an interval of several years does not necessarily mean that no*forgetting has occurred, it simply means that *something* has been retained. Fortunately we do have an answer to the question, based on studies of specialized skills under relatively controlled conditions.

The answer turns out to depend on the type of skill involved. Here we must distinguish between continuous and discrete skills. A continuous skill involves the performer in continually varying his response to a continuously varying stimulus. An example of this would be the steering response

Page 717

involved in driving a car, or the balancing involved in riding a bicycle, or for that matter simply

maintaining an upright posture while walking. Such skills can be contrasted with discrete skills in which a discrete individual response is made; typing or manually changing gear in a car would be examples of such skills.

There was a good deal of interest in the acquisition and retention of continuous skills during the Second World War, since the skill of flying a plane clearly has a continuous component, as indeed does learning to control a missile using a joystick. Over the years, a number of experiments have studied the retention of continuous tracking performance, typically using a task in which the subject is given a joystick and required to control the movement of a spot of light on a cathode ray tube.

Usually an analogue computer is used to simulate the control characteristics of the plane or missile, with a movement of the joystick changing the velocity of the missile or its acceleration, and producing a response that may be immediate or may follow only after a lag.

Fleishman and Parker (1962) studied a very difficult version of such a task. It involved threedimensional tracking under conditions which simulated the problem of flying a plane on the attack phase of a radar intercept mission. They trained their operators over a sixweek period, giving them 357 separate oneminute trials, by which time they were performing the task well. The operators were then split into three groups and given no further access to the apparatus. Retention of the skills was then tested, with one group returning after nine months, one after fourteen months, and one after two years. In all conditions, after a single warmup trial to refamiliarize the subjects with the situation, performance was virtually as good as it had been immediately after the end of training. A number of subsequent studies have replicated this and shown that even the warmup decrement shown on the first test trial can be reduced if the subject is sufficiently highly practised.

In the case of discrete motor skills, forgetting does occur. Consider, for example, the study by Baddeley and Longman (1978) in which a large number of postmen were trained to use a typewriter. The purpose was to familiarize them with the typewriter keyboard, which was subsequently to be used as part of a lettersorting machine. Since the equipment was not ready at the end of the training experiment, it proved possible to study the retention of the skill under conditions where no subsequent practice was occurring, an unusual situation in the case of typing. Even after a warmup period, clear forgetting occurred, with the average rate of keying dropping from about 80 strokes per minute at the end of the training session to about 70 per minute after one month, and to about 55 per minute after a ninemonth delay. At the same time errors increased from about 1 per cent of keystrokes to somewhere in the region of 3 per cent.

Why the difference between the two types of skill? At present we can only speculate, but one possible interpretation is as follows. One source of forgetting is that of retroactive interference. A person learns to associate a particular stimulus with a particular response or action: for example, he learns that a bathroom tap with the letter C on it is likely to produce cold water if turned on. After a while such an association will become relatively automatic. If the situation then changes—for example, if he goes on holiday to Italy where C stands for *caldo*, 'hot'—then he will probably make a number of mistakes before adjusting. On returning to 'Englishspeaking'

bathrooms he is likely to find that, to begin with, the previous habit interferes with his response, causing him to make at least one or two initial errors, although the massive amount of prior learning will mean that it takes very little time to revert. In brief, what has happened is that the person has learned two separate responses to the same stimulus, and at times he will recall the wrong one.

It seems likely that at least some, and some theorists would claim all, forgetting occurs because of interference from other learning (cf. TRANSFER OF TRAINING).

In the case of a discontinuous or discrete skill, the same stimuli probably occur in a range of situations where the relevant motor response cannot or should not be made. For example, our trainee typists would clearly go on being in a situation where they were responding to printed text by reading or writing rather than by hitting the appropriate key. This would be expected to cause some interference and hence some forgetting, although the amount of interference would depend very much on the precise conditions involved in the two interfering tasks. One might contrast this with a continuous skill in which the operator is functioning as if in a closed loop, with his own responses and their interaction with the environment producing the stimulus for further response. In any situation other than that of performing the skill, the essential stimulus situation is simply not evoked, and hence no interference can occur.

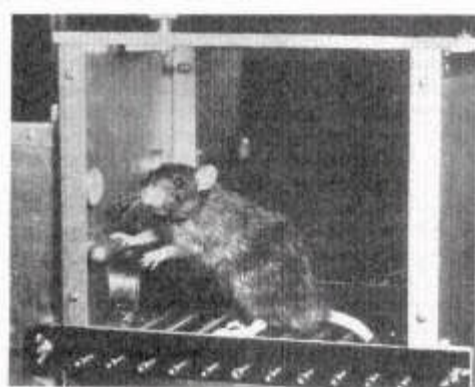

Having presented this view, it should be pointed out that there is very little evidence either for or against it, and our knowledge of the detailed operation of interference effects is certainly not sufficiently great to allow one to regard it as more than a speculation. The basic phenomena, however, are reasonably well established, so you can assume with some degree of confidence that you will not forget how to ride a bike, or perhaps even more importantly, how to swim.

SKINNER, B. F., American psychologist (1904). See BEHAVIOURISM, SKINNER ON.

SKINNER BOX. A type of experimental chamber often used in the laboratory analysis of behaviour, named after the American psychologist B. F. Skinner. As a graduate student at Harvard in 1929, he invented the first such chamber to facilitate the study of eating behaviour in rats, and he later developed many versions.

The prototypical Skinner box for, say, a rat (Fig. 1) would be cubic in shape, a foot (30 cm) long on each edge, and would contain the following elements: (i) an

'operandum', such as a lever that protrudes from one wall, and (ii) an opening in that wall where the rat could obtain a small pellet of food, delivered by a mechanical feeding device. The box would be light and soundproof to minimize distractions and maximize the effectiveness of events that occur inside the box. If leverpressing produces a pellet of food in this situation, a hungry rat will typically press the lever repeatedly and thereby eat.

Since its invention, the Skinner box has been adapted to study many organisms besides the rat, behaviours other than barpressing, and consequences other than food presentation. Behaviour has been studied in the context of auditory and visual stimuli, such as coloured lights and pure tones, as well as more complex stimuli, such as other organisms and slides of the natural environment projected on a screen inside the chamber. In general, the term is now applied to almost any experimental chamber used in the study of the relationships between behaviour, its antecedent stimuli, and its consequences.

The use of the term probably began with Clark*Hull, who made use of what he called a 'modified Skinner box', described in his *Principles of Behavior*. Skinner himself objected to the use of

Fig. 1.

The interior of a typical Skinner box. A hungry rat is poised over a lever protruding from the front wall. Pressing the lever one or more times will operate a feeder; the rat can retrieve a pellet of food which is dispensed at the small opening in the wall. The rat can easily learn to make discriminations—for example, to press the lever when a light is on and not to press it when the light is off.

Chambers for other animals may vary considerably from this one.

the term and in particular to its erroneous extension to the 'aircrib', an enclosed crib for human infants that he invented in the 1940s.

R. E.

SLEEP. A third of our lives is spent in sleep. Of the remainder, some is spent in wishing that our small children would sleep longer, and, during our later years, some is spent wishing that our sleep was less broken. What is sleep? It is a healthy state of inertia and unresponsiveness that is recurrently imposed by unknown mechanisms within the nervous system. In most animals the sleepwakefulness rhythm is coupled to the twentyfourhour lightdark environment, as are the restactivity cycles of lower life forms; there is no sharp demarcation between creatures which can be said simply to have rest phases and animals which certainly sleep. In animals possessing developed brains there are electrical rhythms that differ in sleep and in wakefulness, being generally slower during sleep.

The*biological clock that makes us sleepy every twentyfour hours means that shift workers and those who have just flown to different time zones are often tired and inefficient while they are trying to be alert (see JET LAG). If it is a long time since we last slept then that too makes us sleepy. Monotony, warmth, restricted movement, and a sense of waiting for something that cannot happen yet—all of

these make us sleepy. A sleeplike state of 'animal hypnosis' can also follow extreme stimulation.

The amount of sleep each species takes is proportional to the need for restoration, i.e. to the waking metabolic rate, but is in part also determined by predator status: those animals who sleep safely sleep longer. Among human beings there are wide variations. A few are happy and healthy with under three hours' sleep a night; a minority of others will take as many as ten hours. In general those who habitually sleep longer have shorter*reaction times and higher body temperatures by day.

Infants sleep a lot, but the sleep of ageing people becomes more and more broken with the years. A person sleeps less if he gets thin and sleeps longer if he gets fat.

There are two kinds of sleep that in man alternate with each other about every 100 minutes. Orthodox sleep (nonrapid eye movement, or NREM sleep) occupies 80

per cent of the night, and paradoxical sleep (rapid eye movement, or REM sleep) about 20 per cent. The amount of paradoxical sleep is greater in the newborn, but in adults is proportional to body weight, and among mental defectives to*intelligence. It is diminished by*anxiety and by many drugs.

Neither of the two kinds of sleep should be thought of as deeper than the other: they are different. Mental life continues in both, but whereas awakenings from orthodox sleep and questions about preceding mental life, generally lead to reports of 'thinking', awakenings from paradoxical sleep are generally followed by detailed descriptions of '*dreaming'. However,

Page 719

the recall of dreams is much diminished if as little as five minutes of orthodox sleep intervenes prior to awakening. In paradoxical sleep most body muscles are profoundly relaxed and many reflexes are lost, the blood flows faster through the brain than during wakeful rest, and in men the penis is erect.

Talking may also occur in both kinds of sleep, and reports made after prompt awakenings show concordance between the words and what was being thought or dreamt about. Sleepwalking (see SOMNAMBULISM) and 'night terrors' arise from orthodox sleep early in the night, as do most episodes of bedwetting. The shriekings of a night terror often occur with sleepwalking, and liability to them runs in families. They are never remembered in the morning.

Indeed, memory of the events of sleep is always very poor. 'Sleep learning' by means of a taperecorder playing lessons all night is ineffective: although what has been heard while still awake may be remembered, nothing of what was played during sleep will be recalled; to remember we must have paid*attention, and in sleep we do not pay attention. Even so, sleep is important for memory. If a list of nonsense words is learned, and memory of them is tested eight hours or twentyfour hours later, more of the list will be remembered after twentyfour hours, given an intervening period of sleep, than after eight hours without sleep. It seems that memorytraces are strengthened during sleep, maybe especially by paradoxical sleep; and since they presumably depend upon the durable molecules of brain protein, this can be understood.

Protein synthesis is favoured by sleep and so sleep enhances growth and restoration. Tissues such as the skin are restored by growth of new cells, and this growth proceeds faster during sleep. Throughout the body's tissues there are protein molecules being broken down and being synthesized all the time. There is a twentyfourhour variation in the rate of synthesis, the rate being fastest during the period of rest and sleep. In the cerebral cortex, and the retina, protein synthesis is faster during sleep, and in the anterior pituitary there are more cell divisions. The fact that the balance shifts away from degradation towards greater net protein synthesis is a consequence of a lower rate of cellular work during sleep.

In higher animals there are hormones that reinforce the more fundamental effect of the lower rate of cellular work. In man, growth hormone is specifically released by orthodox sleep with the largest continuous slow electrical brain rhythms ('slowwave sleep': see ELECTROENCEPHALOGRAPHY). Growth hormone promotes protein synthesis. On the other hand, adrenaline and corticosteroids are hormones which are plentiful during wakefulness and which increase protein breakdown. In the blood during sleep, these latter hormones are diminished, and that means that the growth hormone is even more effective. Slowwave sleep is not merely the time of growthhormone release, it is the time when responsiveness to meaningful sounds or to an itchy skin is minimal, when the body's oxygen consumption is lowest, and cellular work is lowest, and therefore slowwave sleep is 'worth more' than lighter (more responsive) stages of orthodox sleep. If there is a greater need for restoration, as after sleepdeprivation, or after an athlete has trained hard, then the next night there is a higher proportion of slowwave sleep and extra growth hormone.

Sleepdeprivation causes sleepiness. It is difficult to keep awake anyone who has been deprived of sleep for 60 hours. Such a person has frequent 'microsleeps' and recurrently fails to notice things he ought to notice, being unable to sustain a high level of attention. Sometimes visual*illusions or*hallucinations are experienced or the individual becomes*paranoid. After about 240 hours there are signs of adaptation to a more uniform but inert and dulled state.

People who complain of lack of sleep (insomnia) actually sleep more than they suppose. Indeed, the most distinguishing feature of their sleep is the degree to which it exceeds their own estimates— but we cannot yet measure its relative restorative value. Complaints are commonest among women, among those of nervous temperament, and among older folk; and it is they who account for most of the sleeping pills consumed. Although most sleeping pills today belong to the benzodiazepine class and are safe and effective, prolonged use leads to dependence, and attempts to stop them are accompanied by heightened anxiety, nightmares, and poor sleep for a week or two. Regular physical exercise; a goodquality, firm mattress; a warm but ventilated room; a malted milk drink, and sexual satisfaction at bedtime—all these promote good sleep; but they will not cure everyone's complaints. It has to be accepted that broken sleep is as normal a part of growing older as are grey hairs or wrinkles, though insomnia of sudden onset can be the result of mental depression, an illness amenable to treatment.

Finally, let it be emphasized that sleep is not a slothful habit. Its study as a necessity encompasses the whole functioning of the body and, with the study of dreams, some of the mind's most intriguing qualities.

SLEEPWALKING. See SOMNAMBULISM.

SMELL. Although all living things, both plant and animal, respond selectively to at least some of the chemicals in their environments, what we ordinarily mean by smell is more limited than this.

Page 720

There are really two ways of deciding whether or not we are dealing with smelling rather than some other chemical sense. In the vertebrates—fishes, amphibians, reptiles, or mammal—we define smell as involving the stimulation of the first cranial nerve, the olfactory nerve. In the invertebrates, however, we refer to smell when the stimulating substance is airborne. Thus, for example, a moth finds his mate by means of smell. This inclusion of the invertebrates is important because much of the best controlled (and economically important) study has been and is being done on insects. In man, of course, both these qualifications apply and we speak of smell as involving the first cranial nerve and as having airborne molecules as its stimuli.

In man and other mammals the receptors for smell lie in the mucous membrane at the top or back of the air passages in the nose. These sensitive cells are in a constant state of decline and replacement. They are equipped with hairlike projections, the cilia, which protrude into the mucus and are the probable sites of odorant-receptor interaction. In man, the region of each nostril that they occupy is about the area of a postage stamp—small compared with, say, that in the dog. The cells send their axons directly into the olfactory bulb, which is also relatively small. (Smell is unique among the senses in not having connections through the thalamus to the 'new cortex' or neocortex that has developed in relation to the other sense departments. In fact, the older portion of the forebrain of mammals is called the 'rhinencephalon', or 'smell brain', because of this.) There are many fewer transmission cells in the bulb than there are receptors, and this fact, in addition to the preservation of spatial distribution from receptor surface to bulb, is thought to be important in the perception of odour quality. The system is sensitive and compares well, even in man, with most laboratory methods of analysis: for example, one form of musk can be detected by a 'normal' person at a dilution of less than one tenmillionth of a milligram per litre of air.

Attempts to understand the manner in which odorous molecules affect the receptor cells have led to considerable theorizing without conspicuous success. The problem to be solved is similar to that for any of the senses: how a stimulating agent so alters a cell as to set in play the series of events that result in one or more nerve impulses being transmitted to the central nervous system. In man it is obvious that the molecules either make their way through the mucus and affect the receptor directly in some way, or act at a distance. Both means have been proposed. In explanation of action at a distance, it has been suggested that the characteristic infrared absorption spectrum of a molecule leads it to absorb radiation from certain of the matching receptors. Unfortunately, this is thermodynamically impossible. Other absorption theories, such as the Raman spectrum and ultraviolet, seem aimed more at classifying the molecules than at implying action at a distance.

Theories supposing action directly on the receptor are better supported by modern research. Many have been developed with pharmacological or immunological models in mind. The current conception of the receptor cell membrane as a lipid (fatty) double layer in which protein molecules are embedded in mosaic fashion is compatible both with the suggestion that the molecules actually dissolve in (or 'puncture') the lipid, rather like the anaesthetic action of ether, and with the notion that adsorption takes place on the proteins. Evidence of molecules that differ only in being 'right' or 'lefthanded' implies that the proteins are involved, and the theory provides a simple basis for understanding the selectivity of different cells. Precisely what energy transfer is involved is uncertain, but with modern membrane research methodology, including the use of radioactive tracers, resolution of this problem should be forthcoming.

The pervasive role of smell in everyday life is often overlooked. Many unpleasant smells, such as of garbage and offal in the city of not so long ago, have been got rid of. Highly sophisticated methods of washing, filtering, and incinerating odorous discharges have been developed, and there is a host of personal deodorants and air

'purifiers'. On the other side of the coin, the flavours of foods are pretty largely determined by odour—a fact recognized by the international flavour industry. Closely related is perfumery, with its long history.

In the fashions that have surrounded perfumery, sexual attractiveness may be involved. Certainly in many species, particularly the insects, naturally secreted odours, pheromones, play a sexual role. In mammals, pheromones also play an important role in the establishment of territories: the 'marking' activities of dogs are well known, and in other species special glands—for example, the cheek glands of the rabbit—produce marking chemicals. In the mouse the sexual and marking functions come together—the female will ovulate after smelling a male, and will, if pregnant, abort upon smelling a strange male. While some Primates—the baboon, for instance—

seem to have female pheromones secreted during receptivity, it is not presently clear what role, if any, such secretions might play in man.

One function of smelling is well known: the detection of leaking gas. To nonodorous gases, a warning agent such as ethyl mercaptan is added. In mines, the ventilating system is used to carry the warning.

An apparent overrepresentation of older people among the victims of a gas leakage in London led to useful research on the effect of age on sensitivity to smell. (See AGEING: SENSORY AND PERCEPTUAL CHANGES.)

For smell, unlike colour, there is no satisfactory classification scheme. One difficulty is the absence of truly abstract terms such as red or blue; rather, the terms refer to objects (for example, lavender or fruity) or condition (burnt or rotten). Possibly no simple scheme will be found, for the basic scale

Page 721

along which we place odours is from pleasant to unpleasant—a scale that may reflect the approach-avoidance nature of behaviour in evolutionary history. It may be the only way for the organism to classify odours.

Three other topics need mention. First, there are considerable differences between the smell sensitivity of individual persons. Some even, because of disease or trauma, cannot smell anything at all—they are anosmic—while others lack sensitivity for specific odours—they are partially anosmic. Second, adaptation (that is, temporary loss of sensitivity with exposure) proceeds fairly rapidly for smells. This is largely a matter of reduced transmission in the brain, rather than fatigue of the receptors. It makes some jobs tolerable; but sensitivity to warning agents is reduced. Finally, it may be that sensitivity declines with age. If this is in fact so, and it is not certain, then among the important consequences would be diminished stimulation from flavours (see TASTE). Possibly some of the nutritional problems of ageing are ascribable to declining sensitivity.

SOCIAL PSYCHOLOGY studies how individuals relate to the societies they live in, particularly in so far as those relations are mediated by face-to-face interaction.

Children first learn languages, moralities and positions in class structures, not by encountering abstract entities labelled 'institutions' or 'social structures' but primarily through everyday intercourse with others. When, as adults, we are in contact with economic, legal or religious institutions, the contacts in practice are usually with employees or agents of the institutions.

Social psychology should continually be interrelating three levels of analysis: the individual, the interpersonal, and the social structural (which should be taken to include economic and political

structures). According to this view, it is something of an interstitial science: it aims to link the study of the individual by general psychology and the biological sciences to that of society by sociology and the other social sciences, and it is thus a very challenging and potentially pivotal social science. Its practitioners, however, have not always fully recognized either the challenge or the potential. To understand why not, a little history is necessary.

The historian of social psychology (e.g. Allport, 1985) can manage without difficulty to appropriate as progenitors of social psychology most of the major thinkers of Western civilization from Plato and Aristotle onwards. But the term 'social psychology' did not appear, as the title of a book for instance, until 1908, when it was used twice, by W.*McDougall, a British psychologist, and by E. A. Ross, an American sociologist. Even so, the immediate origins of what has come to be social psychology are apparent for about half a century before then. Many of the originators were European. Le Bon, Tarde, and Durkheim in France; Simmel,*Weber, and*Wundt in Germany;*Freud in Austria, and*Darwin,*Spencer, and McDougall in Britain can all be seen, in part at any rate, as contributors to the emerging discipline. Had their contributions prevailed, then social psychology would have emerged as a biologically based—or at least 'instinct'based—theoretically oriented endeavour. But they did not. Whether because a psychologically inclined social analysis was more congenial to the pervasive individualism of American social and political life, or because it proved easier for social psychology to become institutionalized in newer American than in ancient European universities, the subject established itself more readily in the United States, where it rapidly adopted the environmentalism of American sociology and the empiricism of American psychology.

The main sociological influences were those of the Chicago school of symbolic interactionism, derived in turn from American pragmatic philosophy. G. H. Mead's (1934) analysis of the social construction of an individual's sense of self must be given pride of place, but other contributors within that tradition have included C. H.

Cooley, W. I. Thomas, and, more recently, E. Goffman. American psychologists who exerted influence on the beginnings of social psychology included J. M. Baldwin, G. S.*Hall, and W.*James, but it has been less the ideas of particular psychologists and much more the practices of psychology in general that have proved most influential. A very early—perhaps the first—line of sustained empirical enquiry started from a study by N. Triplett in 1898. In order to examine the impact of the presence of others on the efficiency of individual performance, he had children wind in string on fishing reels on their own and competitively in pairs. From this study there developed a tradition of research on the consequences of the presence of others which today is still actively pursued as 'social facilitation'. This tradition has asked apparently limited questions and has been content with smallscale theories; its questions appear to be readily answerable and lend themselves to experimental studies in laboratories; it takes universality for granted and hence need only study undergraduates in Ann Arbor. Each of these can be regarded as a legacy from American psychology, and the general approach has been and is typical of most social psychology in North America. The approach reached its zenith with the selfconscious creation in the 1960s of a movement towards 'experimental social psychology', whereby prestigious work would be virtually confined to elegant experiments conducted in sophisticated laboratories and interpreted in terms of carefully formulated minitheories; this latterday

methodological purification would demonstrate that social psychology could be (almost) as rigorous as the asocial parts of experimental psychology.

A decade of such endeavours was enough to provoke numerous criticisms. Two complementary critiques merit mention, those of method and scope. Microsociologists in America, as well as R. Harré in Britain, questioned the appropriateness of laboratory experiments for studying human social experience, because of their artificiality and the mechanistic views of man which, it was claimed, they imply. The main criticisms from resurgent social psychology in Europe, as voiced by S.

Moscovici, H. Tajfel and others, were directed at the narrowness of American experimental social psychology: it studied individuals and sometimes interindividual influences, but had ceased to be social; society must be brought back into social psychology. Despite some soulsearching, mainly about the ethics of experiments, the critiques had a limited impact in the United States. 'Experimental social psychology' was updated, thinly disguised and renamed 'cognitive social psychology'; the detailed psychological examination of individual attributions and judgements contrasted with the poverty of social analysis, and technical rigour was far more obvious than social relevance. H for no other reasons than numbers and resources, this narrow view of social psychology became the dominant one, but it has had to compete with a broader, if more diffuse perspective, derived in part from social psychology in Europe, in part from sociology and other social sciences. This broad view, which has been able to incorporate much of the narrower one, has organized the substance of social psychology around three interlocking sets of issues, each set demanding all three levels of analysis but highlighting one or other of them.

First, there is the social nature of the individual. How has biological inheritance been acted upon so that, within about twenty years, the microscopic egg has become an effective, fully functioning member of society, and over a life span the individual personality or self, while maintaining coherence and continuity, has also adapted to changing situations and roles? In part the self emerges through interaction with others. Parents imputing intentions to the infant help purposiveness and intentionality to develop in the child; and the everincreasing expectations of the child encourage more and more complex, intelligent actions to appear. But the self is, in a sense, a product of social structure as well as of facetoface interaction. In large part one's personal self is made up of one's views of the salient social categories to which one belongs. As a result, the study of differences and supposed differences between the sexes, classes, ethnic groups and the like is intrinsic to a properly social conceptualization of the individual.

The second substantive focus is social interaction. Here the social psychologist studies the acquisition and use of language and the nonlinguistic communication systems not just as an achievement or skill of an individual but as the means whereby dyads and groups can succeed, or fail, in creating an intersubjectivity, or temporarily shared world which makes possible the transmission of information, the exchange of feelings, and the creation and fulfilment of common tasks. And once some understanding of the details of interaction has been achieved, the details themselves can be used to illuminate the operation of largerscale social processes. Who is addressed as 'Sir' and who 'as 'Bill' can quickly tell us much about the operation of status and power within a community; the

willingness, or reluctance, of a speaker of one language, or dialect, to switch to another for the benefit of a stranger can be very informative about the relations between communities. In addition to the details and dynamics of interaction, social psychologists increasingly study the sustained interactions that are interpersonal relationships, their initiation and development through dating, mating and marriage, their maintenance over time, and their dissolution or collapse through, for example, bereavement or divorce.

The third focus consists of representations of the social world. How do we view and think about the social world around us, and what effects do these 'pictures in our heads' have on our actions? Some representations concern individuals and interpersonal processes. Currently a major concern of American social psychology is the attributions to, or inferences about, others that we make—especially whether and how we decide if someone's behaviour is intentional or not. Many complex representations, on the other hand, concern largescale social phenomena: ethnic groups, work, unemployment and the unemployed, to mention only a few. Particular representations held by specific individuals may of course be in large part idiosyncratic, but the representations that merit systematic study will usually be those that are socially shared. Whether idiosyncratic or widespread, representations have traditionally been studied in social psychology via the concept of 'attitude'. For the study of shared representations, European social psychologists have recently shown interest in the French conception of 'social representation' (Moscovici and Farr, 1983), and even the notion of 'ideology' which hitherto they had largely eschewed (Billig, 1976).

The broader, largely European, view of social psychology underlay the definition with which we started, and it is with that view that the best hopes of realizing the potential of the discipline appear to lie.

SOCIOBIOLOGY. See ETHOLOGY.

SOCIOPATHIC PERSONALITY. See PSYCHOPATHIC PERSONALITY.

SOCRATES (469/399 BC). The son of Sophroniscus, a sculptor, and Phaenarete, a midwife, Socrates distinguished himself for bravery in three campaigns at Potidaea, Amphipolis, and Delium. He wrote no books, though the Delphic oracle declared in his own time that he was the wisest man in the world. Physically, he was, as he himself admitted, ugly, with a snub nose. The shrewish temper of his wife Xanthippe is now legend and was probably fact.

Socrates is immortalized in many of Plato's dialogues, including the *Apology*, which gives his defence when he was charged in 399 BC with corrupting the young, as

'an evil doer and a curious person, searching into things under the earth and above the heaven; and making the worse appear the better cause, and teaching all this to others'. He was condemned to death, by a majority of six in a jury of perhaps 500. His friends planned his escape; but he refused to break the law, and in their company he drank hemlock and, still talking philosophy, died. His last days are most poignantly described in Plato's *Phaedo*.

Socrates is celebrated both for his personal qualities of courage and for maintaining the highest moral standards while yet being susceptible at least to wine and no doubt to the other traditional temptations. He was no recluse, or monastic; but lived to the full the life of a man. Philosophically, he represented, at the highest, values of questioning and discussion without bigotry or preformed conclusions, thus exposing feeble arguments and prejudice.

Guthrie, W. K. C. (1971). *Socrates*. Cambridge.

SOMATOTOPICAL. A term referring to brainmaps or representations of the body surface, especially by signals from the skin receptors indicating touch. The somatotopic maps in the brains of vertebrates, including humans, are upside down—so that the feet are represented at the top and the head at the bottom of the map, which can be explored with microelectrode recording from the exposed brain surface. This curious arrangement is probably due to the need for rich relations between visual and touch mapping in the brain. As the retinal image is upside down (and laterally reversed) due to the optics of the eye, the touch maps are similarly inverted to simplify and shorten crosssensory neural connections.

See also LOCALIZATION OF FUNCTION AND CORTICAL MAPS.

SOMATOTYPE. See BODY BUILD AND PERSONALITY.

SOMNAMBULISM. A sleeper may engage in a variety of more or less coherent activities. He may

talk, for instance, or move purposefully, or get up and walk. He then appears dazed, preoccupied, and unresponsive to much that goes on round him. He tends to avoid obstacles, but may incur danger because he is clumsy and unreliable. He may return to bed on his own. After waking he has no memory of the incident. A child may walk half-asleep to the lavatory and return to bed, but usually somnambulism is less purposeful. Sometimes, but not typically, a sleepwalker appears to be acting out, like Lady Macbeth, fragmentary and irrational dream experiences.

Somnambulism is not uncommon among children. It may be repeated several times over a short period and then not occur again. It is said to run in families. It tends to occur early in the night, during 'orthodox' sleep, when large, slow waves are to be seen on the *electroencephalogram.* Dreaming, on the other hand, occurs typically during 'rapid eye movement' (REM) sleep. Somnambulism is distinct from the night terrors shown by children. When it is associated with persistent and severe disturbance of behaviour, as in the case of Lady Macbeth, it may be regarded as a manifestation of the 'twilight state' which occurs in some forms of mental illness.

Although it is very unusual for a sleepwalker to harm anyone else, there are cases on record where it has been claimed that acts of homicide have taken place during an episode of sleepwalking. In some of these the accused person had been drinking before falling asleep, only to wake later to find that he had killed his bedmate. It is difficult to believe that sleepwalking in an undrugged state could possibly persist throughout a violent struggle such as would occur if the victim of a homicidal assault made every effort to resist. Furthermore, because sleepwalking takes place during orthodox sleep, and not during dreaming REM sleep, the sleepwalker who acts violently would be unlikely to be acting out a dream in which he might believe that he is defending himself against attack. None the less, pleas of somnambulism have been accepted as defences against charges of murder both in Great Britain and in the USA.

SOUL, BRAIN SCIENCE AND THE. Mechanistic brain science proceeds on the working assumption that every bodily event has a physical cause in the Page 724

prior state of the central nervous system. Traditional moral and religious thought, on the other hand, has always presupposed that some at least of our behaviour is determined by our thinking and deciding. This apparent conflict has given rise to suggestions that unless some parts of our nervous system are found to be open to nonphysical influences, brain science will effectively debunk all talk of man as a spiritual being, and oblige us to accept a purely materialistic view of our nature. Many people seem to expect a battle to be fought between religion and the neurosciences like that waged by some theologians in the nineteenth century against evolutionary biology.

How justified is this impression? It is true that the seventeenth-century French philosopher-mathematician René*Descartes held that the mind or soul would be powerless to influence bodily action unless some part of the brain could act as a transmitter-receiver for its

controlling signals. He considered that the pineal gland, in the middle of the head, was ideally suited to the purpose. 'In man', he says,

the brain is also acted on by the soul which has some power to change cerebral impressions just as those impressions in their turn have the power to arouse thoughts which do not depend on the will.... Only [figures of excitation] traced in spirits on the surface of [the pineal] gland, where the seat of imagination and common. sense

[the coming together of the senses] is ... should be taken to be ... the forms or images that the rational soul will consider directly when, being united to this machine, it will imagine or will sense any object.

In recent years the neurophysiologist Sir John Eccles and the philosopher Sir Karl Popper have advanced theories of the 'interaction' of mind and brain, which, though they differ in important respects from that of Descartes, agree with him that the brain must be open to nonphysical influences if mental activity is to be effective.

At first sight this might indeed seem obvious common sense; but a simple counterexample throws some doubt on the logic of the argument. We are nowadays accustomed to the idea that a computer can be set up to solve a mathematical equation. The mathematician means by this that the behaviour of the computer is *determined* by the equation he wants to solve; were it not so, it would be of no interest to him. On the other hand, if we were to ask a computer engineer to explain what is happening in the computer, he could easily demonstrate that every physical event in it was *fully determined* (same word) by the laws of physics as applied to the physical components. Any appearance of conflict here would be quite illusory. There is no need for a computer to be 'open to nonphysical influences' in order that its behaviour may be determined by a (nonphysical) equation *as well* as by the laws of physics. The two 'claims to determination' here are not mutually exclusive;

rather they are *complementary*.

The analogy is of course a limited one. We (unlike our computing machines) are conscious agents. The data of our conscious experience have first priority among the facts about our world, since it is only through our conscious experience that we learn about anything else. Our consciousness is thus not a matter of convention (like the mathematical significance of the computer's activity) but a matter of fact which we would be lying to deny. Nevertheless the logical point still holds. If we think of our mental activity as embodied in our brain activity, in the sense in which the solving of an equation can be embodied in the workings of a computer, then there is a clear parallel sense in which our behaviour can be determined by that mental activity, regardless of the extent to which our brain activity is determined by physical laws.

The two explanations, in mental and in physical terms, are not rivals but complementary.

Note that we are here thinking of mental activity as *embodied in* brain activity rather than *identical with* brain activity. The latter is a notion favoured by what is called

'materialist monism', at the opposite extreme from the 'interactionism' of Eccles and Popper. This would simply identify 'mind' and 'brain', and would go so far as to attribute 'thinking' and other mental activities to the matter of which the brain is composed. The objection to this extreme view can be understood by once again considering the example of a computer. It is true that the solving of an equation is not a separate series of events, running in parallel with the physical happenings in the machine. It is rather the mathematical significance of one and the same series of events, whose physical aspect is well explained by the engineer. On the other hand it would be nonsensical on these grounds to identify equations with computers as physical objects, or to attribute mathematical properties (such as 'convergence' or

'being quadratic') to the physical matter in which the equation is embodied.

By the same token, even if we regard our thinking and deciding as a 'mental' or 'inner' aspect of one and the same (mysterious) activity that the neuroscientist can study from the outside as brain activity, this gives no rational grounds for taking the material aspect as more 'real' than the mental, still less for identifying the two and speaking of thinking and deciding as attributes of matter. This would be a confusion of categories belonging to different logical levels, for which nothing in brain science offers any justification.

It might appear that thinking of our conscious experience as 'embodied' in our brains would still be incompatible with the Christian concept of 'life after death'. What we have seen in the case of the computer, however, shows that there need be no conflict. The physical destruction of a computer is certainly the end of that *particular embodiment* of the equation it was solving. But it leaves entirely open the possibility that the same equation could be reembodied, perhaps in a quite different medium, if the mathematician so desires. By the same logic, mechanistic brain science would seem to raise equally little objection to the hope of Page 725

eternal life expressed in biblical Christian doctrine, with its characteristic emphasis on the 'resurrection' (not to be confused with resuscitation) of the body. The destruction of our present embodiment sets no logical barrier to *our* being reembodied, perhaps in a quite different medium, if our Creator so wishes.

SPACE PSYCHOLOGY. The early astronauts were required to be very experienced test pilots, very healthy and resistant to stress, and morally fit to represent the nation. In 1958 the records of 500 qualified men were reviewed, and seven were eventually selected to fly in the Mercury programme, after much psychological and medical screening. Some of the early tests—such as keeping the feet in iced water for seven minutes—now seem bizarre. The validity of the early psychological screening is

not known, since the 'failures' were not allowed to fly. Orbiting in a capsule sent up by a rocket was thought by some to be rather degrading in comparison with piloting an aircraft. Monkeys had been sent up first, so why send a human? It was soon evident that humans had a vital role in space: they could make observations, report back, make decisions, avert disasters, conduct experiments, and make repairs. And on the ground they were national heroes.

Many more candidates were trained for the Gemini, Apollo, and Skylab programmes. The emphasis shifted towards academic qualifications, and scientist-astronauts were accepted in addition to pilot astronauts. The advent of the space shuttle in the 1980s made space flight almost routine, and civilians were now allowed to fly as passengers with relatively little training. Indeed, instead of going to war, the Soviets and Americans now vied with each other to offer rides in space to political allies and 'minority' groups—rather as Solomon bearing gifts to the Queen of Sheba. The official route into space for a Western bloc civilian has been as a payload specialist (PS), his or her job being to look after some specialist aspect of the mission, such as a scientific or industrial experiment. The PS normally trains for one mission only, and should not expect to become a career astronaut. Much of this training is carried out in the laboratory of the payload developer, and relatively little time is spent learning how to operate the shuttle orbiter systems. PS applicants have had to go through the screening procedures of their own countries and those of NASA (the National Aeronautics and Space Administration) or ESA (the European Space Agency), a small number then being selected to train for a particular mission. Final selection has usually depended partly on performance in training, and partly on political and other considerations.

The number of scientific experiments conducted in space has increased enormously, as many as 70 being carried on Spacelab I in 1983. Civilian scientists have a correspondingly greater role in controlling space experiments. They, too, must expect to spend some time training to play their part in the complexities of a scientific mission. They must participate in 'timeline' simulations, and learn how to use the communication systems. Only then can they make full use of the space crew.

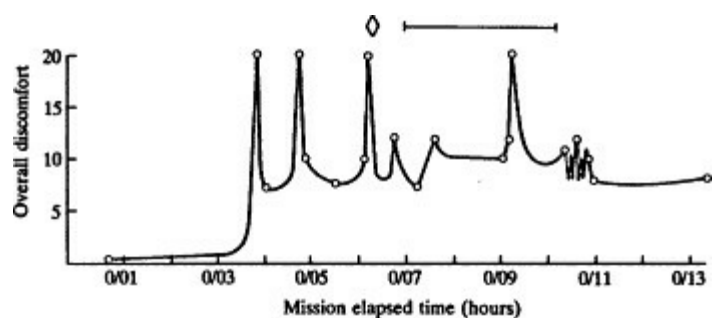

The mission. Many of the difficulties of living in space occur in other confined environments. These include isolation from the normal world and limited communication with it; problems of living in a small space; lack of privacy; social interactions within a small group; artificial day/night cycles and shift of circadian rhythms (see BIOLOGICAL CLOCKS); anxieties about the life-support system and a safe return to the normal world; tiredness due to long work schedules; delays in completing assigned tasks and coping with apparatus failures; and boredom on long missions. All of these difficulties are shared by deep-sea divers operating from submersible chambers.

The unique aspect of space travel is weightlessness. An orbiting spacecraft is in a state of free fall, because the earth's gravitational acceleration is exactly balanced by the radial acceleration produced by the curved flight path of the spacecraft. The resulting microgravity (near zero gravity) causes various physiological changes, such as a shift of body fluids to the head, loss of calcium in the bones, muscular atrophy, and changes in blood composition. One of the most distressing effects is that of space motion sickness, which has affected roughly half of all space travellers during their first two to four days in space. This was not a problem on early NASA missions, but the incidence appears to have increased. One reason for the increase is that crew members move around more in larger

spacecraft. The other reason is increasing detail in reporting symptoms: for example, a crew member of Spacelab I gave magnitude estimates of his feelings of discomfort during the first fourteen hours in orbit (Fig. 1).

Space motion sickness—like other forms of motion sickness—is probably due to sensory conflict. The normal correspondence between visual, vestibular, and tactile stimulation breaks down, and the traveller may feel disoriented and nauseated until his brain learns to reintegrate the sensory information. It is perhaps remarkable that this learning can occur within two or three days. There is, as yet, little evidence for a relationship between susceptibility to motion sickness on the ground and in space.

This may be because astronauts usually avoid subjecting themselves to provocative movements in space, and may not fully report their symptoms. Alternatively, it may be because the nature of the sensory conflict is slightly

Page 726

Fig. 1.

Magnitude estimate of discomfort for one subject during the first fourteen hours in orbit. A score of 20 indicates vomiting. Curves between data points were interpolated by the subject. Diamond represents medication (scopolamine and Dexedrine), followed by horizontal bar representing period of maximal effectiveness.

different in space. Passengers on earth are passively subjected to unusual changes in acceleration, whereas space travellers move in an environment that effectively lacks the force of gravity.

The vestibular system consists of the semicircular canals (whose sense organs respond mainly to rotary acceleration) and the otolithic organs (which respond mainly to linear acceleration and gravity). Head movements on earth produce a familiar combination of signals from the canals and otoliths. Under weightless conditions the canals operate normally, but the otoliths do not. They can no longer indicate head orientation with respect to gravity, but only linear acceleration foreaft or leftright or updown. The space traveller must therefore learn to reinterpret otolithic information. Pitch and roll

head movements seem to be particularly provocative, as are ambiguous visual stimuli such as seeing another crew member 'upside down' or being inverted oneself in relation to the spacecraft. Unlike the terrestrial traveller, the astronaut can remove himself from provocative stimulation: he can wedge himself into a corner, close his eyes and keep his head still. Drugs that protect against terrestrial motion sickness also reduce the symptoms of space motion sickness, though they may produce unwanted side effects such as drowsiness or dry throat.

Current experiments centre on the way in which humans adapt to altered gravitational cues. It seems that, early in a mission, they rely more heavily on visual cues to determine bodily orientation and the direction of gaze. Reflex eye movements of vestibular origin may be reduced, as may vestibulospinal reflexes. Humans learn how to move themselves around in space, using the hands and arms rather than the legs. They learn new patterns of hand-eye coordination: ballistic movements must be reprogrammed so as not to overreach in the absence of gravity. They must adapt to their own loss of arm weight, and learn to judge the mass of objects through inertial cues rather than weight. This appears to be difficult to do, since objects continue to feel light, and mass discrimination remains poor, even after several days in space.

Astronauts report good visual acuity for details seen on earth, and current research shows no consistent changes in near vision or the visual contrast sensitivity function.

The return to earth. The returning astronaut is rather like a swimmer staggering ashore after a long swim. He feels heavy and clumsy. In addition, his vestibular coordination is disturbed, and he may see the world swing round in an unusual manner when he moves his head. 'I felt like my gyros were caged,' explained one astronaut. These effects can cause difficulties for pilots who want to fly the shuttle back to earth manually. It takes a surprisingly long time for complete readaptation to the earth's gravity. For example, after the ten-day mission of Spacelab 1 some crew members were still showing some types of aftereffect a week later. There are a lot of individual differences in this, and it is not clear whether prolonged aftereffects are correlated with slow or rapid adaptation in space.

Some aftereffects may be due to the continued reinterpretation of otolith signals as linear accelerations rather than as head tilt, which results in postural instability with the eyes closed, and an increased reliance on visual orientation cues. There may also be some changes in sensitivity to linear acceleration in different body axes. Other effects may be due to changes in proprioceptive and tactile sensations, such as feelings of heaviness, underreaching for objects, reduction of weight discrimination (Fig. 2), and reduction in awareness of limb position.

Readaptation to gravity is not the astronauts' only problem. They may be short of sleep, or be required to shift their circadian rhythm to local time. They may face several long days of medical, physiological and psychological tests, debriefing sessions and press publicity. They must then face the reality of readjustment to normal life, and of difficult career decisions. The life of the astronaut is not quite as rosy as it is sometimes pictured.

The future. The Challenger disaster in January 1986 has reduced the West's enthusiasm for

Page 727

Fig. 2.

tests himself on return from the Spacelab 1 mission,
and shows impaired weight discrimination.

manned spaceflight, and has emphasized the advisability of launching satellites by remote control. Nevertheless, NASA's shuttle programme is likely to continue, but at a slower rate. Man's usefulness in space has been amply demonstrated, and NASA and ESA are planning to build a manned orbiting space station by the year 2000.

The crews will probably include more scientists and technicians, and will stay in space for weeks or months at a time. Research on the psychology of man in space is likely to move away from the causes of motion sickness (which ceases to be a problem after about four days) to the longerterm effects of living in space and returning to earth. Simultaneously, research will go on into the automation of astronauts' tasks, and efforts will be made to replace men with robots or teleoperators. This is unlikely to be practicable for many tasks, and we can expect to keep the 'manintheloop' for the foreseeable future.

SPATIAL COORDINATION OF THE SENSES. Almost everything that a human being does involves the*perception of the spatial locations of objects. The senses used in perceiving spatial locations are known as the spatial senses: they are vision, hearing, touch, and kinaesthesia. Kinaesthesia is the sense which enables us to appreciate the positions and movements of limbs, and depends on receptors in muscles, tendons, and joints, as well as on the sense of muscular effort involved in moving a limb or holding it in a given position. Movements of the head are detected by a set of specialized sense organs in the head, known as the vestibular sense organs.

The task of judging the spatial location of an object is complicated by the fact that sense organs are attached to mobile parts of the body. For instance, the receptive surface of the eye (the*retina) is attached to a mobile eyeball, which in turn is attached to a mobile head. If we wish to know the direction of a seen object with respect to the torso, the position of the eyes and of the head must be taken into account, along with information about the retinal position of the image of the object. This type of process is here referred to as sensory integration.

The position of an object is often detected by more than one sense organ at the same time. For instance, we may hold an object which we can also see and hear.

Furthermore, we usually see with two eyes and hear with two ears. Spatial information must be coordinated between different sense organs, either two organs of the same type or belonging to different spatial senses. This is the process of intersensory coordination.

Finally, after we have located an object we may wish to reach for it. This requires that sensory spatial information be coordinated with the motor commands which control the movements of limbs. This is the process of *sensorimotor coordination*.

Performance of any spatial task has an accuracy and a precision. 'Accuracy' is the extent to which the mean of a set of judgements deviates from the true value.

'Precision' is the extent to which spatial judgements are scattered about their mean position. A darts player is highly accurate, if the throws are evenly distributed about the target, even though the player is very imprecise because the throws are widely scattered. Another player is very inaccurate if the throws are well to one side of the target, even though all the throws land on the same spot.

Sensory integration. As an example of sensory integration, consider the act of estimating the direction of a seen object with reference to the body. Such a task involves estimating where the object is with respect to the eyes, how the eyes are oriented in the head, and how the head is oriented on the body. The visual direction of an object with respect to an eye is indicated by the position of its image on the retina. However, this task is simplified by the fact that we normally direct our gaze towards an object of interest and bring its image on to the centre of the retina (the *fovea*).

Information about the direction of the eyes in

Page 728

the head is provided by motor signals sent to the muscles that move the eyes, or hold them in a given position. An eye never has to move against a variable load, so that the muscular forces, and hence the motor signals, are always the same for a given position of an eye. There is no need for sense organs to indicate the position of the eyes; their position is always indicated by the sense of effort required to move them or hold them in position.

The direction of the head with respect to the body is indicated by sensory receptors in the muscles and joints of the neck; motor signals are unreliable indicators of head position because the effort required to hold the head in a given position on the body depends on the posture of the head with respect to gravity.

For the total task of judging the visual direction of an object, the information from these three components must be summed, or integrated. Since the eye and the head rotate about approximately the same vertical axis, one would expect the algebraic sum of the angular inaccuracies of the three components to equal the inaccuracy of the total task and the sum of the variabilities (precision) of the component tasks to equal the variability of the total task. This is why this case is referred to here as 'sensory integration'.

A similar state of affairs holds when we judge the direction of a hidden object which we touch with the finger. In this case information from the various joints of the arm is summed in estimating the direction of the object relative to the body. An extra factor is involved in this example because, in addition to summing information about the angular positions of the joints, it is also necessary to know the length of each segment of the limb.

Implicit knowledge about the spatial properties of our own body is known as the 'body schema'. This knowledge seems to be stored in the parietal lobes of the brain;

damage to these areas results in anomalous experiences of the body (Critchley, 1969). A patient with parietal lobe damage may complain that one of his arms does not belong to him, even though he is able to move it and feel with it, or he may feel that his arm is distorted, or not attached to the body. The body schema for a limb changes as the body changes during growth and persists after the limb has been amputated and this creates the illusion that the limb is still present. An amputee will attempt to use his phantom limb when doing habitual things.

Intersensory coordination. In intersensory coordination an object is detected by at least two sense organs and the person is required to coordinate the spatial information derived from these different sources. Consider the act of picking up a small handbell, looking at it, and ringing it. The direction of the bell is sensed by the eyes, by the ears, and by the hand, and yet these separate impressions normally seem to originate from one and the same bell.

Interesting things happen when the spatial information from the various sense organs is not in agreement, that is, when there is a sensory discordance. Such a situation may be induced artificially in several ways. For instance, a person may view a ringing bell through prisms which displace the retinal image to one side. A ventriloquist produces a sensory discordance by moving the lips of his dummy and keeping his own lips still. The same thing happens in the cinema, where the sound that seems to come from the actors actually originates from loudspeakers to one side of the screen. In other words, we misperceive the direction of a sound to make it conform to the direction of a visual object with which the sound is associated; an effect known as ventriloquism or visual dominance. C. V. Jackson (1953) did an experiment to determine how far a visual object has to be separated from an associated sound before the discordance becomes noticeable. Subjects reported that a hidden whistle appeared to originate from a silent steaming kettle if the kettle and whistle were separated by less than 30° . A movement of an isolated sound source by this amount is easily detected.

An experiment by I. Rock and J. Victor (1964) provides a nice example of the dominance of vision over kinaesthesia. Subjects looked through a lens which caused a square object to appear rectangular. They selected a matching object from among a set of objects they could feel but not see and from a set they could see but not feel. Most subjects selected an object which matched the shape as seen rather than the shape as felt, and few subjects were aware of any conflict.

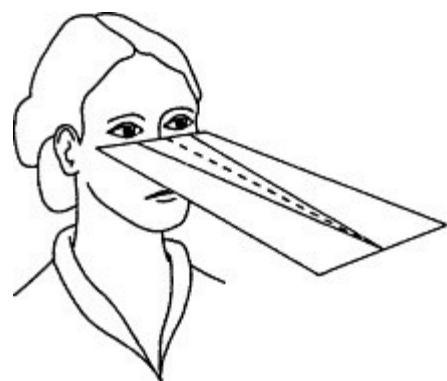

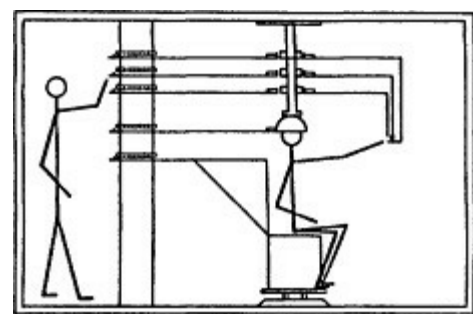

The conflict between audition and touchkinaesthesia was studied by H. L. Pick, D. H. Warren, and J. C. Hay (1969). Blindfolded subjects pointed with one hand to the felt position of the other hand which touched a loudspeaker that was emitting clicks. At the same time, subjects wore a pseudophone which apparently displaced the clicks by 11° to one side. Subjects pointed to the true position of the other hand and ignored the discordant auditory information.

Thus, in a conflict situation, when the person is convinced that the object detected by one sense organ is the same as that detected by another, vision dominates audition and kinaesthesia, and kinaesthesia dominates audition.

If one wishes to determine how precisely a person can bring stimuli detected by different sense organs into coincidence, one must use stimuli which do not evoke a dominance effect. In the procedure shown in Fig. 1 a light, a small loudspeaker, and a small tactilekinaesthesia 'button' are each mounted on a boom at arm's length.

The subject is presented with pairs of stimuli in various positions and reports which member of each pair is to the left of the other. The subject also judges the position of each stimulus presented on its own. In an ideal system—one which makes best use of the available information—the variability of

judgements about the relative positions of two

Page 729

Fig. 1.

Schematic representation of an apparatus

used to measure the accuracy and

precision of intersensory localization.

stimuli should equal the sum of variabilities of the judgements about the positions of each stimulus taken separately. C. Auerbach and P. Sperling (1974) showed that the performance of human subjects on an auditoryvisual localization task, with an apparatus like that shown in Fig. 1, conformed closely to the ideal.

When we direct our gaze towards an object which is straight ahead, it is objectively to the right of the left eye and to the left of the right eye, and yet we experience one object straight ahead. This is because the part of ourselves which we use in making directional judgements is somewhere on a line passing through the bridge of the nose and the centre of the head. This point is known as the visual *egocentre*. Fig. 2 illustrates a simple procedure for demonstrating that lines which extend out from each eye are perceived to lie in a plane midway between the eyes, which is to say that they are referred to a common egocentre in the median plane of the head.

*Stereoscopic vision is a special case of intersensory

Fig. 2.

Procedure for demonstrating that visual directions in the two eyes are referred to a common egocentre. Each line must point accurately to the pupil of an eye, and fixation must be maintained on the point where the two lines meet. When this is done a 'fused' image of the two lines is seen extending towards the bridge of the nose.

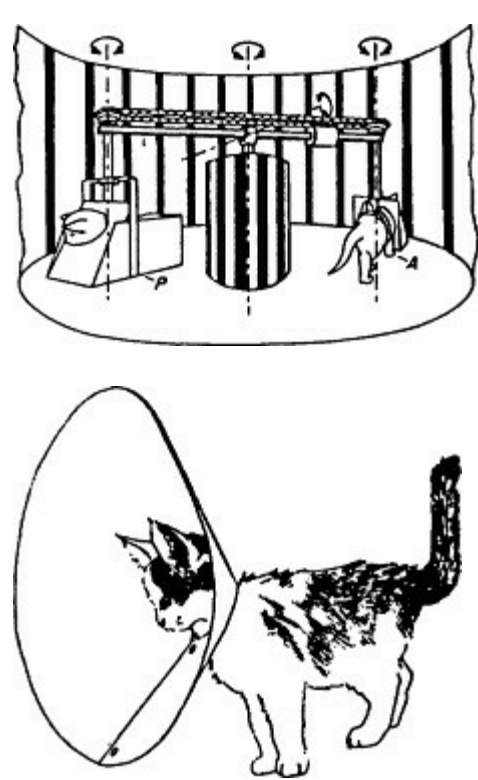

sory coordination. In this case objects are seen by the two eyes, but in slightly different directions, because the two eyes are not in the same place. As long as the disparity in the relative positions of the two images is not too large, we experience only one object, but at the same time use the spatial disparity as a clue to the relative distances of objects.

Another interesting case of intersensory coordination is provided by the way we use information from the two ears to judge the direction of sound sources. This is a highly sophisticated mechanism which depends on the detection of relative intensities and times of arrival of sounds at the two ears (see BINAURAL HEARING).

Sensorimotor coordination. White, Castle, and Held (1964) described the normal development of visual motor coordination. During the first month the child is able to pursue objects with the eyes and head, and by the second month these movements become more refined and show sign of predicting the future position of moving objects. Arm movements are unrelated to vision at this stage. The grasp reflex is present but is wholly under tactile control. Infants under one month of age do not attend to objects within arm's reach, probably because of inadequate accommodation and convergence. In the second and third months the infants visually attend to near objects and begin to take a visual interest in their own arms. The first visually directed swiping movements of the arm develop, but the child grasps an object only if the hand touches it. In the third month the swipe gives way to a more directed arm movement, and the child looks back and forth between object and hand. In the third and fourth months, the child watches the two hands as they contact and manipulate each other, thus producing a double feedback experience. In the fifth month, this double arm action comes under visual control and gradually gives rise to the ability to reach rapidly and grasp an object. White (1970) reported that, for infants nurtured in an environment enriched by a variety of objects hanging within reach, the onset of sustained observation of the hand occurred at a mean age of 50 days, rather than at 60 days as in infants reared in a 'normal' environment.

The spatially coordinated behaviour of adult humans can be adjusted to the changing size and shape of parts of the body during growth, to the demands of novel environments, and to compensate for injury.

Because of their intelligence, humans have dispensed with narrowly specialized sense organs and limbs and have instead evolved highly flexible mechanisms that reach their highest expression in learned skills. There are several ways of studying the flexibility of spatially coordinated behaviour. One way is to rotate or transplant sense organs or tendon insertions surgically: a method applicable to humans only when radical surgery is required for medical reasons. A second procedure is to study animals reared in anomalous sensory environments, or people with severe sensory

Page 730

deficits from an early age. Finally, the flexibility of spatially coordinated behaviour may be studied by temporarily distorting the visual input by placing prisms or lenses in front of the eyes. Some representative experiments of each kind will now be described.

The effects of surgical rotation of the eye. As part of a treatment for a detached retina, R. R. Barrios, E. M. Recalde, and C. Mendilaharszi severed each rectus muscle of one eye in several human patients, rotated the eyeball through 90° , and sutured each muscle back on to a stump of tendon which was 90° away from the muscle's normal insertion. The patients were allowed to use both eyes during the sixmonth recovery period. At the end of this period, when tested using only the rotated eye, the patients reported that the visual scene appeared rotated 90° . Furthermore, pursuit eye movements and visually directed movements made with the unseen hand occurred in a direction at right angles to the movement of the visual targets. The total absence of adaptation in these patients was probably due to suppression in vision in the rotated eye during the recovery period. Human beings are certainly able to compensate behaviourally for the rotation of the visual scene produced by optical means, as the pioneering work of G. M. Stratton (1897) demonstrated. When a similar experiment was done on cats, the animals showed accurate visually guided paw placement and obstacle avoidance when seeing with the rotated eye, but only if, during training, the good eye was kept closed. In this experiment, the projection of nerve fibres from the retina of the rotated eye on to the visual cortex

was found to be unchanged. The behavioural compensation was obviously due to changes at a higher level.

The effects of restricted rearing on visual motor coordination. One can study the kinds of sensorimotor experience required for the development of visual motor skills by rearing animals in environments which restrict experience in specific ways. In the most famous of these experiments (by R. Held and A. Hein) pairs of kittens were reared in darkness, except for a certain period each day when they were placed in an illuminated striped carousel apparatus, as shown in Fig. 3. One kitten of each pair was always placed in the box so that its feet did not touch the ground, and the other kitten was always placed on the other end of the rotating lever so that it could walk and thereby cause itself and its passive partner to be moved round inside the striped drum. Both kittens had the same visual experience, but only for the active kitten was this related to the act of walking. Sensory stimulation which results from self-produced movements is known as refference, and sensory stimulation which occurs independently of self-produced movements is called exafference. Held and Hein found that only the active kitten developed the ability to avoid a cliff, blink at an approaching

Fig. 3.

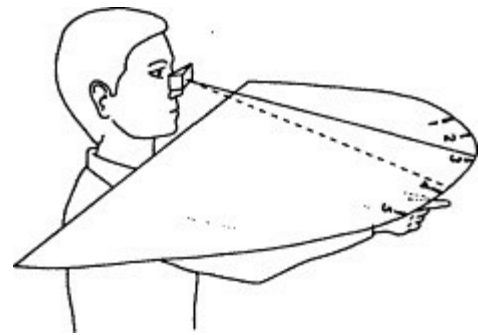

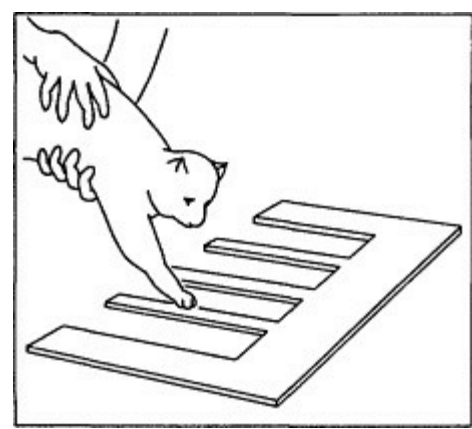

Apparatus used by Hein and Held for equating motion and consequent visual feedback for an actively moving animal (A) and a passively moving animal (P).

object, or extend its paw to a surface. They concluded that refference is necessary for the development of visual motor skills.

Held, Gower, and Diamond subsequently showed that the pawplacing response developed in immobilized kittens which had experienced only diffuse light. The passive experience in the carousel must have interfered with the maturation of this response, which undermines the claim that refferent stimulation is necessary for development of visual motor skills.

Held and Hein developed tests for abilities which, they claimed, do not develop without refferent visual experience. They reared kittens with opaque collars round their necks which prevented them from seeing their limbs (Fig. 4). These kittens could extend their paws towards prongs (Fig. 5) but could not hit them, except by chance, and they could not strike a ball dangled in front of them. Held and Bauer conducted a very similar experiment with monkeys, who for the first 35 days after birth wore a collar which occluded their arms. When the arms were allowed to come into view the Fig. 4.

Kitten wearing a collar that prevents sight of limbs and torso.

Page 731

Fig. 5.

Apparatus for testing the accuracy of
visually guided paw placement in the cat.

monkeys could not reach accurately towards a bottle. It was concluded that '... an infant Primate initially fails to reach accurately for attractive visible objects with a limb that it has never previously viewed'.

Note that the monkeys were not allowed to touch the bottle before the collar was removed, and therefore had not learned to relate seen objects with anything that the unseen arm did. R. D. Walk, and E. K. Bond repeated the experiment but allowed the monkeys to touch one end of a rod, the other end of which they could see projecting above the edge of the collar which occluded the hand. After this exposure, visually guided reaching was tolerably accurate after the collar was removed.

Therefore, sight of the hand is not required for the development of visual motor coordination, only some experience that links its motion to a seen object.

Thus, visual motor skills seem to develop in the presence of any type of information which informs the animal about the accuracy of performance. Certain types of early deprivation have a general debilitating effect, but visual motor learning is usually very specific to the conditions under which it occurs.

The effects of visual distortions on visual motor coordination. When stimuli impinging on one sense

organ are spatially distorted with respect to those impinging on the other sense organs, there is a sensory discordance. The types of visual distortion that have been studied include sideways displacement, tilt, inversion, left-right reversal, magnification, and curvature.

Anyone with a wedge prism can perform the following simple experiment. A few numbers are marked on the edge of a piece of card which is then placed horizontally under the chin as in Fig. 6. With the prism before one eye and the other eye closed, the finger is directed towards a number on Fig. 6.

A simple apparatus for demonstrating
adaptation of pointing to displaced vision.

the far side of the card and allowed to come into view. This arm is then returned to the side of the body, after which the aiming movement is repeated several times to each of the numbers in random order. The error in pointing will be very evident for the first few trials, but accuracy is soon restored. When the prism is removed, it will be found that the first few aims will be off target in the opposite direction to the error first experienced when the prism was in place. This aftereffect illustrates that adaptation to a visual distortion is not merely a question of deliberate compensation.

The nature of the changes underlying adaptation to displaced vision. It is agreed that visual motor adaptation to distorted vision does not involve changes in the sense organs, or in the muscular system which controls arm movements. The change must be in the way sensory or motor signals are coded in the central nervous system. There is no evidence of a change in the internal calibration of the position of the retinal image. This is not surprising because, when a person points to an object, its image falls on the fovea, which is a very distinctive landmark. Other experiments, reviewed in Howard (1981), have failed to reveal any significant effects of visual motor learning on the apparent directions and shapes of objects, even when the objects are not fixated. It seems that simple visual sensations are insulated from events outside vision. There is an old theory, known as the motor theory of perception, in which it is claimed that the way we see is determined by motor behaviour. It would seem that this theory is wrong with respect to simple visual sensations.

Visual motor adaptation has been found sometimes to involve a change in the sense of eye position. For instance, B. Craske (1967) found that the objectively determined position of the eyes, when the subject was attempting to look straight ahead in the dark, was shifted after exposure to displacing prisms. Similar experiments have demonstrated that there may also be a change in the felt position of the head on the body.

If training one arm with prisms affects the way

Page 732

the other arm points, the adaptation is said to show *intermanual transfer*. Intermanual transfer indicates that the change must have occurred in the sense of position of the head or the eyes—parts common to both arms. There is general agreement that intermanual transfer is only partial, so that most of the adaptive change to displaced vision must involve a change in the sense of position of the

trained arm—a change in the way information from joint receptors is coded, or in the spatial coding of motor commands.

Evidence that motor learning may contribute to adaptation of the visual motor system comes from experiments by E. Taub and I. A. Goldberg on monkeys in whom the sensory roots of the spinal cord had been severed. These monkeys could be trained to reach with the unseen arm towards visual targets and to adapt their pointing when viewing the targets through displacing prisms. This must have been motor learning because the animals lacked sensory inputs from the arm.

Thus it seems that all systems beyond the most peripheral processes in sense organs and muscles are capable of adapting to unusual circumstances, given the correct set of constraints and demands. The one exception seems to be that the central calibration of the position of the retinal image is immutable.

The conditions under which adaptation to displaced vision occurs. Held proposed that sensations arising from active movement (i.e. reafferent stimuli) are necessary for visual motor adaptation to displaced vision. In one experiment A. Hein and R. Held asked subjects to watch one of their own hands through a displacing prism as the hand was waved from side to side, either actively by the subject or passively by the experimenter. Only after the active condition did subjects show evidence of having adapted to the prisms when they were tested in an aiming test. They concluded that selfproduced movement coupled to visual reafferent stimulation (sight of the moving arm) is necessary for a change of visual motor coordination. However, subjects probably paid more attention to what they were doing when moving their own arms and, with this factor controlled, other investigators have demonstrated that selfproduced movement is not necessary for visual motor adaptation.

Howard and Templeton (1966) argued that adaptation occurs in response to many forms of discordant information: the important thing is that salient information regarding the discordance (not necessarily consciously perceived) should be available to the subject. The sensory consequences of selfproduced movement may be a particularly potent source of information, but the most reasonable general conclusion is that any consistent relationship between stimuli within a given sense or between stimuli in different senses, or any relationship between stimuli and responses, will be learned and the system changed accordingly.

The posterior parietal lobe of the cerebral cortex is well placed to serve as a centre for the higher control of coordination between vision, somaesthesia, eye movements, and limb movements. It has been shown that cells in this region of the monkey's brain respond when the animal sees an object of interest, such as food, towards which it is likely to reach. Many of the visually responsive neurones also respond when the eyes move, and some also respond to stimulation of touch receptors.

Subcortical centres in the brain are also involved in sensorimotor coordination. For instance, it has been shown that cells in the basal ganglia, which receive highly processed spatial information, probably from the parietal lobes, are active when the animal is tracking a moving visual object. Damage to the basal ganglia in humans, such as is associated with Parkinsonism, results in akinesia, or an inability to initiate movements towards a visual object. This disorder is manifest only in certain

contexts, which suggests that the basal ganglia are concerned with organizing responses to specific visual information. Our knowledge of the neurology of sensorimotor coordination is very fragmentary. Perhaps the development of artificial automata will help to provide theoretical insights which will guide future work.

SPEARMAN, CHARLES EDWARD (18631945). Formerly a cavalry officer, Spearman studied psychology in Germany, taking his doctorate at Leipzig.

Thereafter he worked in London, becoming Grote professor of mind and logic at University College, where he remained until his retirement in 1931. He was elected a Fellow of the Royal Society in 1924.

Spearman is remembered as a pioneer in statistical psychology and a convinced believer in the twofactor theory of*intelligence, which he advocated in a paper written jointly with Bernard Hart in 1904. Making use of factorial analysis, Spearman claimed that the correlations between the measurement of different abilities in man tended towards a particular arrangement that could be expressed in a definite mathematical formula. This became known as the tetrad equation. Wherever this equation held throughout any table of correlation, every individual measurement of each ability could be divided into two independent parts, one called by Spearman *g*—i.e. the *general factor*—which, though varying freely from individual to individual, remains the same for any one individual in respect of all the correlated abilities, while the other part—known as the *specific factor*—not only varies from individual to individual, but even in any one individual from one ability to another.

Thus arose what soon became known as the 'twofactor' theory which aroused wide interest but sharp controversy in Britain and further afield. Although Spearman tended to interpret *g* in terms of a vague and unconvincing concept of 'mental energy', most psychological workers in this field who shared Spearman's views preferred to identify it with 'general intelligence'.

Spearman's work attracted much interest but many critics, among them Godfrey (later Sir Godfrey) Thomson, who advocated instead of a general factor a number of overlapping group factors. Later the interpretation of factorial analysis was extended and discussed with much statistical sophistication by Maxwell Garnett, Cyril*Burt, William Stephenson, L. L.*Thurstone, and many others on both sides of the Atlantic.

The outcome appears to be that whereas factorial analysis has evident value in classifying individuals for educational or occupational purposes, it does not materially contribute to our understanding either of the nature of intelligence or of the rationale of individual differences. It is therefore unlikely to

make a decisive contribution to psychological theory.

Spearman wrote two major works: *The Nature of 'Intelligence' and the Principles of Cognition* (1923) and *The Abilities of Man* (1927).

O. L. Z.

SPEECH AND BRAIN PROCESSES. Natural speech is a communication of information by means of the codes of language. This means that, to communicate, man has to have a definite motive or intention (knowing what and why he has to communicate) and to use for his purposes a particular language, its phonemic, lexical, and syntactic codes (the last relating to the question *how* to communicate).

Systems of language can have different complexities. It was the Swedish linguist Svedelins (1897) who described two basically different classes of verbal communication: *communication of events* ('The house is burning', 'The boy hit a dog') and *communication of relations* ('Socrates is a man', 'That is the father's brother', 'Mary is fairer than Cathy', 'The triangle under the circle', etc.). These basic kinds of verbal communication are different both in content and in linguistic structure. Communication of events can be represented in concrete images; communication of relations cannot. Communication of events can use comparatively simple forms of linguistic codes; for the communication of relations, more complex linguistic codes are required, including complex case markers, and auxiliary words that express relations ('on', 'under', 'before', 'after', etc.). In the communication of relations, special grammatical codes (incorporation of one phrase into another, relational means, inversion, etc.) can be used as well.

These basic linguistic differences in the two forms of verbal communication are related to different psychological structures. The first class of constructions (which is most typical for the communication of events) is associated with an (immediate) sequence of words which constitutes a phrase. This kind of construction can be considered as a *syntagmatic* type, which is sometimes quite simple, and does not necessarily require any transformation for understanding. Communication of relations generally requires more complex grammatical rules and includes a kind of *paradigmatic* organization (Jakobson, 1971). The process of decoding these structures (or their understanding) very often requires a certain transformation, and the meaning of this form of logicogrammatical communication often becomes clear only after such transformations have been performed. So, the understanding of the construction 'brother's father' requires a chain of transformations and a series of additional grammatical or semantic markers, such as: 'That is my brother. He has a father. His father is my father too'; while the understanding of the construction

'Mary is fairer than Cathy' requires analogous transformations:

Page 734

'Cathy is fair; but Mary is even more fair; so she is fairer than Cathy', etc. The loading with these additional transformations is much greater for communicating relations than events.

The most important fact observed in neuropsychology (i.e. in the analysis of the changes of psychological processes associated with local brain lesions) is that the two kinds of verbal communication require different cortical mechanisms, and are based on different cortical systems. In cases where the lesion is situated in posterior ('gnostic') parts of the brain, acquisition of the language codes suffers: both the production and the understanding of paradigmatically organized verbal utterances become difficult, sometimes even impossible; whereas fluent, syntagmatically organized speech remains preserved. This is why patients who are unable consciously to make all the transformations needed for the understanding of complex linguistic structures remain able to use these forms in practice. They are unable to decode the construction 'father's brother' but are still able to include it in a practically preserved syntagmatic system, saying: 'Oh, well, that's my father's brother'. The breakdown of one of the levels (phonerage, lexical, or logicogrammatical) of paradigmatically organized language codes is typical of verbal disorders associated with lesions of the posterior parts of the speech regions of the left hemisphere; in all these cases, practical fluent speech, expressing communication of events or wellimprinted syntagmatic structures, remains basically preserved; that is why these forms of language impairment are called 'fluent aphasias' (see APHASIA).

Conversely, damage to the anterior parts of the 'speech areas' of the left hemisphere results in the opposite kind of deterioration of language. The performance needed for the acquisition of language codes (phonemic, lexical, logicogrammatical) and the systems of opposition these codes include remains basically intact; but the combination of words into fluent sequential (syntagmatic) structures, as well as all kinds of 'kinetic melodies' included in skilled movements, breaks down. This is why patients of this group can easily grasp phonemic oppositions, lexical meanings, and even paradigmatically organized structures—while fluent speech becomes impossible, and may be replaced by separate naming of objects, taking the form of 'telegraphic style'.

The basic brain mechanisms underlying these two forms of verbal utterance are not sufficiently clear, but it seems very probable that the posterior parts of the human brain are associated with the process of transformation of successively arriving information in simultaneous (spatial or quasispatial) schemes, whereas the anterior parts of the brain deal with the 'serial organization' of the processes providing skilled movements or successively organized 'kinetic melodies'. This is why a breakdown of the posterior, 'gnostic' regions of the cortex results in a derangement of the acquisition of complex, paradigmatically organized codes of language, while a breakdown of the anterior parts of the cortex (in both cases, of the major hemisphere) results in disturbance of 'serial organization' of the processes, and in a breakdown of syntagmatic organization of verbal utterances.

SPEECH RECOGNITION BY MACHINE. Until recently, recognition of speech by a machine has seemed impossible—though machines have been talking and singing for the last hundred years. Speech recognition has immense theoretical and practical importance. An example of a now established commercial application for automatic speech recognition is in the sorting of baggage at airports. A human operator reads a destination from a baggage label into a microphone. The spoken destination is automatically recognized and the baggage is routed accordingly. This use of automatic speech recognition has the advantage that it leaves the operator's hands free to handle the baggage.

Speech is a succession of voiced sounds that originate from the vocal chords, interspersed with consonant sounds such as 's' which originates from the hissing of air between teeth and 't' which is produced by an explosive release of air pressure by the tongue. Speech waveforms are often very complicated, and tend to be roughly periodic during short (e.g. tenmillisecond) periods.

Automatic speech recognition is usually a multistage process, in which the first stage is intended to yield a representation of speech that is simpler and less repetitive than the original acoustic waveform. The first stage typically performs various measurements on each successive tenmillisecond portion of the acoustic waveform. For example, in the*Fourier spectrum for each such portion, the energy in various frequency bands spanning 200 to 6,000 hertz may be measured. Alternatively, linear predictive coding coefficients may be taken as measurements. Zerocrossing rates, glottal frequency, and total energy are further important examples of measurements.

For the simplest kind of automatic speech recognition systems, speakers are required to leave silences before and after isolated words. These isolatedword recognition systems usually work by matching the sequence of measurements obtained from a spoken word against various sequences of measurements stored in memory. These stored sequences of measurements are known as speech templates; and there is at least one such template for each different word that the machine can recognize. A spoken word is *recognized* as being the

Page 735

same as the template word that it matches best. Preferably the template words are obtained from the same speaker whose speech is to be recognized. A template can be obtained by having this speaker pronounce the word several times, and in some way averaging the resulting sequences of measurements to make a template. The process of obtaining a stored template from several utterances of one word can be regarded as a *learning* process.

A spoken word is generally a sequence of phonemes, and for example the third phoneme of a spoken word should be matched against the third phoneme of that word's stored template. The total duration of a spoken word may be different each time the word is uttered, and elongation or compression of the timescale may impair the alignment of phonemic data. For short words this problem can be

mitigated by measuring the duration of a spoken word and then elongating or compressing the time scale to standardize the duration of the word before matching it with templates that have been similarly standardized. Speech recognition machines working on these principles became commercially available in the 1970s, and could learn to recognize about thirtytwo words spoken quite carefully by a single speaker.

More sophisticated templatematching technology allows elongation or compression of a word's timescale to vary while the word is being spoken. Timescale variations can be accommodated by dynamic timewarping, which has become popular in the 1980s because of the decreasing cost of computation, and because it yields more accurate recognition of larger vocabularies than can be recognized by less sophisticated matching techniques. Dynamic timewarping techniques have been developed to recognize whole sentences composed of words not separated by silences. Templates for whole sentences are composed of singleword templates, and the timewarping technique that timealigns phonemelike parts of a single word has been developed to timealign wholeword parts of a single sentence. After matching, it is easy to find which part of the spoken sentence corresponds to which part of a template sentence, and thus find when each spoken word begins and ends.

Except for specialized applications, it is not practical to store or synthesize sentence templates, and radically different techniques are required for automating the work of a typist who types unrestricted text that is dictated without silences between successive words. Instead of attempting to recognize whole words directly by template matching, it is usual to attempt to classify successive subword portions, known as segments. A segment may, for instance, be a portion during which the results of measurements on the acoustic waveform do not change by more than a threshold amount.

Alternatively, successive tenmillisecond portions of the utterance may be regarded as segments. Segments may be classified, sometimes erroneously, by means of classical*pattern recognition techniques, which yield one or more plausible labels for each segment. A speech recognition machine contains a dictionary which, for each recognizable word, stores one or more than one combination of segment labels for segments of that word. This stored lexical knowledge is generally not sufficient to cope with erroneous subdivision of speech into segments and erroneous classification of these segments. To bring further order out of this chaos it is usual to employ knowledge of syntax and semantics in addition to lexical knowlege.

In the mid1980s, automatic recognition of unrestricted multispeaker connected speech is an unsolved problem that is receiving attention in many countries because of the commercial value of a viable solution. There is steady progress in the growth of phonetic knowledge and in the development of expert systems techniques, to bring together and apply the relevant knowledge in an orderly manner.

SPENCER, HERBERT (1820-1903). British philosopher. The influence of Herbert Spencer in his lifetime was immense. It was not only in intellectual circles that his books were read, and their popular appeal in America and Asia, as well as in Britain, was enormous. But since the nineteenth century his reputation has suffered an uncommonly severe eclipse, and it is necessary to recall the extent of his influence.

Henry Holt, an influential publisher, declared, 'About 1865 I got hold of a copy of Spencer's *First Principles* and had my eyes opened to a new heaven and a new earth.' And Andrew Carnegie, prototype of the selfmade American, publicized Spencer as 'the man to whom I owe most'. For thirty years, from the 1860s, Spencer's thought dominated American universities. The last of those decades, the 1890s, produced the revolution in educational thought and psychology led by William*James and John*Dewey, Stanley*Hall, and E. L.*Thorndike, all influenced by Spencer. In Britain, J. S.*Mill backed financially the subscription scheme that launched Spencer's work, and the scientists supported him too. Charles*Darwin wrote, 'After reading any of his books I generally feel enthusiastic admiration for his transcendental talents', but added that 'his conclusions never convince me'. (He also wrote, somewhat ambiguously, 'I feel rather mean when I read him: I could bear and rather enjoy feeling that he was twice as ingenious and clever as myself, but when I feel that he is about a dozen times my superior, even in the masterart of wriggling, I feel aggrieved'.) In 1863 Alfred Russel*Wallace visited Spencer, commenting, 'Our thoughts were full of the great unsolved problem of the origin of life ...

and we looked to

Page 736

Spencer as the one man living who could give us a clue to it.' And as late as 1897 Beatrice Webb noted that "'Permanent" men might be classed just above the artisan and skilled mechanic: they read Herbert Spencer and Huxley and are speculative in religious and political thought'.

In the 1880s Spencer was consulted by the Japanese government on education. And in Chekhov's short story 'The Duel' (1891) a female character recalls the beginning of an idyllic relationship: '... to begin with we had kisses, and calm evenings, and vows, and Spencer, and ideals and interests in common'. And, finally, a letter arrived at Spencer's home in the early 1890s addressed to 'Herbt Spencer, England, and if the postman doesn't know where he lives, why he ought to'.

Spencer's fame was based entirely on his books. He rarely appeared in public, save for one triumphant tour of America late in life. He was born in Derby, the only surviving son of a schoolmaster, and he was educated informally at home by his father and later in the family of an uncle. The family was staunchly Nonconformist, with a radical tradition and a keen interest in the social issues of the day. For some years the young Spencer was a railway engineer, but by 1841 he had decided against this career. He became a journalist in London, attended meetings, and was formulating ideas on politics and education. He began to write, and became known for his radical opinions and selfconfidence, traits tempered by great honesty. If in old age he became idiosyncratic, in youth he was a shrewd iconoclast who delighted in argument. Perhaps it was these qualities which

led him to some influential and lifelong friendships. He got to know the young T. H. *Huxley; they had interests in common and walked together on Hampstead Heath in London. George Eliot was a fellow journalist who fell in love with him, before he introduced her to G. H.

Lewes. It was a remarkably tightknit intellectual group in which Spencer moved, and it extended into the next generation. In 1877 when William James was attacking Spencer's books at Harvard, William's brother Henry, the novelist, wrote describing his meeting with Spencer at George Eliot's, and comments: 'I often take a nap beside Herbert Spencer at the Athenaeum and feel as if I were robbing you of the privilege.'

Spencer's first books were published in the serene midcentury. His essays on *Education* (1861) remained a standard text in colleges training teachers for many decades. By 1858 he had conceived the plan of writing a major synthetic philosophy, and the prospectus appeared in 1860. Small legacies, publications, and the support of friends, enabled him to give up journalism and for the rest of his life he was an independent author. He never married, and he devoted his life to completing the philosophy as he had originally planned it. The whole massive project, with volumes on biology, psychology, sociology, and ethics, together with the initial *First Principles* (1862) was finally complete in 1896.

Today one point of pursuing Spencer lies precisely in trying to understand something of the reasons for his great appeal in his own time. The social milieu in which he moved is significant. The immense popularity of his work is due to a rather special way in which it reflected some of the preoccupations of his own generation. In his thirties Spencer suffered a severe breakdown in health. He shared the Victorian syndrome, which Darwin and Huxley also endured, of a crisis in health as a young man and thereafter constant hypochondria, insomnia, and headaches; it suggests some of the tensions in their thought and background.

Spencer had no formal education. He believed this to be a great advantage which 'left me free from the bias given by the plexus of traditional ideas and sentiments', and he adds, 'I did not trouble myself with the generalisations of others. And that indeed indicated my general attitude. All along I have looked at things through my own eyes and not through the eyes of others.' In later life he was never able to work for long, and his reading was severely curtailed. In fact he had never read a great deal; he observed, made biological collections and mechanical inventions, and he enjoyed intelligent conversations and his own thoughts much more than reading books. Although he believed this gave him an independent attitude, it in fact left him more than usually open to the influences around him.

When *Darwin's *Origin of Species* was published in November 1859, evolutionary theories were not new—they had been the subject of of speculation for half a century. Darwin's achievement was to make the elements of the theory coherent and to demonstrate, by massive evidence, that it must be taken seriously.

One man needed no conversion. Seven years earlier, in 1852, Spencer had published an essay on the 'Development Hypothesis', and coined the term of the *survival of the fittest*. Years later Huxley recalled that before Darwin's publication, 'The only person known to me whose knowledge and

capacity compelled respect, and who was at the same time a thoroughgoing evolutionist, was Mr Herbert Spencer ...'. Spencer first came across evolution in a secondary work discussing the ideas of Lamarck, whose theory was partly intuitive and had never convinced professional naturalists (see LAMARCKIANISM). Spencer was won over, before there was convincing evidence, for a characteristically midVictorian reason: 'The Special Creation theory had dropped out of my mind many years before, and I could not remain in a suspended state; acceptance of the only conceivable alternative was peremptory.'

An important feature of Spencer's generation of intellectuals is that they had discarded orthodox religion. Spencer himself was never religious, and he enjoyed setting out for Sunday rambles walking provocatively in the opposite direction to the

Page 737

churchgoers. But unconsciously, the agnostic midVictorians searched for some other system of thought which could answer their doubts and give them clear first principles. Science was one alternative which was widely seized on, hence the battles over evolution and religion. Evolution offered, it seemed, an alternative conceptual framework, universally operating laws of cause and effect. The 'new heaven and the new earth' which Spencer's philosophy opened up to many of his contemporaries was essentially a systematic metaphysical cosmology: everything from the stars to the embryo, from civilizations to the individual, was in process of development, interaction, change, growth—and progress. For Spencer's conception of universal evolution was optimistic, a view which seemed natural to successful midVictorians. 'Progress, therefore, is not an accident but a necessity. Instead of civilisation being artificial, it is a part of the embryo or the unfolding of a flower.' Late eighteenthcentury *laissezfaire* individualism is thus reconciled with the revolutionary changes of nineteenthcentury society.

Naturalistic organic conceptions of society gained a new importance with the addition of evolutionary laws. Spencer was the first to pursue the study of such laws operating in society, and to call his analysis sociology. His book *The Study of Sociology* (1873) was as popular as *Education*. A similar but more dynamic conception was being developed in the same period by Karl Marx.

Fundamentally the reverence for nature which pervades all Spencer's work goes back to Rousseau. It is romantic, not scientific. Spencer's conception of evolution owes nothing to Darwin. Although greatly impressed by science, Spencer never really grasped scientific method: his method was inductive—he generalizes laws without proof, draws facts haphazardly from his own experience, and is fond of asserting his beliefs as 'obvious'. Spencer understood his own romantic, speculative, and basically unscientific attitude, and recounts against himself the witticism of his friend Huxley that 'Spencer's idea of a tragedy is a deduction killed by a fact'. Not until almost a generation later was it realized that evolutionary theories cannot supply an ethical code for human societies. Spencer's only quarrel with Huxley was in the 1890s, when Huxley first publicly dissented from the view that the law of nature in human society was neither just nor good.

The origins of Spencer's philosophy owe much to the provincial dissenting background of his youth.

By the 1880s his individualistic *laissezfaire* views were already anachronistic, though his book *Man versus the State* (1884) had enormous sales. Essentially, Spencer is a Janus figure looking as much backwards as forwards. He only partly understood evolutionary theory and used it considerably to give a systematic framework for the individualistic ethics and organic view of the state prevalent in his youth. John Dewey, in an excellent essay, came to the conclusion that Spencer was essentially a transition figure, preserving the ideals of late eighteenthcentury British liberalism in the only way possible: in 'the organic, the systematic, the universal terms which report the presence of the nineteenth century'.

Yet Spencer really did seize and propagandize the leading idea of his own day. It was Spencer, not Darwin, who opened up the horizons of the evolutionary theory in psychology, sociology, anthropology, and education. He did perhaps more than anyone else to persuade others that the implications of the evolutionary theory were important, and he did it in a thoroughly Victorian manner: energetic, confident, systematic, universal, which a modern scientist, Sir Peter Medawar, salutes with respect:

I think Herbert Spencer was the greatest of those who have attempted to found a metaphysical system on naturalistic principles. It is out of date, of course, this style of thought, it is philosophy for an age of steam His system of General Evolution does not really work: the evolution of society and of the solar system are different phenomena, and the one teaches us next to nothing about the other.... But for all that, I for one can still see Spencer's System as a great adventure....

SPINOZA, BENEDICT (BARUCH) DE (163277), Dutch philosopher, one of the last great metaphysical thinkers of the 'rationalist' period in philosophy. In his major work, *The Ethics*, he starts from supposedly selfevident truths and rigorously develops them through the use of reason and deductive argument. His commitment to the power of reason and to the view that man can gain knowledge of reality through the powers of the mind alone culminate in a profound vision of the world and of man's place within it.

Spinoza was born in Amsterdam of Portuguese Jewish stock. He was educated initially in the Jewish school, but later received Latin lessons from a private tutor, Van Den Ende, who introduced him to the scientific and philosophical developments of the day. Spinoza's growing commitment to secular thought and philosophy brought him into conflict with the Jewish authorities, and in 1656 he was expelled from the synagogue for his 'heretical' views. His Hebrew name, Baruch, he abandoned for its Latin form, Benedictus. The remainder of his life was spent developing his philosophical system while earning a living from polishing and grinding lenses. His reputation as a heretic and atheist did

not prevent him carrying on an extensive correspondence with other major thinkers, but only one of his works, the *Theological Political Treatise*, was published (anonymously) during his lifetime. His other works—*A Short Treatise on God, Man and his Wellbeing*, the *Treatise on the Emendation of the*

Page 738

Intellect, *The Ethics*, and the unfinished *Political Treatise*—were collected and published by his friends shortly after his death, from consumption.

Spinoza developed his theory of the mind partly in an attempt to solve the problems raised by Descartes's account of the mind and body as two fundamentally different substances. For Descartes the mind and body are independent and mutually exclusive systems, and it is well known that this strict dualistic theory made it extremely difficult to explain the apparent causal interaction between mental and physical items (see DUALISM).

Spinoza rejected Descartes's dualistic account and replaced it with a theory of 'substance monism'. This may be explained as follows. Substance is that which is selfdependent—needing nothing other than itself in order to exist. So far, both Descartes and Spinoza are in agreement. But where Descartes asserts that there are many such substances' (including each finite mind and body), Spinoza argues that there can be only one being which has the character of substance, and this being is God or nature itself. All finite things, ourselves included, are dependent upon other things for existence. Only God—the being beside whom there *is* nothing else, for He is infinite—has the nature of substance. This being so, all finite things, in particular minds and bodies, are not substances but 'modifications' or 'modes', that is, beings that are manifestations or fragmented expressions of the one reality. Mental and physical items alike have no reality save that which they have as parts of substance.

God or nature (these are synonymous terms for Spinoza) may, however, be viewed in two ways. We may think of the one substance either as a thinking being, or as extended in space. For Descartes, thought and extension constitute the essence of mental and physical substances respectively. In contrast, Spinoza regards thought and extension as two ways of *conceiving* one and the same reality. He is committed not to mental and physical *things* but to things that may be *conceived* in two different ways. He claims that whether we conceive of God in mental terms or in physical terms, we are thinking of just one being in either case. He then applies this

'conceptual dualism' to all items in the world. Every finite thing or 'mode' can be viewed in two ways, either as mental or as physical. Whatever there is, is fully explicable in either way. But, as in the case of God, there is only one thing that is being described.

When Spinoza came to speak of the human mind and body he said: 'Mind and body are one and the same individual conceived now under the attribute of thought, now under the attribute of extension.' This seems to amount to an identity claim—there is just one thing, which may be viewed and described either as a mind or as a body. This approach to the *mindbody* problem has some adherents today. Many accept that a human being can be described in two fundamental ways, attributing to him

both psychological and physical properties, while also accepting that there is only one being—the human person—which is being so characterized.

With Spinoza's monistic theory, Descartes's problem—that of explaining causal interaction between disparate items—vanishes, for there are not two things at all; the mind and body do not interact, for one thing cannot interact with itself. Anything that occurs in the body can be explained in mental terms and anything that occurs in the mind may be explained and described physically. Spinoza would therefore be sympathetic to those materialist or physicalist philosophers who claim that mental states just *are* physical happenings in the brain. But they would be less happy with Spinoza's reverse claim—that any physical occurrence may be fully explained in mental terms.

Spinoza speaks of the mind as the 'idea' of the body. As such it is aware of the body and of the things that happen to it. When light rays hit the retina of the eye, for example, the physical process may be described in mental terms as an image or sensory idea. But Spinoza thought that such sense perceptions are invariably confused or 'inadequate', because we take them to be the true representations of external objects whereas in reality they are merely reflections of our own bodily processes.

(See PERCEPTIONS AS HYPOTHESES; ILLUSIONS; SENSATIONS.)

Spinoza claims that all finite things endeavour or strive to maintain themselves in being and to perfect their existence. Thus the body will try to avoid those things which are harmful to it and will pursue those things that it needs in order to survive. The mind too, in Spinoza's view, exhibits this endeavour (or *conatus*, as he calls it) in its attempt to resist ideas which are inadequate and confused and to grasp those that help it to understand itself, the body and the external world. Spinoza thinks the mind will be aware that its sense perceptions are inadequate, for they will lack the clarity, distinctness and selfevident character of all true ideas. This being so, the mind will naturally try to replace sense perceptions with more adequate ideas, through a process of reasoned reflection and the application of selfevident principles. Once this stage is reached the mind is active rather than passive: it pursues and grasps the truth through its innate power of understanding, rather than remaining at the mercy of arbitrary and confused images and sense impressions.

This process of replacing sense impressions with adequate conceptions can also be applied to the emotions. For Spinoza, emotions are merely confused and inadequate ideas which befuddle the mind and which, for the most part, make us extremely unhappy. He thinks that to the extent that we allow our emotions to rule us we are in a state of slavery or bondage: 'When a man is a prey to his emotions, he is not his own master, but lies at the mercy of fortune.' Our emotions can be overcome by replacing the inadequate ideas on which they are grounded with a clear and distinct understanding of their causes. If emotions are confused Page 739

ideas and if they arise from inadequate understanding, it seems to follow that increased knowledge will change them, and enable us to become free of their power over us. As Spinoza says: 'An emotion therefore becomes more under our control, and the mind is less passive in respect to it, in proportion as it is more known to us.' This account of active selfimprovement through the analysis and

clarification of ideas has led some commentators to greet Spinoza as an early precursor of Freudian psychoanalysis.

For Spinoza, the mastery of emotions, and the state of improved understanding achieved through the mind's reasoning powers, enables us to become more active and free. But the freedom which Spinoza grants us has seemed to some to be no freedom at all. When the mind understands things adequately it perceives them as necessary, and sees that they could not have been otherwise. Reason, Spinoza tells us, perceives things 'under a certain form of eternity', and we then see that nothing could have been different, because everything results from God, who Himself is a necessary and eternal being.

Our freedom consists in recognizing the necessity of our nature, understanding ourselves as expressions and manifestations of God's power and laws, and as having no existence save that which He grants us. Viewed rightly, we see ourselves and all things as in a sense eternal, for we no longer judge things as contingent happenings in time, but as determined by immutable laws. This understanding, which Spinoza calls 'intuition', constitutes the mind's highest achievement and its complete fulfilment.

Knowing itself and other things in this manner, the mind achieves a certain immortality, and with true contentment realizes that death, which is a mere temporal event, cannot destroy it.

Spinoza thus ends his *Ethics* on a note of almost religious fervour which has encouraged some in the view that he was a mystic. Although his philosophy has influenced many, and has been hailed by idealists, materialists, atheists and theists alike, his vision is perhaps most pertinent today to all those who wish to find a place for spiritual fulfilment in a world governed by natural laws.

A translation by R. H. M. Elwes, *Basic Works*, was published in two volumes in New York in 1955, and *The Correspondence of Spinoza*, trans. A. Wolf, appeared also in New York in 1966.

SPIRITUALISM. Belief in a world of spirits has been a constant feature of all human societies. However, systematic communication with that world through spirit mediumship and possession is a central feature only of certain peripheral cults in primitive societies, and of spiritualism in the Western world since the middle of the nineteenth century. In preliterate societies, spirit possession cults have been described as deprivation cults, attracting women and other downtrodden and depressed categories of person (Lewis, 1971). Through membership of the cult, a measure of lost status and esteem may be regained. In Western society communication with the spirits of the departed has been spasmodic. The voice of God, and intimations of divine presence, though central to the tradition of Christian mysticism, fall outside the province of strictly spiritualist experience.

As an organized movement, spiritualism has a quite precise time and place of origin. Historians of

spiritualism trace its beginnings to March 1848, when unaccountable noises were heard by two young sisters in an isolated farmhouse in New York State. The rappings were attributed to the spirit of a travelling salesman murdered there some years earlier, and were interpreted as his attempts to establish communication with the living. Whatever the significance of the original rappings, within two years of their being heard the Fox sisters and their mother had established themselves as successful mediums with huge followings in New York city. Spiritualist circles and seances mushroomed along the east coast of America, and thence spread in two directions: westwards across the American continent and eastwards across the Atlantic to Europe.

The most striking *characteristic* of early spiritualist experience is precisely its nonreligious quality: messages from spirits are peculiar for their concreteness, triviality and a certain mundane bizarreness. Conan Doyle, a historian of spiritualism, and himself a spiritualist, was sensitive to the bad impression which such trivial preoccupations might create. He therefore reminded his readers that the first message transmitted by cable across the Atlantic was a commonplace enquiry from a testing engineer. 'So it is that the humble spirit of the murdered pedlar of Hydesville may have opened a gap into which the angels have thronged' (1926, p. 56).

The movement which developed was quite remarkable in a number of ways. First, it accorded a very special role to women in that mediumship was thought to be primarily, though not exclusively, a feminine art. Secondly, it involved a startling array of events such as *levitations, ectoplasmic apparitions, telekinesis, and apports.

Thirdly, it led to an alliance between spiritualists and scientists which is unique in the history of religion. While feminine stereotypes have always attributed greater intuitive and mystical powers to women (as they saw it at the time), their alleged passivity, lack of high intelligence, and lack of education made them seem peculiarly fitted to become mediums. In this connection Conan Doyle wrote: 'Great intellect stands in the way of personal psychic experiences. The clear state is certainly most apt for the writing of a message' (1926, p. 2). This congruity between stereotypes of femininity and the requirements of mediumship opened up career opportunities for women. The circles or seances were frequently held in the houses of mediums. However, in addition Page 740

to its domestic setting the concerns of spiritualist messages were also of an intimately domestic and familial kind. The intrusion of scientists into this scene of cosy domesticity seems an unlikely event. The Society for Psychical Research was founded in February 1882 in order to make 'an organized and systematic attempt to investigate that large group of debatable phenomena designated by such terms as mesmeric, psychical and Spiritualistic'. Members of the society included philosophers, scientists and politicians. Among the famous names are Henry Sidgwick, Lord Balfour, William*James, Sir William Crookes, Andrew Lang, Henri*Bergson, Gilbert Murray, and William*McDougall. Although both science and religion are concerned with the ultimate nature of reality, only in the case of spiritualism were scientific criteria thought to be relevant for the establishment of religious truth and falsehood. This overlap of interests and techniques is perhaps to be accounted for by, on the one hand, the concreteness of spiritualist claims, and on the other hand by the direction of much scientific research during the 1880s, which was concerned with radiation physics.

In contrast to the respectable scientific solidity of the psychical researcher, the mediums tended to be young, vulnerable, beautiful, and possessed of a certain childlike naïvety. The relationship between Sir William Crookes and Florence Cook is in many ways typical of the relationship between scientist and medium. Florence Cook's spirit guide was an ectoplasmic apparition called Katie King. It was claimed that this materialization could move and talk quite independently of Florence. However, in 1874 the medium's reputation was dramatically threatened by allegations of fraud and trickery. Florence Cook decided to throw herself at the mercy of Sir William, who was known to have an interest in psychical research, having investigated the Scottish medium, Daniel Dunglas*Home. The move proved highly prudent since Sir William wasted no time in jumping to Florence Cook's defence. The precondition of his investigating her gifts was that he should remove her from her parents' house to his own, in the north of London. From the very outset he felt it his duty to defend Florence, particularly if he could remove 'an unjust suspicion which is cast upon another. And when this other person is a woman—young, sensitive and innocent—it becomes especially a duty for me to give the weight of my testimony in favour of her whom I believe to be unjustly accused' (quoted in Hall, 1962, p. 35). Hall puts forward the hypothesis that Sir William and Florence became lovers and that he extended scientific respectability to her in return for sexual love. Hall's interpretation appears to be highly plausible but, even if he were proved to be wrong in detail, the alliance is illuminating from a sociological perspective. Whereas most religious roles for women provide an exalted status and liberation for women at the cost of rejecting traditional femininity, spiritual mediumship capitalizes on existing relationships and transfers them to a spiritual plane. Spiritualism enthrones women in their traditional roles and relationships.

Although there have been many charges of fraud and counterfraud, spiritualist belief has by and large remained impervious to such exposures. The late nineteenth century was the high point of dramatic apparitions and events. The First World War with its large numbers of bereaved provided yet another peak in the growth of the spiritualist movement. Thereafter, spiritualism gradually reverted to its earlier unassuming concerns. Essentially a domestic religion, it provides women with the opportunity of a religious life without transgressing the norms of traditional femininity. It also provides that much sought-after kind of work, work based at home—and the spiritual attention of circles is directed towards problems associated with marriage, family, and illness.

SPLITBRAIN AND THE MIND. The problem of how the mind relates to the brain stands as the greatest challenge to a scientific age which seeks an objective explanation for all nature. Our physicalist world view and our pragmatic approach to social problems may both be transformed by significant discoveries concerning the way human experience and human social consciousness arise in cerebral activity.

Much has been learned by observing how physical damage to the brain in different locations causes losses or distortions of motives, wishes, skills, feelings, and conscious experiences (see NEUROPSYCHOLOGY). Perhaps the most striking results have come from a brain operation that segregates the highest brain functions into two unlike sets: by cutting some 800 million nerve fibres that connect one half of the cerebral cortex with the other it is possible effectively to divide the mind.

It is a principal characteristic of the mind to exhibit a harmonious unity and a coherent command—to make the*consciousness of an individual person. Ever since nerve conduction was understood it has been speculated that the great interhemispheric bridge, the corpus callosum (meaning 'thickskinned body'), is essential for mental unity (Fig. 1). When it and other smaller interhemispheric connections are cut, communication between the two sides must pass by the stem of the brain, which is normally considered unconscious, or through external relations of the body with the world of stimuli and the effects of actions.

Page 741

Fig. 1.

The corpus callosum (CC) is the principal integrator of mental processes which are carried out differently in the two halves of the cortex. It complements connections through the brain stem.

Famous psychologists, including G. T.*Fechner and William*McDougall, have wondered what would happen to*consciousness if the brain were divided in this way.

McDougall, it is said, even tried to persuade the physiologist C. S. Sherrington to undertake to divide his, McDougall's, corpus callosum if he became incurably ill.

Nerve connectionists tended to think conscious experience would be destroyed or divided, but McDougall, a mentalist, believed consciousness would remain unified.

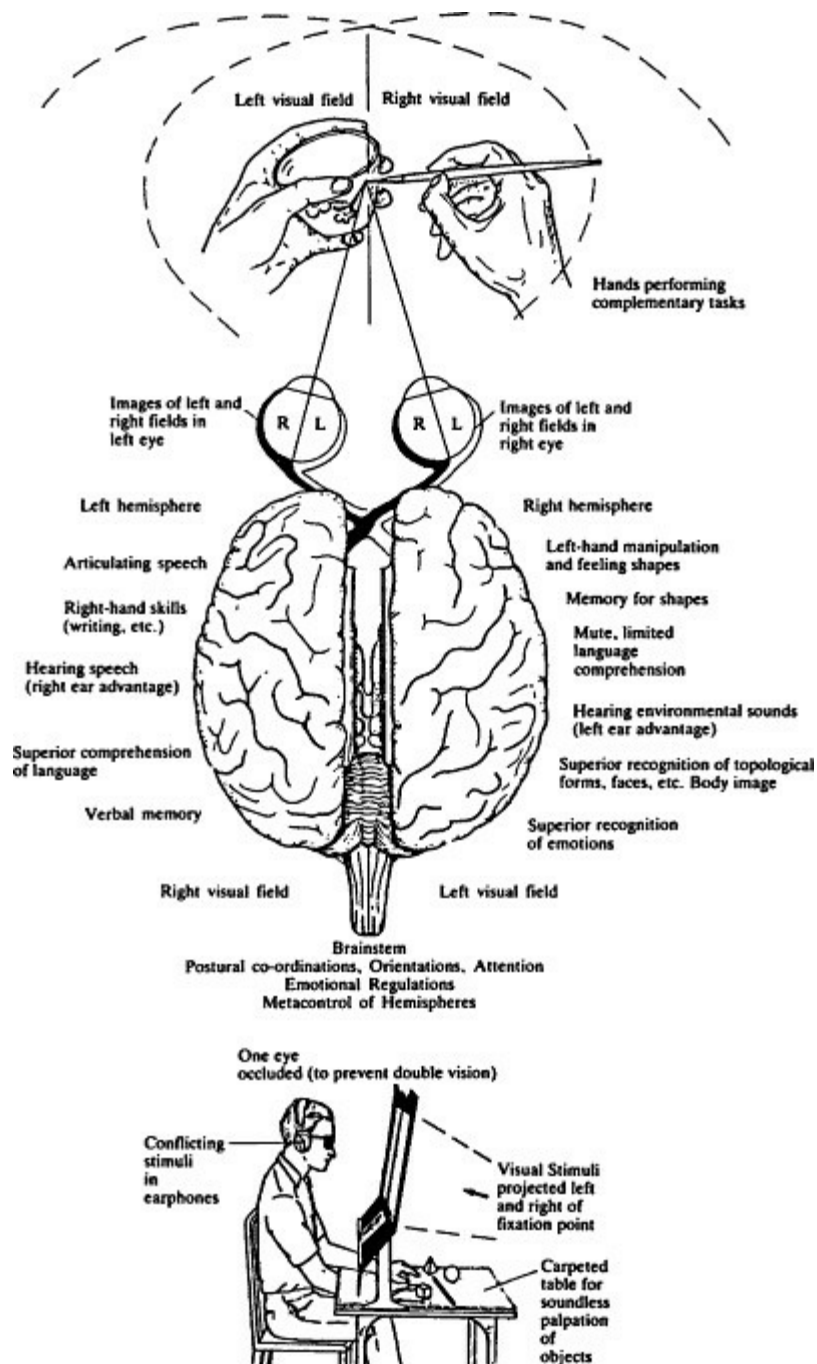

It was frustrating that, for a long time, studies of animals, and a few human cases, with corpus callosum sectioned gave no interesting evidence. Consciousness appeared to be slightly depressed and there were transitory lapses in voluntary coordination, but that was all. In irony, Karl Lashley suggested that the corpus callosum might serve simply to hold the hemispheres together. Warren McCulloch said its only known function was to spread epilepsy.

Cerebral commissurotomy, the splitbrain operation, has been performed with varying completeness on a small number of human beings since the mid 1940s, always in hopes of checking crippling epilepsy, to stop the nonfunctional neural discharges reverberating between the hemispheres and severely damaging the cortical tissues.

The breakthrough in estimation of the mental effects of this operation came from investigations in Roger Sperry's laboratory at the California Institute of Technology, following the first effective experiments on the consequences of commissurotomy in cats and monkeys. The animal studies had established new methods. They revealed simple explanations for why all previous research had observed only trivial and uninformative consequences of so great a change in brain structure. With control for orienting, and of information exchange between the hemispheres through transactions with the external world, the splitbrain animals were found to have totally divided perception and learning. When free, their movements, alertness, and general motivation were entirely normal.

In Los Angeles, the neurosurgeons Philip Vogel and Joseph Bogen concluded that selected epileptic patients would benefit from the surgery and suffer no serious mental loss. Between 1962 and 1968, nine complete operations were performed with success in reducing fits. Psychological tests performed by Michael Gazzaniga, Sperry, and Bogen at the California Institute soon revealed that, while the general psychological state and behaviour was, in most cases, little affected, there was a profound change in mental activities. Other studies with commissurotomy patients carried out since, in the U.S., France, and Australia, have produced similar findings.

For the commissurotomy subject (Fig. 2), direct awareness is no longer whole. An object felt in the left hand out of sight cannot be matched to the same kind of object felt separately and unseen in the right hand. As long as the eyes are stationary,

Page 742

Fig. 2.

Commissurotomy, division of the corpus callosum to relieve epilepsy, causes separate awarenesses in left and right halves of the visual field and for objects in left and right hand. Integrations through the brain stem keep the behaviour of the person coherent, but do not

permit unification of consciousness. Testing

a splitbrain patient involves control of orienting

movements, with one eye covered and stimuli

flashed for 1/10th second on a screen, or objects

felt out of sight on a carpet so no telltale sounds

are fed back to the subject's ears. Using conflicting

auditory stimuli in earphones, division of hearing

may be demonstrated.

Page 743

something seen just to the left of the fixation point cannot be compared to something seen on the right side. Comparable divisions in olfactory and auditory awareness may be demonstrated. Furthermore, although sight and touch communicate normally on each side, left visual field to left hand or right visual field to right hand, the crossed twohemisphere combinations fail, as if experiences of eye and hand were obtained by separate persons. There is no evidence that perceptual information needed to identify an object can cross the midline of the visual field, or between the hands, to unify the patient's awareness. While the division of sight for detail is extremely sharp at the centre of the field, as long as the patient keeps his eyes still, with freedom to look to left and right and to see in both halves of vision what both hands are holding, the division of awareness ceases to be apparent. Indeed, the subject himself seems unaware of anything amiss, except when evidence is presented to him of an inconsistency in his conscious judgement. Then it would appear he feels some lapse of concentration, or absentmindedness.

With stimuli on arms, legs, face, or trunk, there is some transfer of feeling between the sides. These less discriminatory parts of the body are represented in duplicate, with both sides in each hemisphere of the brain, and their functions, sensory and motor, are crossintegrated at levels of the brain below the hemispheres. Interesting results have been obtained with large, longlasting stimuli moving in the periphery of vision. Seeing the spatial layout in surroundings at large, called 'ambient vision', is vital in steering on a confined or irregular route or in a cluttered environment, and even in maintaining the balance of standing or walking. It also functions to give approximate location to offcentre targets of attention before the eyes move to fixate. Evidently the semiconscious appreciation of the location and orientation of major features in outside space, mainly picked up from dynamic transformations of the visual image, is not divided by commissurotomy. Indeed, the general background or context of body coordination and orienting must be intact for commissurotomy subjects to retain the freedom of action and coherence of awareness they ordinarily exhibit. To this degree the operation does not divide the agency of the subject, or the experience of wholebody action. The two halves of the neecortex are kept in functional relationship, coordinated through ascending and descending links with the

subhemispheric regions of the brain stem (Fig. 1).

By far the most dramatic finding of the early tests was the total failure of the right cerebral cortex on its own to express itself in speech. It could not utter words to explain its awareness or knowledge. In contrast, when stimuli were given to the left cortex the subject could say perfectly normally what the experience had been like.

Objects were named, compared, and described, and the occurrence or nonoccurrence of stimulus events was correctly reported. Yet similar tests of the right half of the brain, with stimuli in the left visual field or left hand, totally failed. The subjects often gave no response. If urged to reply, they said that there might have been some weak and illdefined event, or else they confabulated experiences, as if unable to apply a test of truth or falsity to spontaneously imagined answers to questions.

These events not only confirm a division of awareness, but they raise important questions which have been debated in clinical neurology since the discovery, over a century ago, that muteness or disturbance of language comprehension can result from brain injury confined to the left hemisphere. Could the right hemisphere comprehend spoken or written language at all? Could it express itself to any degree in signs, by writing, or by gesture? Could it make any utterance? Could it reason and think? Was it really conscious? The commissurotomy patients offered a wonderfully direct approach to these questions, and ingenious experiments were designed by Sperry and his students Jerre Levy, Robert Nebes, Harold Gordon, and Dahlia and Eran Zaidel to interrogate the unspeaking right hemisphere.

Some comprehension of spoken and written language was certainly present in the mute side of the brain. Information about how the right hemisphere should perform a test could be conveyed by telling it what to do, and if the name of a common object was projected to the right cortex only, the patient could retrieve a correct example by hand, or identify a picture of it by pointing. The right hemisphere could solve very simple arithmetic problems, giving its answer by arranging plastic digits out of sight with the left hand. Nevertheless, it was clear that both the vocabulary as understood and the powers of calculation of the right hemisphere were distinctly inferior to these abilities in the left hemisphere of the same patient. Rarely, a patient was able to start an utterance or begin to write a word with the right hemisphere, but, in these tests, the vigilance of the more competent left hemisphere blocked all such initiatives after the first syllable or letter. In general only the left hemisphere could speak, write, or calculate.

When Levy applied nonverbal*intelligence tests, the results indicated that there were some functions for which the left hemisphere did not dominate: for some modes of thinking the right hemisphere was superior. All these right brain tasks involved visual or touch perception of difficult configurations, judgements involving exploration of shapes by hand or manipulative construction of geometric assemblies or patterns. It appeared that the right hemisphere was able to notice the shape of things more completely than the left. Taken with evidence that systematic calculation and forming logical propositions with words were better performed by the left hemisphere, these results favoured the idea that the right hemisphere is better at taking in the structure of things synthetically, without analysis,

assimilating all components at once in an ensemble, figure, or *Gestalt. Nebes discovered that the right hemisphere may have a clearer memory of the appearance of things, in the sense that it was better able to recognize familiar objects with incomplete pictorial data, and better able to perceive whole shapes from parts seen or felt in the hand.

The way hands are normally used hints at differences in awareness of the hemispheres. (See HANDEDNESS.) In normal manipulation, a righthander supports and orients an object in the grasp of the left hand, to facilitate discrete moves of the right fingers that are more finely controlled. Consider such a simple act as taking the last drop of soup from a bowl with a spoon. To grasp, support, and orient objects, the left hand must 'understand' the dimensions and distribution of matter in an object, and usually this kind of judgement does not need visual inspection. In contrast, the discrete and precise acts of the right hand require a succession of decisions that are aimed or guided by a sequence of brief visual fixations. Writing is a cultivated skill that uses the righthand endowment for rapid repeated cycles of action in the service of language. It may be a learned adaptation of the brain mechanism for gestural communication, the right hand of most persons being dominant for expressive gesticulation. In many tests, the left hand of the commissurotomy patients was more efficient than the right at feeling shapes that resist analysis into highly familiar elements. The left hand palpated complex raised patterns as wholes, as if sensing shape directly. In contrast, the right hand tended to feel the contours, comers, etc., one by one, as if trying to build up an inventory of discrete experiences along a line in time. Recently, experiments with the same subjects have demonstrated that the right hemisphere tends to be superior at metaphorical rather than literal perceptions, and that it perceives the emotions or moods in facial expressions or vocalizations better than the left.

To further explore the processes that direct awareness in the hemispheres, Levy, Trevarthen, and Sperry gave splitbrain subjects a free choice of which hemisphere to use to control responses in tests. Halves of two different pictures were joined together down the vertical midline to make a double picture called a stimulus chimera.

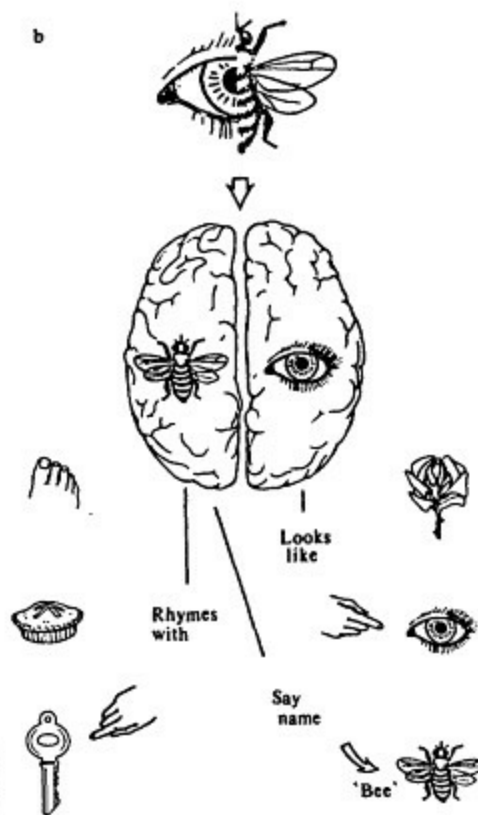

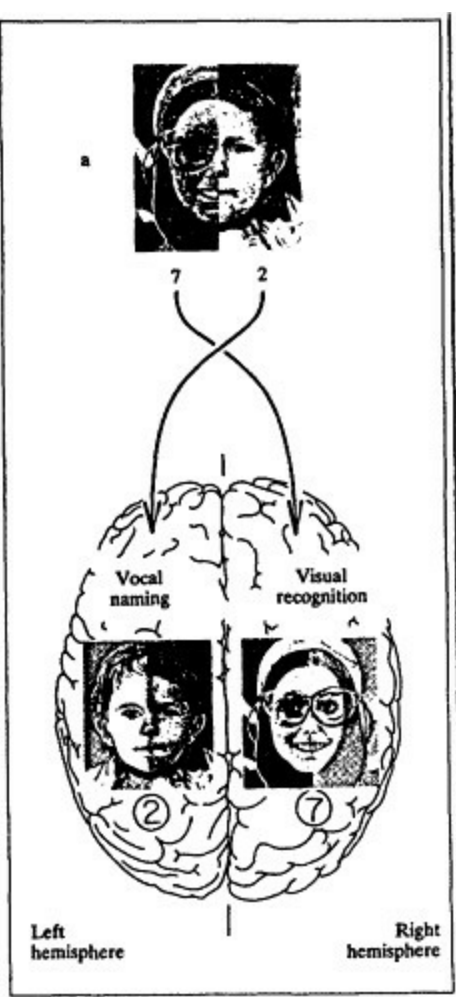

When this is presented to the splitbrain patient with the join on the fixation point, information about each half is received in a different hemisphere. The tasks are designed so that in every trial the correct choice may be obtained by using the experience of either the left or right hemisphere. Preference for one half of the chimera depends on onesided mental strategies that arise in response to the test instructions. With this kind of test, preferred modes of understanding of the hemispheres can be sensitively determined, as well as the cerebral functions that allocate attention between the two hemispheres.

The choices of the commissurotomy patients with chimeric stimuli confirm that thought in words favours the left hemisphere. Single words can be read by the right hemisphere, but the left is always preferred if the meaning of the words must be understood and not just their visual appearance or pattern. Further tests show that the right hemisphere is virtually unable to imagine the sound of a word for an object seen, even a very common one like an 'eye', so it cannot solve a test requiring silent rhyming 'in the head' (for example, 'eye' matches 'pie', 'key' matches 'bee'). It seems as if the habitual,

and inherently favoured, dominance of the left hemisphere for speaking is tied in with a onesided ability to predict how words will sound. The right hemisphere can know the meaning of a word from its sound, but it cannot make a sound image for itself from sight of the word, or from sight of the object the word stands for.

Preference for the right hemisphere in matching things by their appearance becomes strong when meaningless or unanalysable shapes are used, especially if these are not representing familiar objects, with a simple name. An extraordinary superiority of the right hemisphere for knowing a face, especially when it lacks bold distinctive features such as glasses, moustache, hat, or birthmark, relates to a rare consequence of damage to the posterior part of this hemisphere. This inability to recognize even the most familiar faces, called prosopagnosia, can greatly embarrass social life. With splitbrain persons and stimuli restricted to the left hemisphere, face recognition is poor and identification is achieved by a laborious checklist of distinctive semantic elements to be memorized and searched for. There is obviously a stark contrast in hemisphere cognitive style, reminiscent of differences described in the way the two hands go about knowing or using objects. In addition to these apparently fixed differences in the organization of hemispheric cognitive structures, commissurotomy patients show a varying activation of the hemispheres under brainstem control that can favour one or other side independently of task requirements. Sometimes the 'wrong' hemisphere is active in doing a task, and performance suffers. This 'metacontrol' may cause differences in the way normal individuals process cognitive problems; i.e. it may determine differences in mental abilities—for example, making one person skilled at visuoconstructive tasks while another is gifted at verbal rationalizations.

There are still many questions concerning the complementary styles of intelligence and conscious awareness revealed by commissurotomy and about how hemispheric functional states are coordinated. Some of the findings blur classical distinctions. Not all linguistic or propositional functions are confined to the left hemisphere, and though the right hemisphere is better at perceiving resemblances between complex forms, the left can perceive and recognize. In neither case is the monopoly of cognitive style complete, and cerebral asymmetry of function is now regarded as a matter of degree. However, as the chimera studies

Page 745

Fig. 3.

a. Stimulus chimeras, joining left and right halves of different pictures, permit study of preferences in cognitive processes of the hemispheres. The stimuli are flashed in the precise centre of the visual field in a tachistoscope. If asked to say what was seen, the splitbrain subject identifies the right half of the chimera, signifying preferential use of the left hemisphere. If pointing to match the picture that looks most like the stimulus, the left half is selected, indicating that the right hemisphere assumes control of this response.

b. By varying instructions one can obtain three different kinds

of response from one stimulus. Saying the name or pointing silently

to a picture of an object with a name that rhymes with that of the

stimulus causes the left hemisphere to take charge.

Visual matching engages the right hemisphere.

Note that in both these diagrams, the awareness of a half stimulus is

shown as completed. Indeed experiments indicate that the s

ubject imagines freely over the midline, presumably because there

is no information at variance with imagined parts in the hemisphere doing

the imagining.

showed, there are some factors, not necessarily simple in their relationship to conventional psychological tests, but more involved in the strategy by which the brain as a whole allocates mental operations or motivates consciousness, for which left and right hemispheres do have markedly different capacities and preferences. Since the hemispheres of commissurotomy patients become progressively more alike, or less differentiated, by postsurgical learning or other changes compensating for their separation, they probably can reveal to us only weakened forms of hemisphere specialization.

Eran Zaidel has developed a method for blocking off half of the visual field of one eye of a commissurotomy patient. He attaches to the eye a contact lens which carries a small optical system and a screen. The patient can cast his eye over a test array in a normal way while picking up visual information by only one hemisphere.

The subject has to interpret a story or picture or solve puzzles,

Page 746

many involving choice of the one picture from a group that will identify a concept to which he or she has been cued by a preceding stimulus. These tests prove that both hemispheres have elaborate awareness of the meanings of words and pictures. Metaphorical relationships form an important component of consciousness of meaning in both of them. Objects may be linked in awareness by their abstract properties or customary usefulness and social importance as well as by more obvious features. The usual names, colours, temperatures, and many other properties of things may be correctly identified when each thing is represented by a simple black and white picture. The tests of Zaidel and Sperry have shown that both hemispheres of commissurotomy patients have awareness of themselves as persons and a strong sense of the social and political value, or meaning, of pictures or objects.

Comprehension of words, spoken or written, is surprisingly rich in the right hemisphere, and all grammatical classes of words may be comprehended; but its consciousness does fail with relatively difficult, abstract, or rare words. When words are combined in a proposition, the comprehension of the right hemisphere falls drastically. When simplified items of no particular identity, such as plastic chips of differing size, form, and colour, are used as tokens for arbitrary grouping defined by short descriptions (for example, 'Point to a small red circle and a large yellow triangle'), this too proves difficult for the right hemisphere. A token test of this description was discovered by the Italian neuropsychologists Di Renzi and Vignolo to be extremely sensitive to left hemisphere lesions. The linguistic abilities of the right hemisphere thus resemble those of a nursery school child who understands language best when it is fitted into the world of objects, interpersonal acts, and events, all of which sustain the meaning of what is said. Disembedded or contextfree propositions lacking interpersonal force require concentration of the mind on categories, critical formulae, or rules for action. These processes of thought may be developed by transformation of inherent human skills for establishing precise identity or harmony of purpose between thinking agents. Such propositions are difficult alike for young children and the disconnected right hemisphere of an adult.

Commissurotomy patients have helped us understand how consciousness, intention, and feelings are generated in activity at different levels of the brain. Thus separated cortices may experience and learn separately, but each may command coherent activity of the whole body. Feelings of dismay, embarrassment, or amusement, generated in one hemisphere by perceptions of threat, or risk, or teasing, invade the brainstem to cause expressions and emotions of the whole person, in spite of the operation. Levels of attentiveness and the shifting aim of orientation and purpose are also patterned within brainstem regions, which can transmit no detailed evidence of experience. The precautions needed to reveal divided awareness after brain bisection emphasize how, in normal active life, information about the world is constantly reflected to all parts of the brain as it and the body engage in changing relations with the external world. It does not appear necessary to imagine that the 'self', which has to maintain a unity, is destroyed when the forebrain commissures are cut, although some of its activities and memories are depleted after the operation.

The evidence on hemispherical differences reveals inherited motive structures for speech and rational thought that have evolved to establish intentional and experiential communion between persons. The brain is adapted to create and maintain human society and culture by two complementary conscious systems. Specialized motives in the two hemispheres generate a dynamic partnership between the intuitive, on the one side, and the analytical or rational, on the other, in the mind of each person. This difference appears to have evolved in connection with the human skills of intermental cooperation and symbolic communication.

Research with normal subjects stimulated by the commissurotomy studies shows that individuals vary greatly in the development of asymmetrical functions in their brains and in the ways the hemispheres are habitually activated. Such diverse factors as sex, age, handedness, education, and special training correlate with psychological and physiological measures of cerebral lateralization and hemispheric activation. The evidence is that human kind is not only very diverse in outside appearance: minds in any race, even in a single family, are inherently different in cognitive bent. It is not hard to perceive advantages of such psychological diversity in the most highly cooperative of beings, in whom mind

and the experiences of society and culture become inseparable.

SQUINT. See DIPLOPIA; EYE DEFECTS AND THEIR CORRECTION.

STEREOSCOPIC VISION. It is remarkable that the use of the two eyes to provide 'stereoscopic' depth was not appreciated by the Greeks, or indeed at all generally before Charles Wheatstone's invention of the stereoscope in 1832 (published in 1836). Although it was forgotten, and is still not at all well known, the power of the two eyes working together to give three-dimensional perception was appreciated as early as 1677 by a French Capuchin friar, le Père Cherubin of Orleans.

(This is described with a drawing of the instrument by Jabez Hogg, 1854.) Wheatstone made pairs of drawings from slightly separated points of view, which he presented one to each eye, by means of a pair of mirrors placed close to the eyes (Fig. 1). Wheatstone realized that each eye has a slightly different image because of its horizontal separation from the other; so that the 'corresponding points' of the images of the two eyes have a greater separation for near objects than for distant ones.

These 'stereograms' he found are combined into a single 'perception'—of objects in depth. More convenient optical systems were developed in 1849 by the Scottish physicist David Brewster and stereoscopic photographs became popular in the early days of photography.

More recently, it has been discovered by Bela Julesz that it is not necessary for there to be recognizable objects or line features for stereoscopic fusion and depth. He showed that if a region of one of a stereo pair of otherwise identical random dot patterns is displaced sideways, the region appears to lie in front of (or if reversed to the eyes, behind) the rest of the pattern. It is remarkable that each eye system can discover the corresponding dots, because all the dots are identical and featureless (see VISION: THE EARLY WARNING SYSTEM). This discovery has led to a wealth of new knowledge about the visual system. For example, it has made it possible to show that the distortions of many well-known illusions have their origin not at the retina (as had often been thought) but considerably further up the system—at or after the layer of the striate cortex where the signals from the two eyes are combined. This is shown by presenting illusion figures as stereo pairs of random dots, so that neither eye can see the figure or even any line of it; but when the two random dot figures are combined by stereo fusion, then the illusion figures are seen—and they have their normal distortions. The point is that since neither eye alone receives the shapes or contours of the figures, but only meaningless random dots, the origin of the distortion must be at, or after, the neural fusion of the dot patterns in the brain.

Normally stereopsis is important for perceiving random shapes, or objects such as leaves on a tree. It

is interesting, however, that some of the 'monocular' depth cues can actually cancel stereoscopic

Fig. 1

Diagram of Wheatstone's stereoscopic apparatus. Two mirrors at

A',A reflect the drawings at E',E and produce a 'solid' image when

viewed simultaneously from very close range. (From *The Stereoscope*,

by Sir David Brewster (1856).)

Page 748

depth, when pitted against it. Thus a perspective scene viewed in stereo but with the images switched between the eyes (with a pseudoscopic optical system) will generally continue to appear in normal depth—the perspective beating the stereo. Also, stereoscopy will not allow highly unlikely reversals of depth, or correct perception of objects which have unlikely depths—such as the hollow mould of a face. Such a mould will continue to appear as a normal face, though it is hollow, in spite of considerable stereoscopic information when it is viewed from some distance with both eyes.

It is now known that most of the cells in the visual cortex are 'binocularly driven' from the two eyes, and the way in which the signals from the eyes are combined for stereo vision is becoming clear. It is also becoming possible to simulate or produce the equivalent of stereo perception with computer vision (Marr and Poggio, 1976, 1979) though at present this is very much slower than the brain's stereo computing.

STEVENS, STANLEY SMITH (190673). American psychologist, professor of psychophysics at Harvard University, where he spent all his professional career.

He is known, above all else, for the power law which relates physical stimulus magnitudes to the numbers assigned to them in magnitude estimation experiments.

During the last twenty years of his life he and his many collaborators replicated this experimental result many times over with more than thirty different stimulus attributes. The same power relation applies when stimulus magnitudes are adjusted to match a given number and to match the magnitude of some other attribute (e.g.

matching loudness to brightness). Stevens regarded the numbers uttered by his subjects as direct estimates of the magnitude of the sensation experienced, though this has always been a controversial issue (for technical considerations, see QUANTIFYING JUDGEMENTS).

During the Second World War, Stevens was engaged in studying the effects of intense noise in military aircraft, being then director of the psychoacoustic laboratory at Harvard. About that time he conceived his neural quantum theory, the idea that sensory discrimination is limited by the discrete nature of neural conduction. He also edited the 1,400page compilation *Handbook of Experimental Psychology*, which appeared in 1951. But his most enduring contribution to science will probably prove to be his early work on measurement. The names he proposed for different kinds of measurement—'nominal', 'ordinal', 'interval', and 'ratio'—have become so universally used that few people are now aware of their origin.

See PSYCHOPHYSICS.

D.R.J.L.

For a posthumous summary of Stevens's work, see Stevens, S. S. (1975). *Psychophysics*. New York.

STIMULUS. Stimuli are patterns of energy received by the senses; they evoke behaviour and are the basis of*perception. Even so, they may not be noticed or experienced, or they may be only part of what we experience and accept as signals or data for behaviour and perception. In particular,*retinal images may be thought of as patterns of energy from the external world; but we do not see them. We see objects, partly as the result of signals from these optical stimuli and partly from our knowledge of what objects are like.

The role of stimuli is rather differently described in various biological and psychological accounts. 'Stimulusresponse' theories for behaviour emphasize the importance of received stimuli rather than internal processes—a line of argument most radically worked out in behaviourism (see CONDITIONING). Such an approach, perhaps, had its initial plausibility as a psychological theory from observations of highly predictable tropisms (responses to or away from light, chemical concentrations, etc.) found in many lower organisms. The Germanborn American physiologist Jacques*Loeb (18591924) explained the 'forced movements' in simple animals in terms of the 'tonus hypothesis', namely that the muscular tone on each side of the body is affected by the relative intensity of signals from paired sense organs, especially the eyes, the animal moving towards the side having the strongest muscular tension. This view has been largely abandoned as a theory of tropisms in animals, but a similar explanation *is* accepted for plants as they grow towards the light, or grow upright by geotropisms. It is believed that, whereas stimuli can have quite direct effects on plants, their effects on even simple animals are seldom direct, as they are 'read' or interpreted according to

the situation and the needs of the animal.

STIMULUSRESPONSE THEORY. See CONDITIONING.

STRABISMUS (SQUINT). See EYE DEFECTS AND THEIR CORRECTION.

STRESS. Why has the problem of stress become a major issue of our time? Can it really be that life conditions in our society are more stressful, more taxing, than those experienced by our ancestors? From a material standpoint the answer to this question is, of course: no. The conditions in con

Page 749

temporary society are less stressful than those that have been experienced by any previous generation. But our age has its own problems, many of them psychological and social in nature; and we do not need to be starved, or cold, or physically exhausted for stress to occur. Life in technologically advanced societies imposes new demands which trigger the same bodily responses that helped our ancestors to survive by making them fit for fight or flight—responses that may be totally inappropriate for coping with the stresses of life today.

Stress may be regarded as a process of transactions in which the resources of the person are matched against the demands of the environment. The individual's appraisal of the importance of the demands are reflected in the bodily resources mobilized to meet them.

Man as a 'stressometer'. One of the notions underlying the use of physiological and chemical techniques in human stress research is that the load that a particular environment places on a person can be estimated by measuring the activity of the body's organ systems. Technological advances, together with progress in the biobehavioural and biomedical sciences, have made new methods available for investigating the interplay between mental and physical processes. Much of what was previously the subject of speculation can now be recorded and measured, and as more of what happens in the different bodily organs becomes accessible to measurement, the effects that mental and physical processes have on one another become increasingly clear. We can record changes in heart rate that accompany changes in the environment. We can show how psychological processes are reflected in the activity of the brain, in cardiovascular functions, in hormonal activity, etc.;

and we can see how hormonal changes reflect changes in mood, how blood pressure rises to challenge, and how the alertness of the brain varies with the flow of impressions transmitted by the sense organs.

Since feelings and perceptions are reflected in the activity of many of the body's organ systems, individuals can themselves be regarded as 'stressometers', instruments which help to identify factors in the environment that tell hard on their mind and body. The environmental factors may be physical

or chemical, such as noise or smell;

or social and psychological, such as monotonous work, excessive information flow, or interpersonal conflict.

With the development of chemical techniques that permit the determination of small amounts of hormones and transmitter substances in blood and urine, neuroendocrinology has come to play an increasingly important part in stress research. Two neuroendocrine systems, both of which are controlled by the brain, are of particular interest in the study of stress and coping with stressful situations. One is the sympatheticadrenal medullary system, with the secretion of the*catecholamines adrenaline (epinephrine) and noradrenaline (norepinephrine). The other is the pituitaryadrenal cortical system, with the secretion of cortisol. These substances have several important functions: as sensitive indicators of the mismatch between the person and the environment, as regulators of vital bodily functions, and—under some circumstances—as mediators of bodily reactions leading to disease.

What do we know about the environmental conditions that activate these two systems?

Underload and overload. Stimulus underload and overload are typical features of modern society, and both of them trigger the adrenal medullary and adrenal cortical response. In order to function adequately, the human brain requires an inflow of impulses from the external environment; but both lack and excess of stimulation threaten the*homeostatic mechanisms by which the organism maintains an adequate degree of*arousal. The optimal level of human functioning is located at the midpoint of a scale ranging between very low and very high levels of stimulus input. At the optimal level, the brain is moderately aroused, the individual's resources are mobilized, and full attention is given to the surroundings; he is emotionally balanced and performs to the best of his abilities. At low levels he tends to be inattentive, easily distracted and bored. Conditions of extreme understimulation, involving both sensory and social deprivation, are accompanied by a state of mental impoverishment with loss of initiative and loss of capacity for involvement. When the brain is overaroused, on the other hand, the ability to respond selectively to the impinging signals is impaired. Feelings of excitement and tension develop, followed by a gradual fragmentation of thought processes, a loss of ability to integrate the messages into a meaningful whole, impaired judgement, and loss of initiative.

Helplessness. Psychological theories of helplessness emphasize the role of learning in the development of active coping strategies. A sense of hopelessness, paired with a reduced motivation to control, is likely to develop when people realize that events and outcomes are independent of their actions. Empirical evidence from many sources, including both animal and human experiments, show that the organism responds differently to conditions characterized by controllability on the one hand, and lack of control on the other. On the whole it is consistent with the view that increased controllability reduces physiological stress responses, such as adrenaline and cortisol secretion, thus presumably decreasing bodily wear and tear.

Is stress dangerous to health? There is general agreement that mental stress may increase the risk of ill health and affect the course of both somatic and mental disorders. But the biological mechanisms

by which stress translates into disease are still

Page 750

obscure. Relationships exist between stress and diseases such as myocardial infarction, high bloodpressure, gastrointestinal disorders, asthma, and migraine;

however, it is only occasionally that a particular mental factor can be identified as the specific cause of a disease. As a general rule the psychological aspect is merely one thread in a complex fabric in which genetic components, environmental conditions, and learned behaviours are also interwoven.

This lack of a clear picture of the links in the causal chain between stress and disease hampers our efforts to prevent harmful stress responses. However, we know a great deal about the mobilization of stress hormones under conditions of underload and overload, and although it is still not known when such stress responses lead to ill health it is agreed that they should be treated as early warning signals. Moreover, we also know a great deal about how stress that is liable to impair health can be counteracted. Stress responses can be dampened, for instance, by providing opportunities for personal control, which can then serve as buffer, warding off potentially harmful effects of, for example, overload at work.

In short, stress research has already contributed knowledge that can be used to shape the external environment so as to fit human abilities and needs. Such insights are being utilized more and more, particularly in working life, both in the organization of work and in the application of new technology.

STROKE is the third major cause of death in the Western world. It is also the commonest cause of severe physical disability occurring in people living in their own homes. It has major financial implications both for individuals and for nations.

The term 'stroke' is used to describe an acute disturbance of the brain due to an abnormality of blood supply. The onset is usually sudden and, indeed, it is this suddenness which is one of its principal characteristics. The most common initial event is weakness of the arm and leg on one side of the body (hemiplegia). About 15

per cent of 'cases' are accounted for by spontaneous bleeding into the substance of the brain—cerebral haemorrhage— usually the result of rupture of minute aneurysmal weaknesses, on one of the small arteries deep inside the brain. In the remaining 85 per cent, the underlying pathology involves 'infarction' (death of tissue), resulting from partial or complete blockage of an artery, with the resultant cutting off of arterial blood supply.

The term 'cerebrovascular disease' is used to describe abnormalities of the arteries in the brain. The pathology of cerebral haemorrhage has been mentioned above. In the majority of cases, however, there is infarction due to arterial blockage. The underlying process involves atheroma, in which there is deposition of fatty substances on the wall of the blood vessel. The three principal results of this process are stenosis (narrowing), occlusion (blockage), and embolism, which involves the formation of a blood clot on the damaged arterial wall; this becomes dislodged and may itself produce blockage of an artery 'further on' in the arterial circulation.

Cerebrovascular disease is often associated with degeneration of arteries elsewhere— particularly in the heart (cardiovascular disease).

Who gets strokes? The overall incidence (number of new cases each year) of stroke is about 2 per 1,000 persons. About 75 per cent of acute stroke cases occur in people aged 65 or more, but this still leaves 25 per cent occurring in people under 65, many of whom are still working at the time of the stroke. About 35 per cent of patients will die within the first three weeks.

The prevalence (number existing at any one time) of stroke survivors is about 5 per 1,000, about half of whom will be disabled. Thus, in British terms, the average health district of a quarter of a million people will contain about 1,250 who have survived a stroke, about 620 of whom will be disabled. The majority of disabled stroke survivors will have a paralysed arm and many will be unable to walk normally.

Can strokes be avoided? Much attention has been given in recent years to identifying 'risk factors', with a view to setting up programmes of stroke prevention. The major treatable factor is hypertension (high blood pressure). There is now clear evidence that the effective treatment of hypertension can reduce (although not eliminate) the risk of an acute stroke. This places considerable logistical demands on general practitioners and others who have the responsibility of both detecting and treating the condition.

Other risk factors are of less importance and include diabetes, cardiac disease (particularly disorders of the heart valves and of cardiac rhythm), an increased number of red blood cells (raised haematocrit), and an excessive intake of alcohol.

There has been a steady decline in the death rate from cerebrovascular disease in many parts of the world during the last thirty years. The reason for this, however, is unclear.

The acute phase. The precise effects of a stroke are determined by a variety of circumstances, including the pathology (haemorrhage or infarction), and the extent and location of the damage. The

majority of strokes involve one of the cerebral

Page 751

hemispheres, but a minority (10 per cent) affect the 'brain stem'. The initial insult involves local tissue damage and this is later followed, in many instances, by secondary swelling (oedema). This produces a mass effect within the cranium which, if sufficiently large, may cause a marked elevation of pressure. This, in turn, may lead to pressure on the vital centres of the brain stem (coning), causing drowsiness, unconsciousness, respiratory paralysis, and ultimately death.

The diagnosis of 'stroke' can, in appropriate instances, be confirmed by a CT (computerized tomography) brain scan (see IMAGES OF BRAIN IN ACTION). This test reliably distinguishes between haemorrhage and infarction. In addition, it detects those few instances of brain tumour which masquerade as a stroke.

In most countries, patients with an acute stroke are admitted to hospital. A recent study in the UK (Wade et al., 1985) showed that 75 per cent are admitted within the first 12 weeks. None the less, patients *can be* managed at home if the appropriate support services (general practice, physiotherapy, district nursing, etc.) are well developed.

A few patients are suitable for some form of surgery—usually involving the removal of a blood clot within the cranium. There have been attempts to reduce brain oedema by using steroids, mannitol, dextran, and glycerol, but these agents have not been shown to produce consistent benefits. Anticoagulants can be used to prevent intravascular blood clotting, but are rarely of benefit. Lowering of blood pressure in the acute stage of the stroke is rarely indicated. A variety of other drugs are currently being evaluated, but at the moment no specific medication is helpful in the majority of instances.

During the first week, stroke patients require much skilled nursing care with particular attention to swallowing, hydration, and the prevention of pneumonia and pressure sores.

Assessment of neurological deficits. The patient usually becomes 'medically stable' within the first ten days. At the end of this time, he or she is likely to be fit enough to start the process of 'rehabilitation'. Most patients will have weakness or paralysis of the arm and leg on one side of the body (a hemiplegia). In many instances, this

'motor' loss is accompanied by impairment of sensation in the limbs. The paralysed limbs require careful positioning, and it is essential to avoid excessive pulling and stretching of the affected joints. A variety of other deficits may occur:

1. Hemianopia. A homonymous hemianopia occurs if the visual pathways in the affected hemisphere have been damaged (see VISUAL SYSTEM: ORGANIZATION). If the disturbance is severe, the patient will not see objects on one side. Thus, a patient with a right homonymous hemianopia may not react to his wife and family, if they are sitting at his bedside on his right side. If mobile, he may walk into doorframes and other objects on the right side.

2. *Aphasia* (in this context, the terms 'aphasia' and 'dysphasia' are used synonymously) involves a disturbance of *language* function, and usually results from damage to the left cerebral hemisphere. In its mildest form, it may simply involve the inability to name objects such as a table, clock, or pen. In most instances, however, there is a disturbance of comprehension, and reading is impaired. In the worst cases, the patient has almost complete loss of the ability to comprehend language, and cannot speak, though happily, the problem is rarely so severe.

3. *Visuospatial disorders*. Damage to the right cerebral hemisphere often produces disorders of spatial orientation (see SPATIAL COORDINATION OF THE

SENSES) and perception. These can be complicated and difficult to understand, but are of enormous importance to those who are caring for the stroke patient. Some patients neglect one side of the body (usually the left), and may even deny the existence of the left arm. Occasionally, the patient's perception of the arm is distorted so that it appears much longer or shorter than normal, or appears to be covered in hair. Patients with a severe disturbance of spatial function may be, for instance, unable to draw symmetrical objects, such as a house, or a clockface, the left side of the object being usually less well drawn than the right. Such people are frequently unable to dress because they cannot organize their clothes, and may, for instance, try to don a jacket which is insideout and backtofront.

A variety of other deficits may be mentioned. *Apraxia involves a defect of motor programming, so that the person is unable to undertake tasks, although there is no paralysis of the affected part. Thus, the person may be unable to stick out his tongue when asked to do so, although he has no difficulty with licking his lips involuntarily. A patient with visual *agnosia may be unable to recognize common objects, such as a pen or a torch, although his eyesight is satisfactory. The range of scope of cerebral disorders resulting from a stroke is large; their recognition, quantification, and management are discussed in detail in Wade et al. (1985).

Patients with an acute stroke usually remain in hospital for 4-6 weeks and are then allowed home. Their rehabilitation involves physical therapy, designed to help the patient regain lost functions, and to avoid unnecessary complications such as stiff and immobile joints, and fractures (which are often due to falling, associated with premature attempts at walking).

How much recovery will occur? There is now considerable literature on the subject of recovery after stroke (for example, Skilbeck et al., 1983, and Barnett et al., 1986). The three adverse factors

Page 752

occurring in the first few days are unconsciousness, urinary incontinence, and deviation of the eyes to one side. Only 5-10 per cent of patients who are unconscious in the first week will survive, and those that do survive will usually be left very severely disabled.

About 75 per cent of disabled stroke survivors learn to walk again, though only about 20 per cent can walk at a normal speed. Many cannot, for example, get to the shops or pub. Only 15 per cent of those with a paralysed arm eventually regain normal arm function. Dysphasic patients may be expected to

make about a 25 per cent improvement between three weeks and six months. In general, the amount of recovery is largely dependent upon the severity of the initial deficit: those who are severely disabled initially will usually remain with a severe permanent disability, although some recovery usually occurs; and similarly, those with a mild initial deficit may eventually make a full recovery.

Longterm adjustment. We have already indicated that many stroke survivors never make a full recovery. These unfortunate people are faced with trying to rebuild their lives. A few of the younger patients return to work, but most do not. Some stroke patients learn to drive again, often using a car with modified handcontrols.

Many can enjoy everyday activities such as shopping, social visiting, and swimming. A full and worthwhile life is regarded as being the goal of rehabilitation.

Depression is present in about onethird of patients, though they may respond to appropriate treatment with drugs or counselling. Furthermore, the strain on the spouse can be very considerable, and depression and chronic unhappiness on their part are, again, common.

The future. There is increasing interest in the problem of cerebrovascular disease. Future research is likely to concentrate on prevention (including, particularly, ways of detecting symptomless hypertension), the development of techniques to reduce brain swelling in the acute phase, and the trial of different methods of encouraging recovery in the damaged nervous system. Increasing attention is being given to helping stroke survivors rebuild their lives, and this is being done partly by a national network of voluntary Stroke Clubs which have been pioneered in Britain, for instance, by the Chest, Heart, and Stroke Association.

Stroke and its manifestations are subjects of great scientific interest. The present position has been dealt with extensively by Barnett et al. (1986). Until recently, in Britain the amount of money spent on research into the subject was extremely small compared with the sums devoted, for instance, to cancer and heart disease.

However, there is now an increasing awareness of the problems of cerebrovascular disease, and it is to be hoped that in the years to come we shall see a much increased research effort.

SUBJECTIVE FIGURES. See ILLUSORY FIGURES.

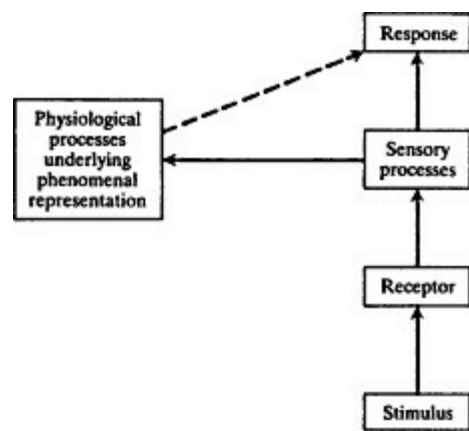

SUBLIMATION is the term used in**psychoanalysis* for the defence mechanism by which the energy derived from an instinct when it is denied gratification is displaced into a more socially acceptable interest or activity. Aggressive impulses are said to have been sublimated when they are expressed in competitive sports.

Dancing may represent the sublimation of sexual impulses.

D. R. D.

SUBLIMINAL PERCEPTION. Few hypotheses in the behavioural sciences have occasioned so much controversy as the suggestion that people may be affected by external stimuli of which they remain wholly unaware. This notion of**perception without awareness*, evidently taken for granted by such philosophers as Democritus,**Socrates*,**Aristotle*, and**Leibniz* but still strenuously resisted by some academic psychologists, concerns a unique and noncommonsensical relationship between brain,**consciousness*, and behaviour.

As depicted in Fig. 1, it implies that the brain processes underlying conscious experience differ from those that mediate between incoming stimuli and outgoing responses. It implies that information may be transmitted through the organism without

Page 753

Fig 1.

ever achieving conscious representation. Three sorts of evidence support this view: that based upon subjective experience, that stemming from neurophysiological studies, and, most specifically, that relying upon the data from behavioural research on subliminal perception. Let us consider these in order of specificity.

The occurrence of *dreams and *hallucinations unrelated to ongoing external stimuli attests to the fact that conscious perceptual experience depends upon brain processes that may operate independently of those subserving the receipt of information from the external world. Conversely, in *skilled behaviour, in situations involving divided attention, in *somnambulism, and in many of the body's involuntary regulatory responses to changes in external stimulation, information may be received, processed, and initiate responses without conscious registration. Taken together these observations suggest that consciousness and information transmission depend upon different systems which may, under certain circumstances, operate independently.

Since 1948 the existence of these two systems, a *sine qua non* of subliminal perception, has been confirmed by neurophysiological research. (see Moruzzi and Magoun, 1949; Samuels, 1959; and Dixon, 1971 and 1981). Whereas the receipt and onward transmission of sensory information, initiated by external stimuli, depends upon the classical sensory pathways linking peripheral receptors with their cortical projections, *awareness* of this sensory traffic—perceptual experience—

relies upon sufficient contribution from the ascending fibres of the reticular activating system, that dense network of cells which arises in the brain stem and then spreads upwards and outwards to infiltrate the cortex. If the reticular system is blocked by surgery or drugs, the arrival of sensory information at the cortex still occurs but the owner of the cortex remains oblivious of the fact! This finding, of considerable significance for proponents of subliminal perception, accords with data from research by Libet and his colleagues (1967). Recording from the exposed brains of fully conscious human subjects, they were able to detect electrical potentials initiated by tactile stimuli of which their subjects remained totally unaware. *Pari passu* with intensifying the external stimulus, the recorded waveform became more complex and the subjects reported, 'I can feel something.' It seems reasonable to assume that the additions to the waveform reflected those contributions from the

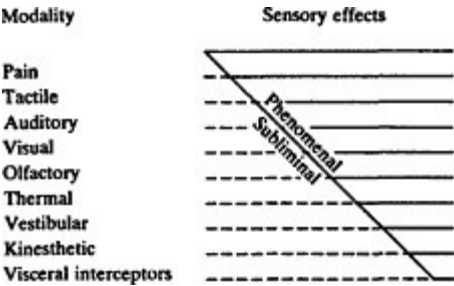

reticular system upon which consciousness depends.

In a subsequent experiment it was found that the amplitude of an electrical response, recorded from the visual receiving area and initiated by a flash of light to one eye, could be reduced by subliminal presentation of an emotional word to the other eye. Since this effect did not occur for emotionally neutral words, we must assume that the brain could analyse and respond to the meaning of words of whose presence the recipient remained unaware. Yet other studies (Dixon, 1971 and 1981) have shown, by its electrical response, that the human brain will respond to the meaning of words presented to the ears during sleep. It is interesting to note that even in the deepest sleep, and without awakening the subject, such words may also evoke dreams that are relevant to their meaning.

The researches involving human brain responses to subliminal stimuli have their counterpart in studies of lower animals. Thus it has been shown that a monkey's recognition threshold for a meaningful pattern may be significantly altered by direct electrical stimulation of the animal's reticular system. It has also been found that even the surgically isolated forebrain of a cat will respond to a previously learned pattern when this is presented to the preparation's one remaining eye. Since what is left of the animal in this experiment could hardly be capable of consciousness, this finding illustrates a simple and direct instance of subliminal perception.

One of the most extensively researched examples of subliminal perception occurs in connection with the fact that the awareness threshold for threatening words or pictures may be significantly higher or lower than that for more neutral material. Experiments which involved the simultaneous recording of EEGs (brain rhythms— see ELECTROENCEPHALOGRAPHY), heartrate, and perceptual thresholds suggest that, prior to awareness of a visual stimulus which is gradually increasing in brightness, the brain may analyse the latter's meaning and, as a result, modify its own level of arousal to hasten or retard awareness of the information that it carries.

That the brain monitors and analyses subliminal stimuli, receives support from many comparable investigations. Thus, emotional words, presented below threshold to the eye, have been found to change auditory sensitivity, and vice versa. By the same token, during binocular rivalry, in which the subject perceives either with the left eye or with

the right but never with the two together, the introduction of a subliminal stimulus to the 'blind' eye produces immediate transfer of perception to that side. Such a mechanism which automatically switches into consciousness a stimulus array that has changed (i.e. one that constitutes a potentially im

portant new stimulus) has obvious survival value.

It can be argued that a capacity for subliminal perception came about with the evolution of attentional mechanisms. Since the span of consciousness is severely restricted, selective processes evolved whereby only a limited proportion of available sensory information could be admitted to consciousness. Subliminal stimuli constitute some part of the remainder—stimuli which, though insufficiently strong or important to warrant entry into consciousness, may nevertheless be received, monitored, and reacted to. A number of recent pieces of research attest to this view. In one (Corteen and Wood, 1972), people were asked to report a stream of prose presented to one ear while words of which they remained unaware were presented to the other ear. It was found that those 'subliminal' words (on the unattended ear), which had previously been associated with electric shock, produced an emotional response (i.e. a change in skin resistance due to sweating) without interfering with the attentional task of 'shadowing' prose on the other ear. In another experiment (Henley and Dixon, 1974) imagery evoked by music presented to one ear, above the conscious threshold, was shaped by subliminal words to the other ear. Considered together, these two sets of data suggest that, at a preconscious level of processing, the brain can 'decide' whether or not information on a subsidiary or unattended channel should be kept isolated from, or used to, facilitate responses evoked by material to which the recipient is devoting his conscious attention.

That a subliminal stimulus can bypass the moderating, rationalizing effects of consciousness has given rise to a number of useful applications of stimulation below awareness. These include the investigating of processes underlying such psychiatric disorders as **anorexia nervosa* and **schizophrenia*. Perhaps the most clearly useful application to date has been in the selection of pilots for the Royal Swedish Air Force. In the Defence Mechanism Test (Kragh, 1962a & b) the candidate for a flying career has to describe what he sees when flashed a composite picture, consisting of a central human figure which is flanked by a subliminal threatening male face.

Numerous applications of this test have shown that those candidates whose responses show characteristic distortions as a result of the subliminal threat are likely to make accident-prone pilots. By using this test to eliminate undesirable trainees, the Air Force has succeeded in making a significant saving in lives and aircraft.

Despite the very great weight of evidence from many disciplines, there are still those who cannot bring themselves to accept the reality of subliminal perception. In the writer's opinion this carefully sustained prejudice is itself a psychological defence against the threat of possible manipulation which is implied by subliminal effects.

There is the suggestion here of an unwarranted equation of consciousness with such nebulous properties of mind as will, self-control, and conscience. Evidence of many kinds, including that from studies of behaviour under hypnosis, suggests that this particular conceit is, to say the least, mistaken.

Besides being used in a diagnostic capacity, subliminal stimulation has now been employed in a therapeutic context. For example, by reducing anxiety through the subliminal presentation of reassuring messages it has been found possible to reduce neurotic overeating in cases of obesity

(Silverman et al., 1978), and improve performance at mathematics (Ariam, 1979). Other techniques involving stimulation below the conscious threshold have proved useful in the treatment of phobias (Tyrer et al., 1978).

From the evidence to date, it seems that all the sensory modalities shown in Fig. 2 have a subliminal range within which excitation can occur without conscious representation. Of particular interest in this connection is the finding (Cowley et al., 1977; KirkSmith et al., 1978) that even subliminal olfactory stimuli—e.g.

pheromones— may have a significant effect. Even though unable consciously to detect the smell of female pheromones, their inhalation by male subjects made the latter perceive photographs of women as more attractive than they would otherwise have been.

The subliminal range for each modality is still not clear but probably depends upon the relative importance, from a survival point of view, of the modality in question and the extent to which its response system can function adequately without the aid of consciousness. Thus, while pain might be expected to have a very short range (i.e. it would be important to be immediately aware of noxious stimuli) the interoceptive senses (i.e. those concerned with internal 'automatic' bodily responses) remain almost entirely subliminal (as indeed we know they are).

Hardly less interesting than the phenomena of subliminal perception has been the resistance to Fig. 2.

Hypothetical extents of subliminal and

phenomenal effects for different sensory modalities.

Page 755

accepting its validity. Since the whole idea of being influenced by things of which one is unaware is repugnant to some people—presumably because it seems to threaten notions of free will and personal autonomy—various arguments have been put forward to discredit demonstrations of the phenomenon. One of the favourites has been to view subliminal perception as merely a watered down version of normal conscious perception. According to this argument, so-called subliminal effects have been explained as no more than responses to consciously perceived fragments of the stimulus array. However, a recent study by Groeger (1984) invalidates this suggestion. Subjects were asked to choose either the word 'SMUG' or the word 'COSY' as a completion for the mutilated sentence 'She looked ... in her new fur coat'. It was found that if they received a liminal (i.e. barely audible) presentation of the word 'SNUG' they chose 'SMUG' as their completion. But if the same cue was given at a *subliminal* level they preferred the completion 'COSY'. In other words, the subliminal response resulted from unconscious semantic analysis while responses to structural features occurred only at or about the threshold of awareness.

SUBNORMALITY and severe subnormality are legal terms which were defined in the UK Mental Health Act of 1959. In the Mental Health Act of 1983 they have been replaced by the words 'mental impairment' and 'severe mental impairment' which are defined as follows. Mental impairment means a state of arrested or incomplete development of mind (not amounting to severe impairment) which includes significant impairment of intelligence and social functioning, and is associated with abnormally aggressive or seriously irresponsible conduct. Severe mental impairment means a state of arrested or incomplete development of mind which includes severe impairment of intelligence and social functioning and is associated with abnormally aggressive or seriously irresponsible conduct.

Incompleteness of the development of the mind has been observed for a very long time, and has been recognized in English law since 1325, whereas subnormality of intelligence is a concept which

depends on the meaning given to the word intelligence by Alfred*Binet, in 1909, i.e. ability to learn. Thus the inclusion of the concept of a minimum level of intelligence in the Act of 1959 was meant to complement and limit the definition of subnormality according to social incompetence. Before 1959

social incompetence was the prime definition of subnormality. In addition, in medieval times the legal definition included the idea of incurability, and was distinguished from mental illness in so far as the 'natural fool' was supposed to be incurable, whereas the lunatic was recognized as a person who might perhaps recover from his illness. These legal definitions were of course related to the protection of the property of those involved. They were also the basis for derisions made on the criminal responsibility of persons accused of serious offences.

Subnormality today is regarded as a condition which, when associated with very low intelligence—for example, below IQ 515 or IQ 50—will have a relatively permanent character, whereas when associated with a level of intelligence between 55 and 70 will less frequently be combined with permanent social incompetence. In fact some authors have claimed that in mild subnormality of this kind IQ levels can be considerably increased by early and continuous educational attention. Whether this can be said with certainty or not, a great deal of research has shown that above IQ 55 ability to survive in the community is not very Page 756

closely related to intelligence. Below this IQ level a relatively small proportion of people will be found to be socially independent, possibly between 10 and 20 per cent.

The prevalence of subnormality, At the beginning of the twentieth century, the prevalence of subnormality was thought to be increasing, because the views of Francis*Galton (*Hereditary Genius*, 1869) and Karl Pearson were uncritically applied to the concept of intelligence. It was supposed, therefore, that because of differential fertility more children would be born to those with less intellectual endowment and that, as a result, the average level of intelligence would decline. Few authorities, with the exception of L. S.*Penrose, disagreed with this view, though today few would agree with it. As a result of later studies, the prevalence of severe subnormality is now better understood and we know more about the intelligence level of the children of the mildly subnormal. If we were to define the prevalence of subnormality solely in terms of the level of intelligence, and if all below IQ 70 were assumed to be subnormal, then, further assuming distribution according to Karl Pearson's 'normal' curve, 2.28 per cent of the population would be expected to be subnormal. The great majority of these cases would be between IQs 70 and 55, say 214 per cent of the total population. The remaining 014 per cent (67,200 in England and Wales) would have IQs in the range of severe subnormality, i.e. lower than IQ 55. When investigations were made, however, fairly firm figures began to emerge for the severely subnormal. These figures were 388 per thousand (E. O.

Lewis), 3.45 per thousand (N. Goodman and J. Tizard), for age ranges 7 to 14 years, and 3.75 per thousand (A. Kushlick) for the 15 to 19 age range. Obviously the actual findings, which for a population of 48 million people would yield a total prevalence of approximately 180,000 severely subnormal cases on the basis of Kushlick's figures, very much exceed the number which would be expected if the definition were based on intelligence level and the normal curve. The difference was accounted for long ago by Pearson and G. A. Jaederholm (*On the Continuity of Mental Defect*,

1914), the excess of severely subnormal subjects being assumed to be due to the pathological conditions so frequently found at this IQ level.

If we turn our attention to the prevalence of the subnormal as distinct from the severely subnormal we find that, between IQ 70 and 55, 21·4 persons per thousand would be predicted on the basis of the normal curve of IQ, which for England and Wales would give an estimate of approximately 1,027,000 cases. In point of fact, the estimates for the mildly subnormal in England have ranged from 1.39 per thousand to 673 per thousand. An intervening figure, that obtained by Kushlick in 1961

in Salford, was for an estimate of 2·60 per thousand. This figure yields a prevalence rate for England and Wales of 124,000 cases. In this instance the discrepancy is in the opposite direction and is easily explained by the fact that the mildly subnormal very often survive in the community despite their relatively low intelligence. As a result they do not attract the attention of the available services, and the actual prevalence rate is found to be much below that which might be expected on the basis of intelligence alone. In this particular group, as was initially pointed out by Penrose (1949), the prevalence is most marked during school years because of the special scholastic demands made at that time. A number of studies since W. R. Baller's initial research in 1936 have shown that, on followup, the mildly subnormal are frequently shown to have succeeded very well in social and occupational situations. They often marry and conduct their own businesses, show stability in their job experience, and in normally favourable social circumstances do not fall foul of the law in a serious way or come to represent a social problem in their later years. A variety of theories possibly explaining the relative success of the adult subnormal have been reviewed by Clarke and Clarke (1974).

While the tendency during the early years of the century was to consider that the prevalence of mental subnormality was increasing, N. Goodman and J. Tizard have argued, on the basis of their survey and by comparison with Lewis's earlier survey, that perhaps it is declining so far as the severely subnormal are concerned. The argument rests on two opposite trends, one being the decrease in infant mortality in England and Wales between 1900 and 1959 and the resulting possibility of a decrease in birth injuries, and the other being the likelihood that better birth conditions might lead not only to increasing survival of the fit but also to increasing survival of the unfit. Goodman and Tizard argue that since many of the severely subnormal, perhaps as many as 25 per cent, suffer from*Down's syndrome (mongolism), and since this group now survive longer than hitherto, an increasing number of the severely subnormal might be Down's syndrome cases. Down's syndrome is of genetic origin and perhaps little influenced by external factors except maternal age. If this were so, then it is possible that the number of the severely subnormal who were not Down's syndrome cases either remained the same or declined slightly between the Lewis survey in 1929 and the Goodman and Tizard survey in 1962.

Obviously, so far as the initial fears that gave rise to the UK Mental Deficiency Act of 1913 are concerned, a decline in national intelligence is no longer thought probable by those who are well informed about the prevalence of mental deficiency. This does not mean, of course, that there is no genetic element contributing to prevalence of subnormality. Perhaps today fewer severely subnormal children are being born, and fewer mildly subnormal adults need care; but of course those severely

subnormal children who are born tend to live longer. B. W. Richards found that from 1949 there had been a steady trend towards ageing Page 757

in the population in a mental deficiency hospital in Surrey. There was an especially great increase in the number and mean age of residents with Down's syndrome, even though the mean age of the Down's syndrome patients was lower than that of their comparable nonDown's syndrome fellow patients. B. Kirman (in Kirman and Bicknell, 1975, p. 57) presented a table showing the trend of ages in National Health Service hospitals between 1954 and 1969. The main feature of this table is the relative increase in the number of patients aged over 55 as compared with those aged below 14. There is, however, some evidence that Down's syndrome cases continue to die somewhat earlier than nonDown's syndrome cases of the same IQ level. It is interesting to note that practically all Down's syndrome patients over 35

years of age show the same pathological changes in their brains as are seen in the brains of subjects who develop the clinical features of senile*dementia of the Alzheimer type.

Clearly, therefore, the tendency is for fewer severely subnormal children to be born but for more of those who are born to survive over longer periods, and for fewer of the mildly subnormal to come to the notice of social aid services. These trends are probably matched by similar trends in the normal population, and it might be said that the subnormal, like the normal, are profiting from the general increase in the standard of living as well as from the improvement in medical care, especially in relation to birth conditions, since the beginning of the century.

For discussion of the causes of subnormality, and the care of mentally handicapped adults and children, see MENTAL HANDICAP.

SUFISM. Sufi individuals and groups became publicly known in Arabia in the eighth century. As mystics, esteemed for religious piety, they were able to exercise the role of mentors of devotion and conduct in the theocratic community of Islam. Observers have been attempting, for a thousand years, to categorize them, but conventional assessment has proved extremely difficult. Accepting Muhammad the Prophet as the originator of the current phase of Sufi manifestation, they also regard Jesus as a Sufi: while one of the greatest of all Sufis, Jalaluddin*Rumi, openly declared that many nonMuslims understood Sufism better than ordinary Muslims.*Al

Ghazzali, one of the foremost Sufis, is credited with having saved Islamic thought from dissolution by Greek philosophy. From his time (d. 1111) all Islamic thought may be regarded as being indebted to Sufism. Like all gnostic systems, Sufism regards conduct as secondary, and divine illumination

primary. Sufi masters are therefore those who, having experienced the 'path' to such cognition, are able to guide others along it and also to relate it to terrestrial social needs.

There are three distinct ways in which assessment of this powerful and extraordinary movement has been approached· (i) The largely Western, scholarly approach, which has sought to analyse literature, seek origins, and identify affinities· The multiplicity of resemblances between Sufi thought and practices and those of other systems has led many of the followers of this technique to 'proof by selected instances'· According to which expert one reads, therefore, one will find Sufism attributed to Christian, Jewish, Buddhist, animist, or other origins. A listing of the proofs invoked by such students shows that they cancel one another out. (ii) The conclusions reached by Muslim nonSufis, mainly in the East, over the centuries. Nasrollah Fatemi (1976) provides a summary: To some it denotes humanitarianism, tolerance, harmony ... love of mankind and the attempt to achieve spiritual fellowship. To a few, the Sufis are dreamers, rebels and meddlers who interfere with the serious rituals of the church and the business of the state: To others, they are the conscience of society and the antennae of the community, who exhibit in their activities a pronounced concern for humanity [and] the values that lie at the core of society, and who accuse the civil and religious authorities of lacking social conscience. The Sufis felt the need to resist the corrupt, tyrannical and arrogant, to ridicule the *cruel* rich and merciless might, to exalt the low and to help the helpless.

(iii) The assertions made by the Sufis themselves about what they are and what they do and why they do it.

Although it cannot be expected that the Sufis' contentions about themselves will be accepted by those with different assumptions, it can be seen that the Sufi rationale provides a better explanation than has been offered heretofore by members of the outside observing groups· The Sufis say that they have no history, because Sufism is experience, not recording information. Their goal is attaining knowledge of a higher reality, of which familiar religion is a lower level: that of social and psychological balance. When the goal is attained, the Sufi acquires not only knowledge of the divine (and of extradimensional reality) but also functions associated with it which are not to be confused with repetitious observance or emotional stimulus. Those alone who have reached this stage may properly be called 'Sufis'. Anyone else is 'on the Path', or a 'dervish', roughly equivalent to a monk or friar. It is this belief that gnosis commands action of all kinds that explains, according to the Sufis, why they are found in so many branches of literature, philosophy, science, administration, and so on. Their instrumental intervention is directed from beyond conventional limitations and, the doctrine continues, cannot be imprisoned in repetitious activity. Although this assertion is not necessarily acceptable to contemporary Western Page 758

workers, the rich writings of the Sufis have in recent years interested psychologists and sociologists. Sufism itself was 'named' by August Thöluck, in his *Ssufismus, sive Theosophia Persarum Pantheistica*, published in Berlin in 1821. Before that it was known as Islamic mysticism and by a number of other names, such as Divine Wisdom (extracted by letternumber substitution cipher from the Arabic).

Sufi 'orders' came into being much later than teachers and schools; and they clearly resemble

traditional orders in, for example, Christianity. The orders are therefore regarded as secondary, and few, if any, of their putative founders, famous Sufi masters, were really connected with their establishment. Their practices are mostly of a devotional autohypnotic nature, and produce conditioned states which are much at variance with essential Sufi theory relating to the need for individual and specific teaching. Most groups which employ the name Sufi in the Middle and Far East and Africa are in fact Islamic prayercongregations of the enthusiast type. Many closely resemble formal churches of whatever religion, and hence have an attraction for people brought up in parallel systems.

The Sufis enjoy, on the whole, a high reputation in the East, and have been extensively appreciated by nonIslamic religionists and scholars, including Western mystics.

The numerous extrasensory manifestations which have always been associated with Sufi activity are regarded by the Sufis themselves as undesirable and preliminary (at best) phases; although they continue to excite those who attempt to study such things. At the present time, selfdeluded and spurious 'Sufis' abound, in the East and West, as in the case of all enterprises of this nature.

SUICIDAL BEHAVIOUR. Man's ability to kill himself has been a source of fascination since the beginning of human society. Philosophers from Marcus Aurelius and Seneca to Camus, writers (especially poets) from Virgil to Sylvia Plath, and sociologists from the beginning of the nineteenth century to the present day, have all contributed voluminously to its study. This widespread preoccupation has, if anything, obstructed the scientific investigation of suicide in two distinct ways. Firstly, the longstanding theological taboo against suicide, still discernible in many legal phrases and public attitudes, has tended to make the rational consideration of the subject difficult. Secondly,

speculation on the theme has tended to spread over all forms of human activity which are potentially harmful or selfdefeating, with a consequence that there is remarkably little that people can do which has not been interpreted as concealing some measure of suicidal intent. Clearly for scientific purposes it is necessary to use a much more precise definition.

In the first place, attention is confined to acts in which selfdestruction is the essential component and not simply a hazard incurred in the course of pursuing another goal. Thus the religious martyr, or the soldier who has volunteered for a dangerous mission during which he dies, are not usually considered as suicides. Secondly, suicide is taken to refer to the behaviour of an individual and not a group, so that expressions such as a suicidal policy being pursued by a nation are to be understood as metaphorical. And lastly, presentday usage restricts the term to human beings; the notorious lemmings are firmly excluded.

Though often difficult to assess, intention thus becomes a central issue in categorizing deaths in which the deceased was an active agent. The law in most European countries requires clear demonstration not only that an individual caused his own death, but that he fully intended to do so. Psychiatrists and behavioural scientists would in general assert that this criterion is too narrow and that assessment should be made on the balance of probabilities, recognizing that a certain number of deaths will be unclassifiable. The important practical point is that official statistics tend markedly to underestimate the incidence of suicide according to psychiatric criteria.

Additional reasons for underreporting are a desire by families and general practitioners to conceal suicidal deaths in some cases, and a reluctance of coroners to reach the decision in an open court for fear of causing offence or having their verdicts challenged in, or reversed by, a higher court. Various studies suggest that the order of magnitude of underreporting is in the region of between 50 and 100 per cent. Nevertheless, official statistics have been widely used and have proved valuable for certain types of enquiry. (For a fuller discussion of the validity of statistics, see SUICIDE: INTERNATIONAL STATISTICS.) A great deal of literature exists on the epidemiology of suicide. Virtually throughout the word the rate for men exceeds that for women, with the former tending to use more violent methods such as shooting or jumping from heights, and the latter more passive procedures such as taking an excess of drugs. However, these differences are rapidly disappearing in most European countries. Where the rate for males is falling, that for females tends Page 759

to remain stationary or fall more slowly; conversely, where the rate for males is increasing, that for females increases even more rapidly. Either way the net effect is towards equality, often interpreted in a rather vague way as reflecting the tendency in recent decades for the social roles of the two sexes to become more similar.

The effects of age are complex and interact with those of sex. In the United Kingdom the rates for males rise linearly with age, though in most developed countries, the curve resembles an inverted U, with the peak in the late fifties or sixties. For women, both in the United Kingdom and elsewhere, this latter pattern has always been the one most commonly reported. In general, suicide is very much a phenomenon of later life, suggesting that Shakespeare was correct in asserting that 'men have died ... and worms have eaten them, but not for love'. Furthermore, old age is often accompanied by painful

illness and chronic impairment of health. Such misfortunes may well precipitate a state of severe depression, when suicidal thoughts and acts commonly occur.

But what is currently true for Europe is not necessarily true for all times at all places. In Japan before the Second World War, for example, there was a distinct peak in the suicide rates for people in their late twenties and early thirties, which then fell away before the rate increased again among the elderly. Commentators ascribed this early peak to the complex and often contradictory social obligations which befell young married Japanese *vissà-vis* their respective families. With the Americanization of Japan following the war, this early age peak virtually disappeared, and the general shape of the curve now approximates that of the United States.

In the United Kingdom suicide became increasingly common from 1945 until the early 1960s. There then followed a decline in the rates for all agesex groups, entirely attributable to the progressive elimination of carbon monoxide from domestic gas, and the virtual disappearance of suicide by this method. This dramatic decline was unexpected. One might have supposed that anyone intent upon killing themselves would use any method to hand and that lack of availability of one particular agent would scarcely make any difference. The facts, however, point in the contrary direction. Extensive research, including for example studies on immigrants from different countries to Australia, has shown that the mode of suicide is strongly influenced by cultural attitudes which appear to favour one method in preference to others. More recently the UK rates have resumed their upward trend.

The role of cultural proscription or prescription has already been hinted at, and a number of sociological theorizes have been proposed which might account for the differences between societies in their suicide rates, differences which often remain surprisingly stable for sustained periods of time. Of the numerous hypotheses that have been advanced, the social cohesion theory developed by Durkheim and his followers still retains the widest support. On this view social cohesion minimizes the risk of suicide, whereas situations in which individuals are dissociated from their groups (leading to *egoistic* suicides), or live in communities that have no adequate normative values and beliefs to meet current social realities (*anomie*), conduce to suicide. The precise meaning of notions such as social cohesion or anomie is debatable, but it is empirically true that the suicide rates are particularly high among the divorced, among childless women, among those living alone, the retired or unemployed, and where populations are highly mobile or subject to economic uncertainty. Conversely, situations which promote social cohesion tend to lower suicide rates, and of these the classical example is the threat of war. In both World Wars suicide rates fell in practically all countries, both belligerent and neutral.

While social factors undoubtedly influence suicide rates, patients with conditions such as severe depression, alcoholism, or epilepsy all have increased risks of dying by suicide. Reviews of comprehensive series of suicidal deaths have now established that the great majority of such individuals were suffering from a dearly recognizable psychiatric illness at the time of their death. In England and Wales the commonest such disorder is the depressive phase of manicdepressive psychosis (see MENTAL

ILLNESS), often triggered by*bereavement. In Scoff and and in the United States alcoholism is

almost as prominent as depression. It also appears that social factors act as additional determinants *within* groups of depressives or alcoholics. Thus among all depressives those who are socially isolated, etc., have an appreciably higher risk of suicide than the remainder. It appears that social and psychological factors are necessary (though not sufficient) causes of suicide.

Such a sweeping statement begs the question of whether there exists such a thing as a rational suicide. The formulation which comes nearest to such a possibility is Durkheim's description of 'altruistic suicide', which he believed occurred only in communities that had extremely rigid codes of conduct, such as the Army in the nineteenth century. The notion that death was to be preferred to dishonour, a sentiment which goes back at least to Roman times, was not simply an empty phrase. It is also said that elderly Eskimos kill themselves in times of food shortage to help preserve the family. However, it appears that under normal circumstances rational suicide is exceedingly rare, if indeed it exists at all. The nearest approach is possibly the not uncommon phenomenon of an individual who kills himself during the course of a painful terminal illness in order, presumably, to put an end to intolerable suffering. Even so, many such individuals show an impaired ability to adjust to their disorder as compared with the majority of sufferers. Severe depression (or alcoholism) may of course also be features of a painful and chronic illness.

Page 760

Whatever the social and clinical context, the meaning of the suicidal act may vary considerably between individuals. For some, death represents simply a termination.

For many others the situation is more complex; suicide notes frequently reflect a theme such as reunion with someone who has already died, or imply that the individual will in some way continue and be able to monitor the activities of his survivors. A desire to inflict revenge on others through their guilt and remorse over the death is often evident. Indeed, a multiplicity of motives which, from a narrow logical point of view, may be mutually incompatible may be displayed. The supremely 'personal'

action of suicide may, at the same time, be intensely 'interpersonal' or social. (Some psychologists would aver that ultimately there is no distinction between the two.) Nothing has been said so far of so-called 'attempted suicide', which in the United Kingdom, at least, is overwhelmingly represented by drug overdoses. The term

'attempted suicide' is profoundly misleading; for the majority of such patients suicide is not what they are attempting. Indeed, advances in the study of the phenomenon have only become possible since it was realized that these individuals do not represent failed suicides, but rather something which, though having a loose behavioural analogy with suicide, should be viewed as a more or less distinct variety of behaviour. To this end the term 'parasuicide' has been introduced.

From the epidemiological point of view suicide and parasuicide are markedly different. Whereas suicides tend to be male, and in the second half of life, the great majority of parasuicides are female and in their teens or twenties. Suicide is prevalent among the widowed and the single, whereas

parasuicide tends to be commonest among the married. Suicide is notable among the physically infirm and the socially isolated, whereas parasuicide has no such association with physical illness, and tends to be commoner among those who are living in congested, overcrowded conditions. Depressive illness and alcoholism certainly figure prominently among parasuicides, but are usually much less severe than among suicides; while lesser emotional disturbance, induced by interpersonal conflicts and other intercurrent events, assumes a much greater significance: an appreciable minority of parasuicides appear to be free of any kind of psychiatric disorder, unless of course the act itself is taken as sufficient evidence of disorder. Whereas, according to the latest figures, suicide shows no obvious social class gradient, parasuicide is very much less common in the upper than in the lower social classes.

Parasuicide is vastly more frequent than completed suicide, and from what has been said it will be appreciated that the magnitude of the ratio varies by age and sex.

Thus, among men aged 55 and over, the excess is approximately threefold, while for young women below the age of 35 it is in the region of twohundredfold.

From a clinical descriptive viewpoint, the typical parasuicide tends to have had a disrupted and disadvantaged childhood, often in a broken home. She will be living in a state of conflict with her family of origin, or of procreation, or both; among men a story of trouble with the law and of interpersonal violence is common, as is excessive drinking. In association with these difficulties the patient becomes anxious and depressed, and in response to a crisis or a quarrel takes an overdose of pills (or more rarely deliberately causes selfinjury).

The details of the psychological processes involved in the genesis of the act are still unclear, and often the patient herself is confused as to what, if anything, she intended. But certain broad themes can be discerned. A wish for a temporary respite, analogous to getting blind drunk, is one common component. In a minority, a desire to die or an indifference to survival will be reported, or may be inferred. Another very important aspect of parasuicide is its communication function, the muchcited 'cry for help'. Unfortunately the cry so produced may or may not lead to the hopedfor response, since families and friends may as readily pick up the aggressive overtones of the act—the hint of 'I'll die, and then you'll be sorry'.

Parasuicide may, thus, serve a number of purposes; but it is perhaps the communication aspect which is of particular interest. If the act does indeed serve as a means of conveying information, then it can be argued that it is a form of 'language' of a rather special kind. Consequently it could be predicted that the patient would commonly be found among a group of individuals who share a propensity to parasuicide when under stress. This supposition has been empirically confirmed. The concept also points the way to the study of parasuicide as a social institution, and here too the evidence suggests that communities exist in which parasuicide appears to have a more or less standard preformed 'meaning'.

Finally, having stressed the numerous differences between completed suicide and parasuicide, it is necessary to point out that there is also an important overlap between the two. About half of all

completed suicides are preceded by a parasuicide. Conversely, if a representative sample of parasuicides is followed up, about 1

per cent would be found to die by suicide in the ensuing year (which is about a hundred times greater than would be expected for the general population), and the increased risk of an eventual suicide persists for many years. Subgroups at high and low risk of later suicide can be identified, but no parasuicide should be dismissed a priori as trivial.

SUICIDE: INTERNATIONAL STATISTICS. All civilized countries compile statistics on their suicides; many have done so for over a century. These deaths are usually investigated in detail by legal authorities and forensic medical experts even in the many countries where suicide is no longer a criminal offence, if only to establish the mode of death in people who might have died because of accidents or homicide. A mass of tabulations has resulted, containing details of age, sex, occupation, agent of death, etc., which appears to constitute an invaluable source of firm data, waiting at the student's elbow for employment. Some of the earliest theorists on suicide, such as Durkheim in *Le Suicide* (1892), unhesitatingly drew on this store, and subsequently Hendin (1964) has used such data in rather speculative studies concerning the susceptibility to suicide of the 'national character' of three Scandinavian countries. All the same, the number of studies that have exploited international statistical material has been relatively modest, probably because of lingering uncertainties as to the exact comparability of the figures.

These doubts were forcibly expressed by Douglas (1967) in bold, not to say polemical, tones. His argument, in essence, was that the classification of a death as suicide is effected not by God but by a judicial structure, and a 'verdict' is a social act rather than a scientific observation. Douglas pointed to the pervasive importance of attitudes and stereotypes in the minds of all concerned—families who might suppress or distort the information given to their doctors, who in turn maltreat the information before it is notified to the authorities, the coroner's officer who prepares the material for the inquest according to informal but powerful normative values, and finally the coroner himself, with his

socially given definition of what a suicide ought to be like. He also emphasized the severe social stigma attached to suicide in some countries, which must inhibit coroners, or their equivalents, from making public pronouncements. Douglas concluded that the social scientist seeking confirmation of standard theories of suicide would always find them demonstrated by suicide statistics, since these very theories had determined the manner in which the data were derived. There was, he concluded, no point in using official statistical material.

This attack evoked a dual reaction. On the one hand, it was readily conceded that suicide has always been underreported in official figures, since there must be some instances in which the evidence is more or less suppressed, but few where it is spuriously manufactured. It is also evident that a coroner does not like to upset grieving relatives, and in cases of doubt would incline to some alternative verdict; in the United Kingdom his ruling is also subject to appeal to a higher court. Moreover, the legal definition of suicide is a very narrow one, and requires proof beyond reasonable doubt that the deceased not only caused his own death but that he fully intended to do so; whereas the traditional psychiatric viewpoint would stress, rather, the balance of probabilities. For the United States, Dublin's (1963) investigations suggested to him that a further 30 per cent of suicides went unrecognized, while in Eire McCarthy and Walsh (1975) thought that a figure of 100 per cent would be more appropriate.

Attempts to correct for underreporting have taken the form of adding to the official suicide figures all those deaths in adults which are officially classified as

'undetermined', i.e. where the coroner is unable to come to a decision, plus deaths due to selfadministered poisoning in adults, irrespective of the declared intent of the individual. The rationale for these procedures is that detailed casestudies have shown that according to psychiatric criteria the great majority of such individuals should be regarded as suicides. Interestingly, their aggregation to the official suicide figures makes no difference to trends occurring over time, nor does it materially influence the pattern for age and sex subgroups.

On the other hand, the assertion that official statistical data are of no value at all has been hotly contested. Critics point out that Douglas's attack on the role of ideology in determining the figures was advanced without any empirical evidence. It is a truism, which may be generally accepted, that all data reflect the conceptual organization of the observer as well as the natural world, but this is probably true for all science. More specifically, studies have been carried out to determine whether differences in legal procedures and the like do make any material difference to suicide statistics. One of the bestknown of these (Sainsbury and Barraclough, 1968) showed that for immigrant groups to the United States, the rank order of their suicide rates closely correlated with that of their home countries, despite the fact that they were being assessed by a completely different set of social agencies. This work has been broadly supported by other studies in Australia. Another study considered the effect of a change in coroner on the suicide rates for his district, arguing that if personal bias played much of a role, then a greater variation in rates should occur at such transitions than in control groups where the same individual remained in office. In fact no differences emerged. Other studies have looked into the training of coroner's officers, with the broad conclusion that this makes virtually no difference to the way in which they prepare information for the coroner's court, or to the final suicide statistics derived

from these proceedings.

Another type of investigation has exchanged data between two or more countries and compared the classifications of death that emerge. Evidence Page 762

was found, in a study comparing Danish and English coroners, of considerable disagreement at the individual case level and, worse, that almost as much disagreement existed between the officers within each country as between the two nations as a whole. This particular series, however, was not meant to be a representative sample, so it is not yet clear how far the results can be generalized. Another investigation, in which records were exchanged between the Scottish Crown Office and a sample of English coroners (the two systems are really very different), again showed that there was appreciable misclassification at an individual level, but that the net effect of this was mutually cancelling and that the final discrepancies were trivial (Ross and Kreitman, 1975).

What, then, can be concluded? There is undoubtedly considerable, and variable, underreporting. Even after allowing for this, however, consistent differences do persist and are not modified to any great extent by alternative statistical classifications or legal procedures. The data, then, are usable, a conclusion much strengthened by their uniformity in certain respects. For example, it is almost universally the case that the rates are higher among men than among women; among the middleaged and the elderly rather than the young; in urban centres rather than rural regions; among the*bereaved; among the widowed, divorced, and childless; and possibly in populations undergoing rapid industrialization. Without data of this kind from many sources, the student can never be sure that his own findings reflect more than a purely local scene.

Even so, it would be wise never to accept international statistical data as *proof for any particular* hypothesis. Their prime role, rather, should be to suggest ideas which could be explored in more closely controlled investigations. This conclusion is particularly relevant when one turns away from the muchbelaboured question of validity to the problems attendant on the interpretation of these statistics. Table 1 shows the rates by sex, for a sample of countries, calculated after corrections to allow for differences in their age structure. Most published statistics are based on total population figures, but as in most countries suicide by children aged less than 15

years is a rare event, the figures in the table give the suicide rate among adults, with due allowance for age variation between populations.

These figures pose the immediate question of why, within Europe, Hungary should have a (male) rate nine times greater than that of Greece, and thirteen times that of Mexico. Clearly differences between these areas are legion, and, as with any other type of crosscultural comparison, there are so many discrepancies between pairs of countries or cultures that to propose any one of these as the cause of a difference in suicide rates is a highly hazardous exercise. What is required, rather, are general hypotheses that might explain the overall pattern. Some are mentioned below.

There remains the use of international data analysed for longitudinal trends. Data collected over the years within a particular country are free from many of the hazards already cited; it can reasonably be assumed that such biases as operate will remain reasonably constant. It is thus possible to venture

certain generalizations. For example, the effect of war on suicide rates has been studied in some detail, and has invariably been found to be associated with a steep decline, especially at the outbreak of hostilities. This decrease is not due to suicide masquerading as death in combat, as it affects all agegroups, to varying degrees, and women as well as men. Interestingly, the decline can also be shown for neutral countries faced with the threat of war but never actually engaged in conflict. A likely cause of the decrease is thought to be an increased sense of national cohesion, coupled with a decrease in unemployment. (Without data of international scope this important conclusion would have been difficult to establish.)

A similar type of analysis has been applied to economic recessions. Sainsbury (1963) showed, by an ingenious series of trend analyses, that economic reverses and unemployment both conduced to higher suicide rates, but that poverty *per se* was not particularly relevant. Again, conclusions of this kind require information from many sources, if

Page 763

the effects of numerous confounding influences are to be dissected out. More recently, similar techniques have begun to be used to elucidate the effects on suicide of improved psychiatric services, the availability of lethal agents, such as guns or toxic domestic gas, the increased deployment of social work services, the role of alcohol abuse, and similar influences.

SUPPRESSION. In psychoanalytical (especially*Freudian) theory, the pushing down of painful

memories, so that they are unavailable in consciousness. It is, however, supposed that they may in some sense persist in the unconscious, sometimes to create psychological havoc.

SYDENHAM, SIR THOMAS (1624-89), British physician, born at Wynford Eagle, Dorset, studied medicine at Oxford and Montpellier. He was remarkable in his time for insisting on accurate and detailed descriptions of disease, thereby making important contributions to medical classification. In his Epistolary Dissertation to Dr Cole (1692), entitled 'De Affectione Hysterica', he made some timely observations on hysteria, a disorder with protean manifestations which, he believed, affected one-sixth of his patients.

At the time of his writing, two main theories dominated thinking about hysteria. Firstly there was the ancient belief that the condition was confined to the female sex, being caused by a disturbance of the womb, which it was alleged caused symptoms by becoming displaced into the affected part of the body—see Edward Jorden (1603), 'The Suffocation of the Mother'. A contrary opinion came from Thomas Willis, the anatomist, in 1667 when he denied that the uterus and humours were responsible for hysteria, claiming that the condition arose from disturbances of 'the Brain and Nervous Stock'. He observed similarities between hysteria in women and hypochondriasis in men, conditions which Sydenham likened 'as one egg to another'. Willis emphasized the importance of 'hysterical' convulsions, most of which today would probably be diagnosed as epileptic; but he firmly rejected the wandering womb hypothesis, when he wrote, 'As to the cause of these symptoms, most ancient and indeed Modern Physicians, refer them to the ascent of the womb and vapours elevated from it' and went on to point out that the womb was 'so small in bulk in virgins and widows, and so strictly tied by the neighbouring parts round about it, that it can not of itself be moved, or ascend from its place...'.

Sydenham, like Willis, repudiated the uterine theory of hysteria, although he considered that women were more prone to the disorder than men; none the less he agreed that men, particularly those 'who lead a sedentary life and study hard, are afflicted by the same'. His other major contribution was his observation that hysteria was more likely to follow 'disturbances of mind which are usual causes of this disease'. He also noted that hysterical symptoms were often accompanied by depression, but could coexist with physical disease.

In making these observations Sydenham placed hysteria firmly in the category of the psychological disorders that could be said to be the forerunners of the psychoneuroses today. No doubt he tended to diagnose hysteria as a psychological disorder far too frequently, and many of the signs and symptoms he described would probably be more indicative of physical than of neurotic illness. None the less, despite his emphasis on psychological causes for hysteria, the ancient uterine hypothesis has continued to influence medical thinking over the past three centuries. Freud faced opposition and ridicule when he described hysteria in men, and the revival of the notion of hysteria as a women's disease, under the title of Briquet's syndrome (1859) shows that Sydenham's observations have not been so influential as one might have hoped.

When it came to treatment, Sydenham was very much a man of his time, and prescribed bleeding and purging to purify the blood; but he made a point of enquiring whether his patients had suffered from 'fretting, or any disturbances of the mind'. He and his contemporary Dr Thomas Fuller, both of whom

had seen service in the cavalry during the Civil War, strongly recommended horseriding as a therapeutic measure for hysteria and hypochondriasis, although probably not for 'slender and weakly women, that seem consumptive, and girls that have the green sickness...'. No doubt—unless the patient fell off—horseriding was safer and more beneficial than some of the other widely used remedies of the time.

SYMBOLS. A symbol, broadly speaking, is something that stands for something else. Subordinate questions arise: what sorts of things can stand for

things?

Page 764

for what sorts of things? and how do they do so? Also, certain reservations need to be made.

A five pound note once stood for five gold sovereigns, serving the same purposes. Usually a symbol stands for its object in a less robust way: it reminds us of it. It may do so by resembling it, or by standing to it in a known causal relation, or by some conventional connection of whatever origin. Hence C. S. Peirce's trichotomy of

'signs' into 'icons' (e.g. a diagram), 'indices' (e.g. a thermometer), and 'symbols' in a narrower sense (e.g. a name).

Whereas association itself is symmetrical, the relation of symbol to object is not; it is limited to situations in which the object commands more interest than the symbol.

The fish symbolizes Jesus, because the Greek

is an acrostic of a five-word description of Jesus; but it does so in churches, not kitchens. The relation is asymmetrical and intermittent.

A physical object, or state, may stand for a physical object or state: a fish for a man, an inscription for a man, a map for a province, a mercury level for a temperature.

Often, the symbol is better seen as a whole class, such as that of ichthyomorphic carvings. A name, indeed, may be seen as the class of its inscriptions and utterances.

Sometimes, as when gods are said to have symbolized seasons, or Janus to have symbolized wholeness, the symbols are evidently neither physical objects nor states nor classes of such; it is hard to categorize them otherwise than as ideas. A better account might take nominalistic lines, appealing

to visual patterns and linguistic expressions.

The heat and wind activate their symbolic indices, the thermometer and weathervane. But primitive peoples have believed, conversely, in an efficacy of symbols upon their objects. Thus effigies and the magic of names. Thus also, presumably, the cavepaintings of thirty thousand years ago.

Fanciful subconscious resemblances must be assumed between symbol and symbolized, if we are to make sense of iconography or of Sigmund*Freud. The flights of creative imagination in our*dreams are undeniable, but their mechanism remains a mystery. Such symbolism must have figured in the origins of language. Paget had an imaginative theory of private gestures within the mouth, private muscular contortions that bore a subjective resemblance to some visible traits of objects. It is in language, at any rate, that symbolism attains the age of discretion. Let us look to its workings.

One way in which a linguistic expression often stands for something is by *designating* it. Designation is the relation that the names 'Plato' and 'Wales' bear to Plato and Wales, and that the phrases 'the author of *Waverley*' and 'Whittington's cat' bear to Sir Walter Scott and Whittington's cat. Symbols that purport to designate are *singular terms*. Some fail—for example, 'Pegasus'—for want of a designatum.

A way in which symbols more commonly stand for things is by *denoting* them. A *general term*, typically a common noun or adjective or intransitive verb, denotes each of the things it is true of. Thus 'horse' denotes each horse, 'green' each green thing, 'swim' everyone who swims.

There has been since antiquity an urge to view general terms as designating. Thus 'horse' was seen as designating some trumpedup abstract object, a universal—the property equinity—besides denoting each horse. This facile positing of universals was deplored by the medieval nominalists, as a confusion.

It was in part a happy confusion. In mathematics, and to some degree elsewhere in science, abstract objects serve theoretical purposes that cannot, evidently, be served by just talking of general terms and denotation. Classes do suffice in lieu of properties, but they are next of kin. Still, there is no need to view the general terms themselves as designating universals in addition to their job of denoting. If properties or classes are to be designated, we do have singular terms for the purpose:

'equinity', 'horsekind'.

General terms are meaningful, surely; and the urge to accord designata to them was due partly to confusing designation with meaning. Meaning is not designation, even among singular terms. The terms 'the Evening Star' and 'the Morning Star' (Frege's example) designate the same thing but differ in meaning. 'Pegasus' is meaningful, though designating nothing.

The notion of meaning is elusive. Jeremy*Bentham appreciated that meaning accrues primarily to whole sentences, and only derivatively to separate words. Setting aside emotive or poetic meaning, and looking only to the cognitive meaning of declarative sentences, we may say that the meaning of a sentence consists in its truth conditions. We know the meaning of a sentence in so far as we know in

what circumstances the sentence counts as true. To understand a sentence is to know when to affirm it.

There are sentences, such as 'It's raining', 'This is red', 'That's a rabbit', that count as true only in circumstances observable at the time of utterance. Their meanings can be learned by conditioning, unaided by auxiliary sentences. To proceed from these beginnings to higher levels of language, unaided by translation from another language already known, is an impressive feat, but the child achieves it. He exploits analogies: from the apparent role of a word in one sentence he guesses its role in another. Also, he discovers that people assent to a sentence of some one form only contingently upon assenting to a corresponding sentence of some related form.

Exploring, thus, the interrelations of sentences, and corrected by his elders, he learns how to compose innumerable sentences and when to affirm them.

Once he is well started, we could teach him harder sentences by constructing a dictionary along the following lines. Each entry explains some

Page 765

word—for example, 'putative'—by general systematic instructions for paraphrasing all possible sentential contexts of 'putative' into sentences lacking 'putative'. Each word in the paraphrase is either a word of the old sentence or a word more frequently heard than 'putative'. Words very frequently heard are left unexplained. Thus, though meaning belongs to sentences, words serve in generating it. The concept of a dictionary, just presented, shows how.

The sentential contexts of some words can be paraphrased simply by substituting some more frequent word, or some phrase. That word or phrase is then said to have the same meaning as the original word; and thus it is that the notion of word meanings is derivable from that of sentence meanings. Two expressions have the same meaning if substituting one for the other never disturbs truth conditions of sentences.

We saw that singular terms have their designata, when all goes well, and general terms their denotata. Many words claim neither—thus 'or', 'to', 'however', 'which',

'very'. Scholastics called these syncategorematic: lacking in intrinsic meaning, and meaningful only derivatively, through their contribution to the meaning of the containing sentences. There is a trace here of the confusion between meaning and designation, or denotation; words were thought to forfeit intrinsic meaning by not purporting to denote or designate. But let us take it that words generally are meaningful only through their contribution to the meaning of the containing sentences. Then we may keep the term 'syncategorematic' for the words that do not purport to denote or designate, but without thereby imputing any distinctive shortage of meaning.

Consisting, as it does, primarily in the truth conditions of sentences, meaning is pretty thin stuff. In the special case of observation sentences, it can be inculcated by sensory conditioning, or direct demonstration; for the rest, only by other sentences, paraphrases. We give the meaning of a sentence by explaining the sentence, and the meaning of a word by explaining how it works in sentences. Serious confusions could have been avoided if a practice had been made of speaking thus of

explanatory activities, rather than of meanings as somehow separable entities that symbols might stand for.

The meaning of a symbol was often confused, we saw, with the designatum. When it was not, it was usually viewed as an idea. This circumstance doubtless delayed the demise of an uncritically mentalistic psychology. Meanings had to be admitted, it seemed, on pain of rendering language meaningless; and it was not easy to see what meanings could be, if not ideas. Hence a dualism of symbol and idea, language and thought.

John Horne Tooke denounced this dualism as early as 1786, protesting that John*Locke would have done well to write 'word' in place of 'idea' throughout his *Essay*.

The way was opened for J. B.*Watson to identify thought primarily with language, subvocal speech. The medium becomes, in Marshall McLuhan's phrase, the message. The incipient muscular tugs that constituted the thinking process, according to Watson, were not indeed wholly confined to the speech apparatus; the inarticulate painter or engineer must think partly in his fingers. Without language, however, thought would be meagre.

Mathematics affords the ultimate example of the power of notation as a way of thought. In school, when we did problems about roving across the current, the hard part was putting them into equations; that was the programming, and algebra was the computer. The boon of arabic numeration goes without saying, and the mere use of brackets to unify a complex expression is a cornerstone of mathematics. It is the use of brackets, together with the variable, that enables us to extrapolate our laws and iterate our operations beyond all finite bounds.

SYNAESTHESIA. Confusion between the senses: for example, some musicians experience colours for particular notes. The effect can become dramatic in some drug states, presumably through loss of normal inhibitory mechanisms which isolate the central processing of the senses.

SYNAPSE. A junction between two nerves. Synapses contain 'transmitter substances', of which it is now known there is a remarkable variety. The synapses allow the action potentials in axons to cross in one direction only into contiguous nerves. They are set by the activity of many other nerves (up to 2,000) and by chemical signals, especially hormones. See NERVOUS SYSTEM; NEUROTRANSMITTERS AND NEUROMODULATORS.

SYNDROME. In medicine, a typical grouping of features of a physical or mental disease. Thus the syndrome of measles includes spots, a high temperature and photophobia (dislike or fear of bright light). This raises the question: Is a disease more than its symptoms? The symptoms are what are apparent, and used for diagnosis; there is much that is hidden and causative in diseases, beyond the symptoms.

SYNERGIES. There are two related approaches to the 'units of control' employed by the brain in
Page 766

controlling movement. Both are called synergies. The first, formulated by C. S.*Sherrington, posits a reflex unit above that of the motor unit; while the second, formulated by Nikolas*Bernstein, suggests that a restricted number of programs may underlie most of our behaviour.

To understand Sherrington's views we must start with the notion of a reflex. To take two familiar examples: in the kneejerk reflex, the tap of the physician's hammer stretches a tendon, and this is sensed by a sensor (proprioceptor) which activates a motor neurone which contracts the extensor muscle (which had 'appeared' to be too long) so that the foot kicks out. In the scratch reflex, an irritant localized to part of the skin activates receptors which in turn activate motor neurones which control muscles to bring a foot or hand to the irritated skin and rub back and forth. In each case, we have a reflex loop which mediates direct stimulus-response behaviour: from external world via receptors to the spinal cord, where motor neurones respond by controlling muscles to yield movement in the external world.

Now consider the scratch reflex more carefully. We may see it as made up of two components. The rubbing component needs the limb movement to ensure that it contacts the (right place on the) skin, the limb movement is tuned into contact by feedback from the rubbing movement. The two reflex actions 'synergize', or work together. More generally,

The executant musculature ... provides a reflex means of supporting or reinforcing the cooperation of flexors with flexors, extensors with extensors, etc. The proprioceptors of reaching muscles operate reflexly upon other muscles of near functional relation to themselves. Active contraction (including active stretch) and passive stretch in the reaching muscles are stimuli for reflexes influencing other muscles, and the reflex influence so exerted is on some muscles excitatory and on others inhibitory; it is largely reciprocally distributed, knitting synergists together (Creed et al., 1932, p. 129).

Thus, for Sherrington, the synergy is an anatomically based reflex linkage of a group of muscles.

The Bernstein school is informed by notions of control theory. The brain is to generate control signals which will cause the muscles to contract with just the right timing to bring about some desired behaviour. But there are so many muscles, they suggest, that to control every muscle independently to its optimum would be a computationally unmanageable problem. They thus see the crucial problem in the 'design' of a brain which controls movement to be that of reducing the number of

'degrees of freedom', i.e. the number of independent parameters which must be controlled.

In order for the higher levels of the central nervous system to effectively solve the task of organizing motor acts within a required time, it is necessary that the number of controlled parameters be not too large, and the afferentation, requiring analysis, not too great. [This is achieved] by the so-called synergies.... Each synergy is associated with certain peculiar connections imposed on some muscle groups, a subdivision of all the participant muscles into a small number of related groups. Due to this fact, to perform motion it is sufficient to control a small number of independent parameters, even though the number of muscles participating in the movement may be large (Gel'fand et al., 1973, p. 162).

So far, the general framework is consonant with Sherrington's synergies. But these are restricted to stimulus-response patterns. Bernstein had a more general concern with dynamic patterns changing over time during some motor act: '[A] complex synergy is involved in walking. ... "The biodynamic tissue" of live movements

[appears] to be full of an enormous number of regular and stable details.... [In old people] the synergy existing in normal walking between the action of the arms and legs is destroyed' (Bernstein, 1967, pp. 67, 93).

However, this was too global a view of synergy, and later work of the Moscow school came to view synergies as the functional buildingblocks from which most motions can be composed:

Although synergies are few in number, they make it possible to encompass almost all the diversity of arbitrary motions. One can separate relatively simple synergies of pose control (synergy of stabilization), cyclic locomotive synergies (walking, running, swimming, etc.), synergies of throwing, striking, jumping, and a certain (small) number of others (Gel'fand *et al.*, 1973, p. 162).

One thus comes to see a synergy in general as a program for controlling some distinctive motor performance extended in space and time, built upon synergies of coordinated reflexes as substrate. The entry FEEDBACK AND FEEDFORWARD places this notion in a controltheoretic perspective. See also SCHEMAS.

T

TACHISTOSCOPE. An instrument used for studying visual pattern and object recognition, by controlling viewing time. It may be merely a shutter placed before the eyes; but sophisticated instruments switch pictures alternately with blank fields of similar intensity in order to maintain adaptation (see VISUAL ADAPTATION) and minimize*afterimages. Some instruments allow successive presentation of pairs or up to six or so alternative pictures. These can be used for studying 'masking' and many other phenomena of visual perception.

TAOIST IDEAS OF THE MIND. See CHINESE IDEAS OF THE MIND.

TASTE. Flavour is usually defined as the overall sensation of taste and*smell. Taste refers to sensations arising from the taste receptors in the mouth and throat while smell arises from receptors in the nose. When a person has a cold or blocks his nose, he will taste but not smell food adequately, so the flavour is reduced. It is unfortunate that in everyday language the words 'taste' and 'flavour' are used interchangeably. Taste and smell, together with texture, visual appearance, and sound will give the overall sensory percept of the food, which is important in its choice and enjoyment. People who cannot perceive the flavour of food will often not maintain an adequate diet.

There are two main groups of scientists who are interested in understanding taste. The first group consists of food scientists within the food industry, who are interested in discovering the precise mechanisms of flavour perception so as to be able to maintain and control the flavour of the products being manufactured. Furthermore, food scientists use human judges to measure the physical and chemical characteristics of foods that are important for the flavour, texture, appearance, and sound of the food. They exploit the fact that the human senses are often more sensitive than laboratory instruments, to the minute quantities of chemicals present in a food that endow it with its characteristic flavour.

The second group of scientists are more interested in the workings of the senses and the brain *per se*. Knowledge of how a taste stimulus reacts with the membrane of a taste receptor would provide information not only about mechanisms of flavour, but also about other similar chemoreceptive functions involved in drug, hormone, brain, and cell mechanisms. Changes in taste Perception are beginning to be utilized as diagnostic tools in medicine, while further research is providing insights into areas ranging from genetics to the working of insect and animal attractants and repellants. For

this reason, taste, along with smell, is of vital interest to a broad range of scientists.

The behavioural measurement of taste, whether for the sensory evaluation of a food flavour or for elucidating taste mechanisms, can pose problems. People do not pay as much attention to taste as they do to vision and are thus less practised at assessing the taste sensations that they experience. One consequence of this is difficulty with language, for our language is largely concerned with visual stimuli. There are many adjectives available to describe colour but few for taste. Furthermore, parents teach their children to name colours but do not do so for tastes, so that, while young children are fairly skilled at colour naming, even adults can misname common sweet, sour, salty, and bitter stimuli. In particular, the terms 'sour' and 'bitter' are often confused, but this is merely a matter of definition. The confusion can be remedied by giving tasters citric acid and quinine to compare and informing them that the correct descriptions are 'sour' and 'bitter' respectively.

Aside from these common descriptions, there is little agreement on the use of taste adjectives and individuals usually acquire their own sets of definitions or taste concepts. For precise evaluation and communication of the taste or flavour of a foodstuff, however, a precise language has to be invented, for which the breadth of use of the taste adjectives has to be precisely controlled and agreed upon by those using the language. Usually, *ad hoc* languages are invented for a given food, so that although say, expert tasters may be able to communicate amongst themselves, their language would be 'foreign' to expert wine or mayonnaise tasters.

The method of language invention generally adopted is to follow the way that children learn colours: words are paired with appropriate sensations. Thus, languages are invented to describe the tastes, odours, and textures of foods, using a set of physical taste standards which are always available to define the adjectives used. These methods fall under the general heading of flavour profiling. There are problems, however, in ensuring that judges have the same breadth of use of the words in their invented language and this is still a subject of research. Without any special training, our command of vocabulary for taste is so poor that the merest suggestion of a word denoting a taste, in the instructions to a person judging a taste, will bias him to use that word. In fact, the power of suggestion is so strong that people have reported

Page 768

experiencing smells that they were told had been transmitted by television.

Different cultures have their own, idiosyncratic languages and confusions about taste, dependent probably on their dietary habits. Just as 'sour' and 'bitter' are confused in English, so it was reported at the beginning of this century that the islanders of the Torres Straits confused 'sour' and 'salty'. Many tribes of North American Indians were unfamiliar with salt until they had contact with Europeans, when they described salt as 'sour'. Some inhabitants of Polynesia and New Guinea had only one word to describe sweet, sour, and bitter. Recent studies have shown a tendency among Malay speakers to qualify taste adjectives. Thus, *masin* meaning 'salty', is often qualified: *masin ayer laut* (salty like seawater), *masin garam* (salty like salt), or *masin kitchup* (salty like soy sauce). It is not clear why Malay speakers should spontaneously volunteer more detail, though it may be because mothers teach

their daughters to cook by telling them to add the various ingredients until the food has a specific taste, rather than to add premeasured amounts of ingredient according to recipes. The need for precise communication about taste would encourage the development of a precise language. Whatever the reason for such precision, it would be a useful strategy for flavourprofiling techniques.

Spanish has three words for sour and bitter: *amargo* (bitter), *acido* (sour), and *agrio* (sour or bitter). Spanish dictionaries vary in their definition of *agrio*, and Spanish speakers, although eager to explain the correct usage as they see it, are generally inconsistent in the use of this word. The Japanese have words for 'sweet' (*amai*),

'sour' (*suppa*), 'salty' (*shiokarai*), and 'bitter' (*nigai*), and, in addition, a commonly used tasteword that is absent from the English language: *umami*—the taste encountered in several broths that are used as a stock, in which foods are cooked and to which they give their characteristic *umami* taste. Such *umami*tasting broths can be made from *kombu* (a type of seaweed: *Laminaria japonica*), from *katsuobushi* (dried bonito flakes), or from *shiitake* (a large mushroom, *Lentinus edodus*). Nowadays, the taste principles of these foods are commercially available as *umami* seasonings such as monosodium glutamate. Although the scientific term for the taste is *umami*, many Japanese call it the 'Ajinomoto' taste, after the name of the company that first made monosodium glutamate commercially available.

Although English speakers can perceive the taste, they do not have an appropriate word to describe it, unless they are specially trained, and will often call it 'salty', with the qualification that it does not taste like common salt. The situation is rather as if there were no word in English for 'orange' and people had to describe the colour as 'sort of red'.

Interestingly, the idea that there are four primary tastes, sweet, sour, salty, and bitter, is quite arbitrary. In any case, what is meant by the term 'primary taste' has not been defined. It could mean the unit of types of reaction that can take place on the membrane of the taste receptor, or of types of neural code that can communicate sensations to the brain, or even of processes that can take place in the cortex which result ultimately in the sensation of taste. Whichever of these candidates for primacy is adopted, the operative number is not known, for the idea that there are *four* primary tastes came into the taste literature by misunderstanding and accident.

In spite of the absence of any firm physiological evidence, some scientists still cling to the idea. The notion is often reflected in the way that taste experiments are designed: the taste stimuli used in research studies being limited to just four, or judges being allowed to use combinations of only four words to describe their whole range of taste experience.

Measurement of taste, as with the other senses, can produce difficulties. One interesting problem is the effect of adaptation. The brain tends to protect itself from having to cope with too much information, by simply 'turning down the volume control' on stimulation that is unchanging (see HABITUATION). There is no point in paying attention to a message that is merely repeating itself. This phenomenon of sensory adaptation is often experienced with smell. Should a person enter a room that smells of sweat or perfume, the smell receptors will send corresponding smell messages to

the brain. However, because the person does not leave the room, the same smell message will be repeated and the smell sensation will gradually vanish. Should the person leave the room and return, the smell sensation will reappear. Another way of envisaging this is to think of the smell mechanism as resetting the 'zero level' for smell—the concentration at which the smell stimulus is perceived as odourless.

Taste receptors are bathed in saliva, which is secreted from the salivary glands, and contains low concentrations of taste stimuli such as sodium chloride or potassium chloride; these can come from the blood and reflect the physiological state of the organism. The taste receptors adjust so that the zero level for taste (or taste zero) is set at the stimulus level in the saliva. For example, the level of salt in saliva is highest in the morning, drops until the afternoon, and then rises again to the high morning value. The taste zero appears to do the same, so that these salivary changes cause no sensation of taste; rather, the taste zero changes with the slow rise and fall of secreted salivary constituents. This constant adjustment is a useful way of ensuring that tastes are registered only when sudden large changes take place, such as when foods are placed in the mouth. Salivary concentrations can vary tenfold in value and may form the basis for changes in taste sensitivity connected with various diseases;

however, they are comparatively unimportant compared to the effect described next.

When, during an experiment, a taste stimulus

Page 769

like salt is tasted, it is sipped and then expelled from the mouth by spitting. However, spitting will not expel all the stimuli and while the person is spitting out the residual stimulus, his taste zero is rising to a higher level to render the residual tasteless. Thus, when the subject believes he has expelled all the residual stimulus, because his mouth feels tasteless, there will still be considerable amounts remaining and these will maintain a higher taste zero. The next stimulus will then be tasted with this new, higher taste zero; the taste system will not be as sensitive. This constant zero drift has caused considerable trouble in taste measurement; the resulting changes in salivary concentration can be 100fold and highly significant. If the residual stimulus is continually expelled from the mouth by a regime of water rinses between tastings, a lower average taste zero will be maintained. This confers a greater sensitivity, as well as ensuring that given stimuli taste more intense. Thus, the practice of rinsing between tastings, once thought to be an unimportant experimental detail, can be shown to have a major effect on taste sensitivity, and accounts for major variations in experience reported in the taste literature. One way of circumventing the problem of zero drift in taste measurement, is to flow taste stimuli over the tongue. This prevents any residual taste stimuli from remaining in the saliva and affecting taste sensitivity. It also allows the taste receptors to be reset to a constant zero level, between each tasting, by using a standard adapting flow. The taste receptors can adapt to tastelessness in this standard flow, thereby resetting the taste zero to the same level before tasting each new stimulus. The technique is powerful enough to allow tasters to distinguish between once and twice distilled water. However, little is yet known about the mechanisms of taste adaptation; even the extent to which taste receptors can 'zero adjust' has not been explored.

Thus, *a* stimulus becomes tasteless to the extent that it can resemble saliva. Certainly the osmotic properties of saliva are nearer to those of tapwater than to distilled water, so distilled water has more of a taste than tapwater. The flat taste of distilled water is a subzero or subadapting taste; in fact, pure water can appear to have a whole range of tastes depending on the adaptation state of the taste receptors. Changes in taste zero for a range of receptors during eating or experimentation will lessen or accentuate certain aspects of the taste of other stimuli. This may form the basis for the choice of certain wines with certain foods. A sweet wine may be more suitable for drinking with a sweet dessert because adaptation to one would lessen the sweetness of the other.

TAUTOLOGY. In logic, saying the same thing in a different way, often unwittingly. For example, 'A fairhaired blonde' is tautologous if 'fairhaired' and 'blonde' are taken to have the same meanings. But if 'blonde' means the natural hair colour, then a darkhaired girl who is fair because her hair is dyed

fair could be fair but not a blonde, and then 'fairhaired blonde' is *not* a tautology. Tautology always depends on accepted definitions.

When black, swanlike birds were discovered in Australia, there was doubt as to whether they could be 'swans'—for swans were supposed to be white. But it was allowed that though black they were swans—so 'black swan' was not contradictory. Conversely, it is not tautologous to call a swan white—though it would be if the quality of whiteness was part of the *definition* of a swan.

TELEKINESIS. Movement of objects from a distance by supposed*paranormal means. The alleged forces are generally acknowledged to be small; but if they exist at all it is exceedingly hard to understand why it is possible to carry out delicate experiments and operations, with galvanometers and so on: surely eager experimenters would exert their telekinetic powers, though unwittingly, to affect the results of experiments; and this would produce nonsense in science, and much else. Such negative evidence brings strong weight to the opinion that there is no such thing as telekinesis.

Page 770

Army in 1920. He is particularly known for his studies of gifted children. Perhaps his best-known book is *The Measurement of Intelligence* (1916).

TERROR is the specific*fear that some evil event or action is going to occur. Its origins go back to the notion of trembling. Strictly speaking, it should be distinguished from horror in that horror implies something disgusting and negative, whereas terror does not.

In the field of myth, terror has often been associated with visitations from an all-powerful god controlling life and death in a seemingly indiscriminate manner. The Delphic oracle went into a kind of trance or frenzy, during which the awesome god spoke through the prophetess. All this, even the ambiguities of the prophecies themselves, was designed to inspire fear of the god in the onlookers. (See PARANORMAL PHENOMENA IN ANCIENT GREECE.) Terror appears to fit into the category of instinct-response which humans share with most animals. For example, most humans and animals fear the sight of mutilated bodies. Experiments with chimpanzees during which the animals were shown pictures of chimpanzees with their heads or limbs cut off elicited instinct-responses of extreme trepidation. This fear of violence done to the body is at the basis of the terror process.

In the ancient world terror was the basis of tyranny, as in Rome under Marius and Sulla. Historically many political leaders have chosen to rule by terror tactics rather than customary, legal means—that is, by the systematic use of violence to inhibit political opposition. Presentday 'acts of terrorism' bear a different sense, as they are designed to disrupt a given system by violent actions.

While the causes of terror have changed over the centuries, the human mind continues to be highly susceptible to it. Our ancestors gathered round lighted fires not only to keep warm but to ward off 'the terror by night': there were terrifying animals lurking in the darkness. The 'nightlight' in a child's room reflects this fear of darkness, of the unseen and the unknown. Even so, most humans seem to enjoy the feeling of terror under controlled conditions. Grandmothers have traditionally told tales of terror around the fireplace to countless generations of children, in a role which today has been supplanted by the so-called horror film. Perhaps the monsters who march across the screen are designed to purge the real monsters within the human psyche. (See FRANKENSTEIN.) Contemporary science and technology have created new sources of terror, such as the threat of nuclear annihilation and highly sophisticated means of electronic surveillance and control of human behaviour. Modern adult human beings may no longer fear the presence of huge animals in the darkness, but most humans experience terror born from technology.

R. T. M.

TEUBER, HANSLUKAS (1916-77). German-American psychologist, born in Berlin, who studied in the University of Basel until 1941, when he emigrated to the United States. He took his doctorate at Harvard in the field of social psychology but his interests thereafter deviated to neuropsychology, in which his reputation became firmly established. He was a full professor at Bellvue Medical Center, 1947-51, and thereafter head of the department of psychology at the Massachusetts Institute of Technology, until his untimely death by drowning.

Teuber had a wide scholarship and he was an inspiring leader of research. His own work was mainly concerned with the psychological effects of warwounds of the brain, studied wherever possible through the use of quantitative methods, many of which he devised himself. His most important books were *Somatosensory Changes after Penetrating Brain Wounds in Man* (1960) and *Visual Field Defects after Penetrating Missile Wounds of the Brain* (1960).

THEOLOGY AND MINDBRAIN IDENTITY. If a human individual's mental life, conscious and unconscious, is identical with the functioning of that individual's brain, it is clear that when at death the brain ceases to function the mental life must thereby come to an end. And if by the soul we mean the mind, then clearly there can be no immortality of the soul. In*Plato's apt analogy, as the music ceases when the musical instrument which produces it is destroyed, so the soul ceases to exist when the bodily organism which produces it dies (*Phaedo*, 856). And so it might well seem that the mindbrain identity theory is directly incompatible with Christian belief in 'the life everlasting'.

The relationship of the identity hypothesis to Christian belief is more complex than this, however. The reference to Plato is a reminder that Page 771

the idea of the immortality of the nonphysical soul was developed, in the West, in Greek philosophy (see PSYCHE), particularly Platonism. And Platonism undoubtedly powerfully influenced the growth of Christian thought. But Christianity grew even more directly out of ancient Judaism, and it is from this source that it received its other main idea in this area, the idea of resurrection. The full phrase in the Apostles' Creed is 'the resurrection of the flesh and the life everlasting'.

The background of this belief is the ancient Hebrew view of the human being as, in modern parlance, a psychophysical unity. Generally speaking, a person was not thought of in the Hebrew scriptures (comprising the 'Old Testament' of the Christian Bible) as a nonmaterial spirit inhabiting a physical organism, but as a completely corporeal being, 'an animated body, and not an incarnated sou!' (H. W. Robinson in *The People and the Book*, ed. A. S. Peake, 1925, p. 362). Made out of the dust of the earth, at death we return to dust. We have no natural immortality, such as Plato believed the soul to have. If we live again beyond death, this can be only because God raises us up again on 'the last day' as bodily beings. This is the basic meaning of 'resurrection'; and it is in principle compatible with mindbrain identity.

But again the full picture is more complex. For we have to ask both what resurrection meant in the ancient scriptures and what it might mean today. The idea of the resurrection of the dead only developed within Hebrew religion during the last two or three centuries prior to the Christian era. In its popular form it was the belief that, at the end of the Age, God would raise the dead from their graves to a renewed life on this earth—a belief reflected in the statement in Matthew's Gospel that at the time of Jesus's death 'the tombs also were opened, and many bodies of the saints who had fallen asleep [i.e. had died] were raised, and coming out of the tombs after his resurrection they went into

the holy city [Jerusalem] and appeared to many' (Matt. 27: 523). But a tendency was also developing to think in terms, not of a reanimated and transformed physical body, but of a 'spiritual' body inhabiting a different and 'heavenly' environment. St Paul spoke of a spiritual body (*soma pneumatikon*) as well as the natural or animal body. Using the analogy of the seed which is buried in the ground and the plant that later springs up, he says, 'It is sown a physical body, it is raised a spiritual body' (1 Cor. 15: 44). There has been much discussion of St Paul's meaning; but the most generally held view is that, according to St Paul, the individual in the resurrected state will be embodied, with a 'spiritual' rather than an earthly body, and that this body will express the inner self in relation to the world of which it is a part as the physical body now expresses it in relation to the present world. (See Dahl, 1962, ch. 1.) Thus, without attempting to say what the resurrection body will be like, St Paul is suggesting that it will be appropriate to the heavenly world; and presumably, that different resurrection bodies will have individual characteristics appropriate to the different personalities which are thus embodied.

Can such an idea be further spelt out? If resurrection bodies have size and shape, and thus occupy space, it is a tempting option to postulate two (or more) spaces, in the sense of systems within each of which objects are spatially related to one another but such that each system is spatially unrelated to the other system(s). Within a resurrection world, constituting another space, the simplest model for a resurrection body would be an exact 'replica' of the former earthly body, including its detailed brain state. (More generally on the notion of replicas, see Parfitt, 1984.) A 'replica' is to be distinguished from a replica: there can be many replicas of the same original, and these can coexist with the original; but, we must stipulate that there can be only one 'replica' of a person and that the 'replica' and the original person cannot exist at the same time. That is to say, while there are many other kinds of possible universe, a universe in which resurrection, as here construed, takes place is one in which an individual's death on earth is succeeded by the coming into existence of his or her 'replica' in another space. In such a universe the identity of the

'replica' person with the earthly person consists in a total similarity of all attributes, with the consequent continuity of consciousness, character, and memory. The question, debated in discussions of the idea of*personal identity (such as Williams, 1973, ch. 1), 'What if there were two or more replicas of the same person?' no more arises in such a universe than it does in our present world; and, as in our present world, if there suddenly began to be such duplicates all that we can say is that they would disrupt our present concept of personal identity.

However, this notion of the postmortem 'replica' provides only a startingpoint, from which any building up of the idea of resurrection has immediately to diverge. For the exact 'replica' of a dying person would be a dying person, who would then proceed to die! Thus, while we have to postulate sufficient continuity as a basis for personal identity, we also have to postulate sufficient change, within this continuity, to make possible renewed life and indeed qualitatively better life. A number of the older Christian writers, including St Augustine (*City of God*, bk. 22, chs. 1516) and St Thomas*Aquinas (*Summa Theologica*, part iii (suppl.), q. 81, art. 1), suggested that in the resurrection men and women would revert, or advance, to their optimal age, which was taken to be about 30. This is no doubt one possible way of meeting the problem. But whatever the followon, the 'replica' theory provides a startingpoint for a conception of resurrection. Indeed, apart from the

popular notion of the literal raising of buried corpses to a new life, something like this would seem to be the only intelligible interpretation of the idea of resurrection which is compatible with mindbrain identity. (See Hick, 1976, ch. 15.)

Page 772

According to a very different conception, resurrection bodies are minddependent images. On this view the resurrection world has a status like that which*Berkeley, in his *Principles of Human Knowledge* (1710), attributed to our present world. Such a hypothesis is not, however, compatible with mindbrain identity. For on this theory consciousness survives the death of the body and forms its own 'world' by the mechanism through which*dreams are produced; though conceivably such an image world might be common to a number of percipients as a result of telepathic interaction between them (see Price, 1953).

A number of contemporary theologians and philosophers of religion have offered conceptions of 'the resurrection of the dead' other than the 'replica' conception—

which presuppose some form (whether or not strict mindbrain identity) of the view that man is an indissoluble psychophysical unity, so that there can be no mental life without a living brain. Very briefly, these are: the theory that eternal life consists in one's endless preservation, as a bodily historical being, within the divine memory (Hartshorne, 1962, ch. 10); the theory that it consists in sharing the eternal divine view of one's present earthly existence (Pannenberg, 1962); and the theory that

'eternal life' is a moral quality of one's present life and does not entail any further existence after death (Phillips, 1970). These theories have in common the exclusion of any continuation of conscious life involving responsible decisions and actions through which the human person might continue to develop and change. There are however other theologians and philosophers of religion who hold that a coherent religious interpretation of life requires us to postulate the continuation and completion of the personmaking process in a further life, or lives, whether involving the survival of mind after the death of the body, or the resurrection in some form of the bodymind complex, or both.

THERAPY. See BEHAVIOUR THERAPY, ENCOUNTER GROUPS; GESTALT THERAPY; INTERACTIONAL APPROACH.

THINKERS, INDEPENDENT. On the whole, *Homo sapiens* tends to be conventional: that is, very few people have revolutionary ideas. At an early age, for instance, virtually every child is taught that the earth is a globe, revolving round the sun in a period of one year—and he (or she) will believe it. Yet a mere six hundred years ago, children who were taught at all learned that the sun goes round the earth, and they believed that with equal fervour.

Of course, there have always been rebels who have opposed what may be termed official doctrine. A Greek, Aristarchus, did so, long before the time of Christ, when he maintained that the Earth was not the centre of the universe. Nobody persecuted him, but very few people believed him. Some of the later protagonists of the Suncentred theory were not so lucky; one of them, Giordano Bruno, was burned at the stake in Rome as recently as 1600 (though it is true that this was not his only crime in the eyes of the Inquisition, and the Church of those days was not noted for its kindliness).

Obviously, Aristarchus and Bruno were right. Bruno was to all intents and purposes following in the footsteps of Copernicus, a Polish churchman who had scandalized his contemporaries in 1543 by publishing a book in which he rejected the idea of a central earth. One of Copernicus's fiercest critics was Martin Luther, who referred to him as a fool who wanted to turn everything upsidedown—a comment which cannot have worded Copernicus, who had prudently withheld publication until the last days of his life, but which faithfully reflected official views of the time. It is fair to call Copernicus an 'independent thinker', because he had no respect for orthodox science, and it is equally fair to say that throughout history there have been men of similar calibre who have been responsible for tremendous advances in knowledge.

On the other hand, most modern rebels against scientific orthodoxy are not only wrong but so ready irrational that it is by no means easy (or kind) to argue with them.

Consider, for instance, the Flat Earthers. The belief in a word shaped like a pancake is very old, but the fact that it lingers on is strange. A few decades ago there was a kernel of fiatearth believers in Zion, Illinois, presided over by one Wilbur Glenn Voliva, who believed that the world was discshaped, with the North Pole in the middle and a wall of ice all round. (To forestall any questions, let it be added that in Voliva's universe there was no South Pole!) Below the earth there was a kind of

bargain basement inhabited by the spirits of a race of men who lived on the surface of the world before the arrival of Adam and Eve. Voliva died in 1942, but the International Flat Earth Society is more modern, and was for years controlled by the late Samuel Shenton, whose views were of the same overall type as Voliva's.

Even the Apollo flights to the moon did not daunt him, and he continued to maintain that the moon is a very small body, while even the sun has a diameter of a mere thirtytwo miles. He also maintained that the spacepictures of earth were deliberately faked by those who were intent on suppressing the truth.

This is highly significant. One of the modern

Page 773

hallmarks of the Independent Thinker is that he is convinced that Orthodoxy is persecuting him. Generally, of course, he has no official support— but this is not an invariable rule, and there are a few rebels who have made their mark. Of these, the classic example in recent years has been Academician Lysenko, in the Soviet Union. He was (or claimed to be) a pioneer geneticist, and he produced a whole crop of revolutionary theories, together with experiments which signally failed to work. Yet he remained in favour with the Soviet authorities for an amazingly long time, and to disagree with him was to court official disapproval. All in all, Lysenko managed to put Soviet genetics back at least half a century.

Another case, less extreme but still important, was that of Hans Hörbiger, an eccentric Austrian engineer who believed that the most important material in the universe was, simply, ice. To him almost everything was icy; the stars were gigantic iceblocks, and the moon an iceglobe which would eventually spiral down and hit us—as at least six other moons had previously done.

Hörbiger's book, *GlazialKosmogonie*, was published as long ago as 1913, and is regarded as a classic of pseudoscience. It is lengthy, heavy in style, humourless, and entirely without value except as a curiosity, but it led on to what was called WEL (*Welt Eis Lehre*, or Cosmic Ice Theory)—a cult which became popular in Germany between the wars, and continued to be so even after Hörbiger's death. Hörbiger himself was absolutely typical of his type; to him, everyone who disapproved of cosmic ice was to be treated as an enemy.

Most scientists were sceptical, but not all; one nearconvert was Philipp Fauth, who had a considerable reputation as an astronomer, and who had compiled a large, albeit rather inaccurate, map of the moon. Some of the politicians were impressed, though they did defer to convention sufficiently to issue a statement that it was still possible to be a good National Socialist without believing in WEL. There is still a Hörbiger Institute with a British branch, though its members cannot have failed to be discouraged when the Apollo astronauts landed on the moon and had no need to use skates.

Yet another Independent Thinker who has met with a surprising amount of support is a psychoanalyst, Dr Immanuel Velikovsky, who was born in Russia but made his home in the United States.

Velikovsky's book *Worlds in Collision*, published in 1950, is fully up to Hörbiger's standard. He believed that planets can turn into comets, and vice versa; that Venus used to be a comet, and that it made several close approaches to the earth in biblical times, on one occasion stopping the earth's rotation and leaving the Red Sea dry for long enough to allow the Israelites to cross.

Velikovsky's theories, elaborated in subsequent books, are so full of scientific absurdities that it is hard to see how even the most naive reader could take them seriously. None the less, many people did—and still do. The extensive biblical references are quite correct, and the trouble is that one cannot argue—because there is no common scientific ground at all. Anyone who maintains that, for instance, the sun is 193,000,000 miles away instead of 93,000,000 can be challenged and disproved; but Velikovsky's whole theory is based on the possible interchange between planets and comets, which is no more rational than believing the earth to be flat (in fact, rather less on the whole).

There are two cults which are even more widespread: astrology and flying saucers. Both have not mere hundreds of supporters, but millions. Astrologers are found everywhere, both on seaside piers and in lavish offices. Many are quite sincere, and when asked to explain how the apparent positions of the sun, moon, and planets can affect human destiny generally have the grace to admit that they do not know. Here, too, there is no rational basis for argument. It is useless to point out that a

'constellation' is merely a line-of-sight effect, and that the patterns are made up of unassociated stars at wildly different distances from us; it is equally useless to comment that the patterns themselves are arbitrary, and that anyone who can see the outline of two fishes in Pisces, or a seagoat in Capricornus, must have a lively imagination by any standards. And now and then, of course, an astrologer makes a correct observation or prediction; it is impossible to be always wrong.

Astrologers are linked with the flying saucer enthusiasts, who now call themselves UFOlogists, and of whom there are two definite types. Type I follows men such as the late George Adamski and the rather mysterious Cedric Allingham, who published books describing their meetings with men from other worlds—a Martian in Allingham's case, and initially a longhaired Venusian in Adamski's. Even more astounding are the members of the Aetherius Society, who believe that they are in constant touch with Mars, Venus, and other worlds, and that messages of vital importance are telepathically relayed. Everything is regulated by the Interplanetary Parliament, which meets on Saturn and whose representatives look like huge ovoids perhaps forty feet in diameter (one might even describe them as large balls).

Among various contactees are Confucius and Jesus Christ. On one occasion the earth was under attack from fishmen living on the far side of the Galaxy, though fortunately the Interplanetary Parliament took prompt action and the oncoming missile was blown to pieces by something equivalent to an Olympian thunderbolt.

The Type II UFObelievers have no faith in the Adamskis, the Allinghams, or even the Interplanetary Parliament, and content themselves with maintaining that various phenomena seen in the atmosphere are due to visiting spacecraft. Unfortunately, no saucer pilot has yet shown himself to the world at large, and most UFO pictures look so strikingly like lampshades that people with

critical minds go so far as to suggest that they *are* lampshades. There is a real problem here, but psychological rather than astronomical. Nobody will deny that there are atmospheric phenomena which are difficult to explain (ball lightning is one), but to suppose alien spacecraft is frankly irrational. Moreover, recently there have been even weirder theories, some UFOlogists believing that the saucers come from inside the earth—popping out from a hole at the North Pole with the intention of keeping a watchful eye on us.

Quite apart from all this, the idea of a hollow earth lingers on—an echo of the episode of 1823 in which an American Army officer, Captain John Cleves Symmes, asked Congress for funds to send an expedition to the north polar entrance. (Congress declined, but it is on record that twentyfive members voted in Symmes's favour.) And in Germany, the presentday Society for Geocosmical Research believes that the Earth is nothing more nor less than the inside of a hollow globe; the sun is in the middle, with Australia and Britain on opposite sides, while the solid ground below our feet extends infinitely in all directions.

Such examples of independent thought could be multiplied almost *ad infinitum*. There are those who believe the sun to be cold; those who fear that the accumulation of ice at the North Pole will make the world tilt over, producing disastrous floods; and those who have a profound disbelief in evolution, preferring to think that each species appears fully fledged as if by magic. Few of these people have any scientific qualifications, but most of them are sincere, wellmeaning people acting from the best possible motives. Some of the astrologers are less desirable; and there are some cults—mostly quasireligious—which are to be deplored: they do immense harm by influencing gullible people and breaking up families. But fortunately these are the exceptions, and they are easy to detect.

Generally, the Independent Thinker has one particular theme, and one only. (It was once said that every crank thinks that every other person is a crank.) His exceptional belief does not debar him from accepting all the conventional facts of life: thus President Kruger of South Africa was a Flat Earther, while Gladstone believed so firmly in the lost continent of Atlantis that he asked the Treasury to finance an expedition to the seabed—a request which was turned down. Furthermore, he does not deliberately set out to be different from his fellows; he believes that he has a message, and he will do all he can to propagate it, usually for motives which are entirely altruistic.

What are regarded as erratic ideas are generally greeted with ridicule; but there are occasions when the Independent Thinker has been proved right. Only a few decades ago the concept of flight to the moon was regarded with contempt; some time after the Wright brothers had made their first 'hop' in a heavierthanair machine, the famous astronomer Simon Newcomb was stating that nothing of the sort could ever be achieved, and that a raft pulled by birds was a more rational idea;

and in preStephenson days it was maintained that no human being could possibly stand up to the strain of being carried along at thirty miles per hour. To be dogmatic is always dangerous, and science fiction has the uncanny habit of changing into science fact.

THINKING: HOW IT CAN BE TAUGHT. Is thinking simply IQ in action, or is it a separable skill that can be developed just as we develop*skill at cooking, skiing, or riding a bicycle? It seems that when asked to think about matters within their own experience, children of relatively low IQ do much better than expected when compared with children of high IQ. It seems that the practical operating skills of thinking (decision, judgement, assessment of priorities, breadth of scan) are not the same as the knowledgeabsorbing skills (perceiving relationships, attention skills, ordering information, memorizing).

If thinking is a skill, then it seems likely to be a natural skill that we can pick up in the ordinary course of events just as we pick up the skill of walking, talking, or breathing. We may indeed pick up the skill, but as a 'twofinger skill'. The expression comes from the world of typing. Someone who has to pick up the skill of typing as he goes along acquires a fair degree of skill using two fingers, but the skill never develops much beyond this point of coping with immediate needs. Someone else who sets out to train to be a secretary learns touchtyping from the start, and within eight weeks has a greater skill than the twofinger operator. Quite soon the skill of the touchtypist is far ahead. A skill that is built up by coping with the immediate situation may never develop beyond this level. For example, 'prejudice' is an excellent twofinger thinking skill since it allows action without reflection and removes the need for decision. But in a wider field prejudice can be inhibiting.

Twentyfour groups of children, aged 9 to 10, from six London primary schools with widely differing social backgrounds, were asked to consider the suggestion that

'bread, fish, and milk should be made freely available'. The discussions were taperecorded and analysed. Some of the children came from families that were too poor to afford milk on a regular basis. Yet twentythree out of the twentyfour groups decided that the suggestion was a bad one. Their reasoning went something like this:

'If bread, fish, and milk are free the shops will be overcrowded.'

'So the buses going to the shops will be overcrowded.'

'The drivers will ask for more pay.'

'They won't get more pay so they will go on strike.'

'Other people will join the strike and then there will be chaos.'

'So it is a bad idea.'

ing in which one point becomes the startingpoint for the next idea and so on. It often occurs with younger children. Teaching some scanning strategy allows the child to broaden his area of attention and to avoid getting pulled along a pointtopoint track.

At the other extreme is the highly skilled, highly intelligent, highly articulate thinker. He makes up his mind instantly on an issue and then uses his skill of argument to support the position that he has taken up. The sheer brilliance of this supporting effort makes it unlikely that the thinker will ever feel the need to change his position.

And yet at no time has he ever tried to *explore* the subject. Similarly we put a lot of emphasis on debating skills, with the assumption that if you can prove the other fellow wrong, somehow that proves you right. In terms of thinking skill both these strategies are highly inefficient and indeed dangerously so.

In the past, attempts have been made to teach thinking by teaching the rules of logic or the rules of the syllogism. Taught this way, logic can become an abstract, idealized system with little relevance to everyday life. More importantly, logic can only process the material presented to it by perception, and it is at the perception stage that most ordinary thinking has to take place. The general approach to teaching thinking is not to teach it directly but to criticize pupils when they make logical errors. Unfortunately, thinking that is free from logical errors is by no means necessarily good thinking. Bad logic makes for bad thinking, but good logic makes for good thinking *only* if the starting perceptions are themselves appropriate. Logic is only a servicing device for perception. It is far too much part of our culture to assume that a logical argument proves a point.

In education we also assume that from an interested discussion on some subject, pupils will abstract certain habits and skills of thinking and transfer them to new situations. This does not seem to happen. Such discussions increase fluency but seem to provide little transferable skill. If, rather, we create, quite deliberately, various attentiondirecting tools, these tools can then be practised on a rapidly changing variety of situations. This change is necessary so that attention stays on the tool and does not drift to the content—as it would if the content remained constant.

In the perception stage, much of thinking is concerned with directing attention. After all, a question is only a device for directing attention. The very first lesson might introduce the PMI device. This requires the pupils deliberately to look for the Plus, Minus, and Interesting points in a situation. It is intended to prevent the instantjudgement habit and to encourage exploration before decision rather than after it. Most people would of course claim to carry out this simplistic procedure, and no doubt they do in doubtful situations. But very few people carry out the procedure if they have a firm opinion on the matter. In one experiment two random groups of adults were asked to consider the suggestions 'that marriage should be a fiveyear contract' and 'that currency should be dated so that at the year end the exchange with the new currency could be altered according to the rate of inflation'. In the first

group 23 per cent were in favour of the fiveyear marriage contract and in the second group 35 per cent were in favour of the dated currency. The questions were then switched over and each group was asked to do a deliberate PMI on the matter. The 23 per cent in favour of the contract marriage now rose to 37 per cent in favour. The 35 per cent in favour of the dated currency now fell to 11 per cent.

So asking people to do what they would have claimed to do anyway made a huge difference. A group of thirty children, aged 9 to 11, was given the suggestion that all children should be paid some money each week for going to school. Each one of them was in favour of the idea. They were then asked to do a PMI on it. Five minutes later twenty-nine out of the thirty had changed their minds and derided it would be a bad idea.

Eight groups of primaryschool children were asked to consider the problem of a girl whose parents were being posted abroad. The girl wanted to continue her studies to be a teacher: should she stay behind or go with her parents? The four groups who had had no special training considered the following number of aspects of the situation: 3, 5, 5, and 5. The four groups who had had ten thinking lessons considered 17, 17, 13, and 19 aspects.

It is not really surprising that skill can be developed by direct attention and practice.

E. B.

Bono, E. de (1977). *Teaching Thinking*. Albuquerque, New Mexico.

THORNDIKE, EDWARD LEE (1874-1949), born in Williamsburg, Massachusetts, is best known for his contributions to the psychology of learning, and secondarily for his work in educational psychology and mental testing (see INTELLIGENCE). While doing graduate work with William James at Harvard in the 1890s, he became interested in animal intelligence; he studied the intelligence of chicks in James's own basement. For financial reasons he soon transferred to Columbia University, where he studied under James McKeen Cattell. His thesis, 'Animal Intelligence: an experimental study of the associative processes in animals', became one of the most influential works ever written in American psychology. In it are described the famous 'puzzlebox' experiments with cats, dogs, and chicks. In a typical experiment, a cat could escape from a box by clawing down a rope, lifting a latch, or engaging in a series of different manipulations; and escape would give the cat access to food. From trial to trial, Thorndike plotted the times it took for an animal to escape; over trials, animals were found to require less and less time to make the escape response.

Page 776

These data composed the first 'learning curves', and were said to show something fundamental about the nature of learning.

As formalized in his later works (notably *Animal Intelligence*, 1911), Thorndike's theory of learning may be summarized as follows. Learning occurs 'by trial and error, and accidental success', or, as we

have come to simplify this view, by *trial and error*. Correct movements—for example, movements toward a doorlatch in a puzzlebox—will lead to a 'satisfying state of affairs' and be 'stamped in'. Wrong movements will lead to an 'annoying state of affairs' and be 'stamped out'. Over time, only correct movements will survive; a cat at this point would have learned the correct response to the puzzlebox and could escape quickly. The learning process could be reduced to a number of 'laws'. The *law of effect* describes the trialandsuccess process noted above: a response is more or less likely to occur depending on whether it produces a satisfying or annoying state of affairs. The *law of exercise* states that learning improves with practice. Other laws and sublaws were presented, and occasionally changed, over the course of Thorndike's career.

Thorndike's work on learning was a step away from the earlier psychology of mind and towards the*functionalist and*behaviourist movements that came to dominate American psychology. Prior to Thorndike's work, all learning, even in simple animals, was said to show some sign of*consciousness. But for Thorndike, learning occurred simply as the result of the satisfying or annoying effects of instinctive movements. Though he described the learning process as affecting associative bonds between stimuli and responses, in the tradition of the British associationists, his emphasis on the trialanderror nature of learning and on observable movement made consciousness seem a less important factor in the learning process.

From 1899 to 1940 Thorndike taught at Teachers College of Columbia University, and his contributions to educational psychology are many. His textbook, *Educational Psychology* (1903, later revised and expanded), became a classic in that field. In 1901 he published a paper with Robert Sessions*Woodworth dispelling the myth that training on one task necessarily transfers to training on a different task (see TRANSFER OF TRAINING); this paper foretold the end of traditional classical education in schools. He also did work on mental measurements and the study of individual differences, applied animal learning theories to human education, constructed a scale to measure children's handwriting, and with I. Lorge compiled an important table of wordfrequency counts. By far America's most prolific psychologist, he published more than 450 articles and many books in his lifetime.

R. E.

THOULESS, ROBERT HENRY (18941984). British psychologist, born in Norwich and educated at Corpus Christi College, Cambridge. He became a lecturer in psychology at Manchester and later at Glasgow before returning to Cambridge as a lecturer, later Reader, in educational psychology, a post which he occupied with distinction for almost thirty years.

Thouless is best known for his experimental work on size and brightness constancy, to which his approach differed substantially from that of the*Gestalt psychologists.

He laid the emphasis not on constancy of appearance of objects *per se* but on the element of compromise which he thought to be involved in its genesis. If, for example, a subject is required to match a circular disc placed obliquely so that its retinal image is elliptical, with a series of ellipses placed at right angles to his line of sight, he was found invariably to choose an ellipse which is less

elliptical, i.e. more circular, than the retinal image. This Thouless described as phenomenal regression to the 'real' object, and it appeared to indicate that a property of an object, such as its size, shape, or brightness, is intermediate between that of the peripheral stimulus pattern on the one hand and the actual property of the object on the other. At the same time, Thouless insisted that phenomenal regression, although it might show marked individual differences, could not be assigned to learning. Although his work attracted considerable interest, he was not without his critics, in particular Kurt*Koffka.

Thouless had wide interests in general and social psychology, among them psychical research and the psychology of religion. He was for many years a consultant to the National Foundation for Educational Research and was president of both the British Psychological Society and the Society for Psychical Research.

O. L. Z.

THURSTONE, LOUIS LEON (1887/1955), American pioneer in psychometrics (mental measurement). Thurstone was born in Chicago of Swedish ancestry, obtained his doctorate at the University of Chicago, and taught there until he retired to Chapel Hill, North Carolina. Earlier he had studied as an electrical engineer, and worked with Edison on cine projection; but in 1914 he turned to psychology, and became involved in the production of tests for army recruits in the First World War.

From then on the main goal of his researches was the measurement of mental qualities, whereby psychology could become a quantitative and rational science. This was not merely an academic exercise; he succeeded in developing and applying his new techniques to a wide variety of practical problems.

The earliest attempts at mental measurement were the so-called*psychophysical methods, developed by German psychologists in the nineteenth century for studying people's sensitivity to touch, sound, and other sensations. For example, what was the smallest difference in pitch between two tones that people could detect?

Thurstone showed that such methods could be extended to

Page 777

much more complex qualities, such as the strength of attitudes, e.g. like or dislike of communism, capital punishment, negroes, or the Church. He published a number of such attitude scales, and used them for measuring the effects of propaganda on people's prejudices. Many subsequent research workers in social psychology have constructed, and made use of, Thurstonetype scales.

Another topic was the measurement of progress in learning (i.e. the plotting of learning 'curves'), and in mental development generally. He showed how to express such development in absolute units, comparable to physical measurements. This made it possible to predict the zero point of mental growth, namely around three months before birth.

Thurstone was prolific in the construction of intelligence tests, and, being dissatisfied with current definitions of intelligence, he published a thoughtful book, *The Nature of Intelligence* (1924). This he approached from the biological angle, rather than the logical or statistical. In the 1930s he contested Charles Spearman's view of intelligence as a unitary, general or 'g' factor. He proposed that it is a combination of several distinctive abilities, e.g. verbal comprehension, reasoning, memory.

And he superseded Spearman's statistical technique of measuring g with a much more flexible procedure known as multiple factor analysis, which could handle numerous ability factors simultaneously. With his Primary Mental Abilities tests, constructed for various agegroups, he could obtain a profile of each person's strengths and weaknesses (see *Vectors of the Mind*, 1935, and *Multiple Factor Analysis*, 1947). It is for this work on factor analysis that he is most widely known;

and it was applied by him, or his numerous followers, to many practical problems: for example, isolating the main distinguishable types of mental illness, analysing human perceptual abilities, or developing new tests of such special aptitudes as mechanical ability.

Thurstone was interested too in the measurement of personality characteristics, and published a widely used test of psychoneurotic tendencies. In each of the many areas that he touched he produced original ideas, and innovative techniques of measurement. He also advanced the study of his subject by founding the outstanding journal *Psychometrika*, and guiding it for nearly twenty years, until his death.

P. E. V.

TIMEGAP EXPERIENCE. Quite frequently, during the course of a longdistance journey, motorists reach some point—a crossroads for instance—and find they have no conscious recollection of covering the miles since the last village. They usually interpret this in terms of time, reporting, for example, 'a lost half hour'. Having consulted their watches, they may reflect, bemusedly, 'How did it jump to three o'clock?' For this reason, the term 'timegap experience' has been coined for discussion of the phenomenon (Reed, 1972).

The sudden awareness of a 'time gap' is usually experienced as 'waking up'; part of the puzzlement felt by the individual is due to the experience of 'waking up' when one is already awake. But more perturbing is the belief that there has been an inexplicable blank in one's awareness of the passage of time. In part this is due to the strict temporal structuring of our civilization. For most of us, our workaday lives demand continual reference to clock time, and assessment of temporal duration. Only in certain occupations or during holidays can we enjoy release from the constant need to be aware of the passage of time. But more importantly, our sense of self is intimately related to the subjective awareness of the continuity of life. Any break in personal time is alarming, because it suggests some disintegration of psychic synthesis.

There is considerable evidence to suggest that our awareness of temporal duration is determined by *events*. These can be of both external and internal origin. What the timegapper describes as his failure to register a period of time is really a failure to register a series of external events which would

normally have functioned as his timemarkers. The problem is primarily one of **attention*. The question, then, is how he could fail to register so many sequential events. How can a person completely fail to 'pay attention' over a prolonged period while successfully performing a very complex task like driving a car, which itself is largely dependent on reactions to external events?

The answer may be found by considering the nature of skilled behaviour. (See SKILL.) This is hierarchically organized, so that its elementary components become progressively automatized. The skilled driver does not need to pay conscious attention to such basic matters as the position of the controls, or the movements of his hands and feet. He can afford to reserve his attention for the assessment of input at a strategic level. If the situation is relatively undemanding, and external events routine or predictable, he may require only a low level of conscious attention. He will deploy his attentional resources elsewhere—typically, to his own thoughts. In one sense, he has 'switched to automatic pilot'. But any significant change in the situation will involve the processing of new information, the assessment of probabilities and the making and implementation of decisions. All this requires heightened conscious awareness, a switching back to 'manual control'. The crossroads, for example, introduces a sudden increase in information load, which demands the sharp refocusing of our motorist's attention. And this is the moment when the timegapper describes himself as 'waking up'.

TITCHENER, EDWARD BRADFORD (1867-1927). Born at Chichester, Sussex, he studied philosophy at Oxford and took his doctorate under Wilhelm*Wundt at Leipzig. He moved to Cornell in 1892, where he spent the rest of his life. Much

Page 778

influenced by Wundt's psychological outlook, he translated a large part of the 5th edition of his *Physiologische Psychologie*, published in America as *Principles of Physiological Psychology* in 1904. His own work was mainly on sensation and*attention. Although highly respected, he never felt really at home with American psychology, and wholly rejected 'behaviourism as irrelevant to psychology as he understood it. (None the less, he liked and respected J. B.*Watson and, unlike his colleagues, supported him warmly after he lost his post at Johns Hopkins University in consequence of a personal indiscretion.) Titchener's principal works are: *Experimental Psychology: a manual of laboratory practices* (1901, 1905); *Lectures on the Elementary Psychology of Feeling and Attention* (1908); *Lectures on the Experimental Psychology of the Thought Processes* (1909); and *A TextBook of Psychology* (1909-10).

O. L. Z.

TOLMAN, EDWARD CHASE (1886-1959). American psychologist, born at Newtown, Massachusetts and educated at the Massachusetts Institute of Technology and at Harvard, where he obtained his doctorate in 1915. He spent almost the whole of his active academic life at the

University of California at Berkeley, where he evolved a theory of learning which, while behaviouristic, owed little to J. B. Watson; though the theory was formulated in purely behavioural terms, reflexes were not central to his ideas. Tolman, who worked almost exclusively with rats, placed much emphasis on the importance of latent learning, reward expectancy, and the formation of hypotheses in animal learning. He also placed emphasis on spatial orientation and cognitive maps in maze learning.

Tolman's most important book was *Purposive Behavior in Animals and Men* (1932). Jointly with the former Viennese psychologist Egon Brunswik, he wrote an influential article entitled 'The Organism and the Causal Texture of the Environment' (1935).

TOUCH. Objects in contact with the skin can arouse a variety of tactile sensations, of which introspection allows several qualities to be distinguished: for example, vibration, steady pressure, light touch. The sensations can be graded in intensity in a predictable manner in relation to the magnitude of the stimulus, as described quantitatively by the Weber-Fechner and Stevens's power law relations (see PSYCHOPHYSICS). The position of an applied stimulus, both absolute for a single point and relative with respect to two loci of stimulation, can be detected, with varying degrees of accuracy, in different parts of the body surface.

The physiological mechanisms underlying these perceptual properties can be analysed in a systematic manner, starting with the neural receptor elements in the skin.

These are at the ends of axons connected with the spinal cord and brain stem. Neural processing occurs at the spinal, brain stem and thalamic levels on the pathway from the skin to the cerebral cortex. Further processing in the somatosensory area of the cerebral cortex and in the adjacent association areas of the cortex leads to final elaboration of sensation, where perception is assumed to occur.

The groundwork of knowledge, as of other sensory systems, was laid in experiments on anaesthetized or conscious animals, in which very precise studies of morphology, physiology, and behaviour could be made. This knowledge has recently been extended, in a dramatic way by electrophysiological and correlated psychophysical studies, to conscious human subjects, with a remarkable degree of concordance with the animal studies.

Cutaneous sensory tactile receptors. The skin contains several kinds of encapsulated mechanoreceptors (tactile receptors) innervated by myelinated dorsal root nerve fibres, and each kind is specialized to detect particular parameters of a mechanical stimulus. The *Pacinian corpuscle*, the first cutaneous receptor to be discovered, is relatively large, up to 2 mm long and 1 mm in diameter, and is present in the deeper layers of both hairy and hairless (glabrous) skin. It is pear-shaped and comprises a lamellated structure, with an outer capsule, outer lamellae, inner lamellae, and in its core the specialized rod-like nerve terminal. The corpuscle is adapted to respond to vibration, with maximal sensitivity at 200-300 hertz and a range (band width) of 20 to 1,500 hertz. It is capable of detecting movements smaller than a micrometre (about one-twentyfifth of one-thousandth of an inch). The lamellae are high-pass filters that prevent steadily maintained pressure from penetrating to the

nerve terminal in the core, but allow rapidly changing pressures to, so that vibrations can be detected, even in the presence of maintained pressure.

Meissner's corpuscles are encapsulated and present in the glabrous skin of Primates, including man. They lie in rows just below the epidermis, in dermal papillae. The papillae correspond to the familiar surface ridges of the fingers and toes that form each individual's distinctive fingerprint. Meissner's corpuscles are innervated by myelinated axons and, like Pacinian corpuscles, also detect vibration, but at lower frequencies and with lesser sensitivity. Their maximal sensitivity is at 2040 hertz and their frequency range from about 1 to 400 hertz. The corresponding receptors in nonPrimates are the Krause end bulbs, which also detect changing stimuli.

In hairy skin, the *hair follicles* are innervated by myelinated fibres that have terminals arranged in a 'palisade' round the hair shaft. They too respond to changing stimuli, and can be subdivided into at least three subcategories, with different band widths for maximal sensitivity to hair movement Page 779

and different thresholds of movement sensitivity.

All these kinds of mechanoreceptors have one feature in common—they do not respond to a steadily maintained displacement of the skin, and thus are incapable of detecting steady pressure. On the other hand, they can encode with great precision the magnitude and wavelength of vibratory stimuli of different frequencies, covering a range from less than 1 hertz to greater than 1,500 hertz.

Static or steadily maintained mechanical stimuli are detected by two other specialized cutaneous receptors. The first and more numerous are the *Merkel* cells, which occur in small clusters in the lower margin of the epidermis. In hairy skin these clusters are scattered, each innervated by a single myelinated axon, and form Iggo

Pinkus domes visible at the skin surface, especially after depilation of the skin. The receptors form *Sa I* mechanoreceptors that can sustain a discharge during static deformation, as well as during superimposed vibrations. The mechanical thresholds in hairy skin are about 1 micrometre, and the receptors can fire at rates higher than a thousand a second when the skin is stroked. The *Sa I* receptors are also present in glabrous skin, the Merkel cells there lying in the so-called fete pegs of the epidermis.

The other slowlyadapting receptor, the *Sa II*, has the *Ruffini ending* as its receptor. These are present in the dermis. They are spindle shaped, up to 2 mm long, with a distinct capsule, and a densely branched nerve ending in the central core of the receptor. These receptors are structurally similar to the Golgi tendon organs, and have the similar property of responding with a sustained discharge to maintained displacement of the skin. The mechanical sensitivity of the *Sa H* receptors is less than that of the *Sa I*.

Receptive fields. Each of these receptors occupies a small region of skin, from about 100300 micrometres in diameter for the *Sa I* and Meissner's corpuscles in the fingertip, to several centimetres

for hair follicle receptors in the arm and trunk skin. These small spots are the*receptive fields from which a discharge of impulses can be evoked by an appropriate stimulus. The sizes of individual receptive fields and the density of innervation (the number of receptive fields per unit area) are important factors in determining the location of a stimulus, and for twopoint discrimination, the ability to distinguish two Stimuli applied simultaneously.

Central processing. This array of mechanoreceptors provides the central nervous system with a great deal of information about the characteristics of mechanical stimuli (intensity, duration, band width, location) that is further processed at spinal, brain stem, and thalamic levels before it reaches the cerebral cortex.

Direct pathways. The most direct routes go via the dorsal columns of the spinal cord to the lower end of the brain stem, where the ascending branches of the incoming sensory nerve fibres make synaptic connections with neurones that in turn send axons to the ventrobasal thalamus. Thalamic neurones in their turn send their axons to the somatosensory region of the cerebral cortex. An important feature of this direct system is that it can preserve, to an astonishing degree, the information encoded by the cutaneous receptors—the system has the property of specificity. Individual neurones of the somatosensory cerebral cortex may have characteristics analogous to the different kinds of primary cutaneous sensory receptors, in terms of their responses to mechanical stimuli, encoding parameters such as amplitude, static/dynamic aspects, and frequency response range; but supplemented by additional properties, such as feature extraction, e.g. location of stimulated skin and direction of a moving object.

Indirect pathways. There are several other sensory pathways in addition to those via the dorsal column, medial lemniscus system. These others are more elaborate, since additional neurones are present in them, and may also be nonspecific, because an admixture of inputs from different touch receptors, as well as from thermoreceptors and nociceptors, can interact. The ascending information in these pathways (such as the spinothalamic tract) may have lost, to varying degrees, some of the spatial and specific attributes of the dorsal column system. Their role in 'touch' is still open to question, but they provide sensory pathways in parallel with the direct dorsal column routes.

Central control of sensation. A further important feature of tactile sensation, also present in other senses, is that not all the stimuli delivered to the skin surface necessarily cause excitation in the somatosensory cortex and an associated sensory awareness. There are very potent control systems, usually originating in the brain, that can modify the transmission of exaltation from the skin on its way to the cerebral cortex. This is achieved through descending inhibition that interacts on neurones, at several levels in the sensory pathway, with the incoming excitatory information. This inhibition can totally or partially prevent the onflow of information, and may be used to enhance contrast between a stimulated area and adjacent regions, or to admit only certain inputs to higher levels. In this latter context it is analogous to

'attention'—a familiar capacity to attend to certain stimuli and disregard others. These interactions are based on excitatory and inhibitory synapses playing against each other on individual neurones and, therefore are accessible to pharmacological manipulation, although this has been little exploited in

relation to cutaneous touch.

Recent studies in man. In the past there was considerable controversy about the cutaneous Page 780

sensory mechanisms, including the existence and function of cutaneous receptors. Although experimental evidence from animal studies leads to the conclusion that the general rules of specificity operate, it has only recently become possible to provide direct evidence from studies on conscious man. When a thin insulated tungsten wire electrode is inserted through the human skin and into a peripheral nerve it can, by suitable adjustment, record the impulses in a single axon coming from a cutaneous mechanoreceptor. This technique has been applied most rigorously to analyse cutaneous receptors in the hand, by recording from the median nerve in the arm. Four principal kinds of mechanoreceptor, with myelinated axons, exist in human glabrous skin, corresponding to: Pacinian corpuscles, Meissner's corpuscles, Sa I (Merkel receptors), and Sa II (Ruffini endings). The general characteristics of the receptors closely match those already well known from animal studies. The sensory function of the receptors was assessed by comparing the subject's report of his sensations with the responses of individual afferent fibres recorded at the same time. Criticism of this approach has been directed at the likelihood that a mechanical stimulus, even though controlled with great precision, could excite other receptors in addition to the one recorded from electrically, so that a one-to-one correspondence of sensation and unit receptor activity would be difficult to assert. In a refinement of the technique, electrical stimulation through the recording electrode was used as a means of precise excitation of a single, functionally identified, sensory axon. The exciting, and fundamentally important, result of this approach has been to establish in a quite convincing way, that the different kinds of receptor can indeed cause perceptually distinct sensation. Thus, the Pacinian corpuscle receptors caused a sense of tickling or vibration when stimulated at frequencies above 2050 hertz, with a sensation of vibration related to the actual frequency of stimulation. Meissner corpuscles (Fa I) evoked a sense of tapping, flutter, buzzing, or vibration (related to the frequency of stimulation) that did not change its sensory quality if the stimulation continued for several seconds. Sa I (Merkel receptor) units did not evoke a sensation if only two or three electrically induced impulses were evoked at frequencies of 510 hertz, and for larger numbers of impulses at higher frequencies they evoked a sense of sustained pressure or sustained contact, lacking either the vibratory or tapping quality of the Pacinian and Meissner units. In contrast, activity in Sa II units did not give rise to any sensation, and so may be more concerned with muscle reflexes and proprioception which are not in consciousness.

These results brilliantly confirm the suggestions coming from the correlative studies in man and make possible the restatement of Muller's now ancient Law of Specific Nerve Energies. As originally stated, this asserted that excitation of a sense organ, by whatever means, always gave rise to the same modality of sensation, whether—

in the case of, say, vision—the stimulus was the normal one of light acting on the retina or was an abnormal one, such as pressure on the eyeball. In late nineteenth-century elaborations, the Law came to be restated as asserting that every kind of sensation required its own kind of nerve fibre, and that each kind of nerve fibre with its end organ had a 'specific energy', giving rise to a certain definite sensation and no other. The experimental results cited above give credence to Muller's original proposal—

namely, that a given kind of receptor or its nerve fibre, when excited by whatever means, gives rise to a certain sensation. The sensation resulting from the simultaneous excitation of several kinds of receptor, such as mechanoreceptors and thermoreceptors, can, however, yield a sensation that arises from central interactions among the sensory inflow.

A further consequence of this new work is that the old controversy between 'specificity' and 'pattern' theories of cutaneous sensation has been resolved in favour of the 'specificity' theory.

Relation to other skin senses. This review of the 'tactile' sensory system has concentrated on the sensory receptors because it is in that area of knowledge that dramatic progress has been made in the last two decades, with the resolution of the longstanding controversy about the nature and role of the sensory receptors. Two other cutaneous sensory systems that coexist with the tactile system provide specific information about nociception (painful stimuli) and thermoreception (temperature sensation). Each is served by its own set of specific sensory receptors. The central processing of sensory information from these receptors is by the indirect route through the dorsal horn of the spinal cord. The three systems, tactile, nociceptive and thermal, do however interact. A striking example is the reduction in pain that can, in appropriate conditions, be achieved by the concurrent application of a tactile stimulus and a noxious stimulus. A familiar instance is provided by the instinctive act of rubbing a sore place on the skin. Rubbing or stroking excites sensitive tactile receptors that interact on neurones in the spinal cord with an inflow from the nociceptors and block or reduce the excitatory action of the latter. TENS (transcutaneous electrical nerve stimulation) is a method of pain relief, now in clinical use, that is based on this interaction.

TRANSFER. This essential concept for appreciating learning concerns the benefit of, or impair

Page 781

ment from, what has been learned on later performance. Where there is resulting improvement, transfer from the past experience is *positive*; when impairment, the transfer is *negative*. The same learned knowledge or components of skill may transfer to be helpful (Positive) in some situations, but may impair (be negative transfer) in other situations, or for some other skills. Thus transfer from practising table tennis may impair one's ability to hit a tennis ball with the appropriate arm movements.

To understand the concept, it is important to note that the neural mechanisms for positive and negative transfer are exactly the same: the only difference is whether what has transferred is useful or not.

Transfer tends to be thought of in general terms, rather than for particular items of knowledge. Thus the skill of learning Latin is generally supposed to transfer positively to the learning of other languages, although it may transfer negatively to differently constructed languages. A commonly experienced transfer problem occurs when driving in a different country, on the opposite side of the road from that to which one is used. Accidents from negative transfer are particularly likely to occur when starting off in the morning on the wrong side, and when faced with situations such as complicated crossings. It is remarkable that complete reversal of accustomed patterns of behaviour is not more difficult than it generally is.

Precisely what it is that transfers, and why it transfers, are far from understood, though these are essential questions for education. They are also extremely important in appreciating the difficulties a pilot may experience in transferring from one type of aircraft to another, and in designing flight simulators to give as much positive transfer in training, with as little negative transfer as possible. There may be features of a simulator (such as horizontal raster lines on a video screen) which allow 'flight' with cues that are not available in actual flying, and which may be dangerous.

It is interesting that perceptual abilities and skills can transfer from one part of the body to other parts. Thus, discrimination of twopoint touch practised on the back of one hand (with a pair of dividers) can transfer to improved twopoint discrimination on the corresponding region of the other hand.

See also TRANSFER OF TRAINING.

TRANSPERENCE. A patient in psychotherapy tends to transfer into his relationship with the therapist the sometimes intense feelings he experienced at an earlier stage in his life, in his relationship with his mother or father or other important figure. The formation of a transference relationship thus facilitates the overcoming of resistances to the recall of painful experiences from his past. The transference relationship (entirely different from*transfer above) is said to be positive if the patient is compliant, negative if he is defiant. The formation of a positive relationship may by itself relieve symptoms, but this is no more than a false 'transference cure'. If it is strong and persistent, and the patient becomes dependent on the therapist, the relationship amounts to a 'transference neurosis'. By 'countertransference' is meant the transfer by the therapist of feelings derived from his past into his relationship with the patient: such feelings have to be recognized and overcome.

Sigmund*Freud described transference in 1895 in one of his first papers on psychoanalysis. Seeing the trouble that was caused to his colleague, Josef*Breuer, when he became the object of the erotic feelings of his patient 'Anna O.', he argued that these feelings referred not to his colleague personally but to a fantasy figure. He was later to encourage the development of fantasy about the therapist by his habit of sitting unseen behind the patient lying on a couch. The therapist thus becomes a blank screen on to which the patient projects his feelings. However, the emphasis in psychoanalytic treatment gradually moved from the analysis of dreams (see FREUD ON

DREAMS) and the overcoming of resistances to the opening up of communication between therapist and patient through the analysis and elucidation of the transference relationship. This was the main therapeutic tool of psychoanalysis, and its hallmark, during the years between the wars. The transference relationship is an inevitable necessity, Freud argued. Psychoanalysis does not create it. It brings it to light so that it can be combated at the appropriate time. It has to be dissolved before treatment ends so that the patient can reassert his independence and resume an adult role. Dissolution proves difficult in some cases.

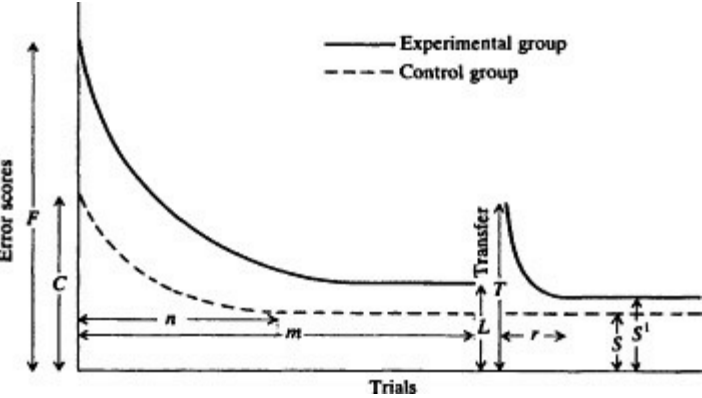

Schools of psychotherapy differ in the balance they seek to achieve between the advantages and disadvantages of the transference relationship. (See FREUDIANISM: LATER DEVELOPMENTS.) Some modern schools counteract the tendency from the beginning and regard the reenactment of the conflicts of the past within the relationship with the therapist as inessential. More important is what happens in the patient's relationships with members of his family and others. The relationship with the therapist is then regarded as mediating, and interpretations are concerned with the difficulties the patient experiences outside the treatment sessions, or in his relationships with others in a therapeutic group.

TRANSFER OF TRAINING. It is often evident in*transfer situations that a very considerable amount of learning has been carried from one task to another. For both theoretical and for practical

$$a = \frac{(n-r)}{n} \quad (1)$$
$$b = \frac{(F-T)}{(F-S)} \quad (2)$$

Fig. 1.

Curves showing form of typical transfer experiment.

reasons, it is desirable to be able to measure the amount of this transfer.

Let us consider a typical transfer experiment or situation. An experimental group of subjects learns some task or skill A. Initially, as we might expect, their errors are many; but after some time, or number of trials, they reach a satisfactory and stable level of performance characterized by few errors. They then attempt some new task B; and again proceed, more or less rapidly, from making many errors to making only a few. (The mean performance of this group is shown, smoothed for the sake of argument, as the continuous line in Fig. 1, whose notation will henceforth be used.) A control group has learned task B *ab initio* (dashed line in figure), and it is generally the case that the final error levels of performance of the two groups (S and S') are virtually indistinguishable—and may, indeed, be zero.

All the quantities labelled in the figure can be measured. F , C , L , T , S , and S' are all measures of performance in terms of error; while m , n , and r are either numbers of trials or elapsed time. Since all these are available, it is natural to ask how they may best be used and combined to express the amount of learning transferred by the experimental group from task A to task B.

The number of expressions and formulae that has been proposed is very large (Gagne et al., 1948; Murdock, 1957); but they all fall into one of two categories: there are those which measure the saving of training time, or number of trials (i.e. which in some way compare r with n), and those which are concerned with the initial performance of subjects immediately after transfer (i.e. which evaluate T). The former class we may call *savings* measures; the latter we may call *firstshot* measures.

Unfortunately, although the contrary was often tacitly assumed, these two classes of measures can give sharply contrasting impressions; for it is quite possible to save a great deal of training time on the second task ($r \ll n$) while still finding a marked transient decremental effect of transfer ($T > C$) (Hammerton, 1967; Hammerton and Tickner, 1967). The measure selected must answer the question the user wishes to put; and he must always be aware that it may not answer any other question.

The simplest question is: What proportion of training time in task B is saved by prior training on task A? This is clearly and straightforwardly measured by the quantity a , given by:

It is worth pausing to note how difficult it is to apply even the simplest psychological findings in a practical situation. Suppose someone was being trained to use some complex industrial equipment (task B) by practice on a simulator (task A). The proportional saving of time is given by (1); but in practice the following questions arise: What is the running cost per hour of the simulator as compared to that of the real equipment? Does even a poor operator of the real equipment produce some useful output which can be set against cost? Is he, on the other hand, likely merely to waste raw materials or damage the equipment itself? Evidently the practical utility of a training programme or device cannot be measured by any simple expression, but is a complex psychological and economic question.

If we recall that there is often a brief but marked impairment in performance immediately after transfer, it will be evident that there are many practical situations in which some measure of firstshot transfer is necessary. Again, more than one question may be asked about this. One is: How does the

learning immediately after transfer compare with that required by the control group to reach a stable performance? This comparison may be given by: But a user may raise a practical objection to this;

$$c = 100(1-T/S) \quad (3)$$

$$d = (F-T)/(F-L) \quad (4)$$

$$e = (C-T)/(C-S) \quad (5)$$

Page 783

for he may not be concerned with the comparative measurement of learning, however interesting that may be theoretically. He generally needs to know whether expensive equipment is liable to be misused when first handled: in other words, how does firstshot transfer performance (T) compare with the stable performance of the control group (S)? The information required may be given as a simple percentage: Another question which can arise in practice is this. Suppose that you have no control group—i.e. suppose that all trainees start on some simulator device, and that no man is allowed to begin with task B. How much of the skill acquired with the simulator (A) will be retained upon first transfer? This is not the question answered either by (2) or by (3) above, and it is more precisely answered by:

However, in pursuit of understanding, a quite different question may be put, namely: How does the learning shown by the firstshot performance of the experimental group compare with that acquired by the control group? A measure for this is:

It is by no means claimed that the expressions given here are the only, or necessarily the best, answers to the questions discussed; and certainly many other questions can be put, of both theoretical and economic significance. As we have shown, it is important to be clear about what question is being asked, and especially important to be clear about the extent and limitations of the information obtained from the answer. For example, an answer to a question on saving of training time—such as (1)—gives no information at all about firstshot performance: the one may be excellent and the other deplorable. In one particular case (Hammerton and Tickner, 1967) the several expressions given here yielded values (rendered as percentages) from 92 to *minus* 54. If any one had been taken as 'the' measure of transfer, the oversimple question 'How much learning was transferred?' could have received any answer in the range from 'almost all' to 'less than none'.

Evidently there is no such thing as 'the' measure of transfer; but if a specific question concerning transfer is precisely formulated, expressions exist for answering it, and a useful and informative numerical measure can be obtained.

TRUTH. There are three main epistemological theories: *correspondence*, that a proposition is true when it corresponds to some kind of reality; *coherence*, that propositions are true when they cohere to form a consistent body of what is taken to be knowledge; and *pragmatism* (or pragmaticism), that propositions are true when useful. Undoubtedly coherence and usefulness are very generally accepted *criteria* for truth; but they are not normally what is *meant* by 'truth'. Some kind of correspondence is what is meant; but it is ultimately impossible to observe correspondences between appearance and reality. It would require a kind of God's-eye view to see that the observations of a man, or the understanding of science, correspond to the world. So, although what we generally mean by 'truth' is correspondence with reality, correspondence is not, ultimately, an available criterion for truth.

Most empiricists have supposed that propositions can be individually tested for truth, by suitable observation or experiment. This is a tenet of 'logical atomism'. But the now current view is, rather, that not all can be tested at all directly and that perceptions, observations, and experiments require assumptions (which may be hidden) in order for us to interpret them. The American philosopher Thomas Kuhn (1962) has put forward the highly influential notion of scientific*paradigms: that there are accepted, though often implicit, assumptions in all 'normal' sciences. For example,*Darwinian natural selection is, or sets, a paradigm for current biology.*Newton's and Einstein's accounts are paradigms for physics and cosmology. One of the problems of modern psychology is the difficulty of making explicit the ruling paradigms and assumptions in terms of which its daytoday experiments are assessed and interpreted. Where these assumptions are regarded as*'common sense', they may in fact reflect the philosophical and scientific presuppositions of previous centuries, which may change with changes of assumptions or paradigms. But only God knows what the next paradigm will be.

TURING, ALAN MATHISON (191254). British mathematician, born in London, and educated at King's College, Cambridge, graduating in mathematics. He was the key figure in the conception of electronic digital computers and*artificial intelligence (AI), the only other contender being the brilliant American mathematician John*Von Neumann. Working almost entirely independently, they set the stage and wrote the script for the computer revolution; and concepts of mind in Page 784

terms of artificial intelligence are based on the technology of the electronic digital computer, of which they were the principal inventors.

Turing made a fundamental contribution, shortly after graduating, with his paper 'On computable numbers with an application to the Entscheidungsproblem' (1937). In this he showed that there are

classes of mathematical problems that cannot be proved by any fixed definite process or heuristic procedures. At the same time he proposed an automatic problemsolving machine that is the starting point of philosophies, and practical hopes, of digital computerbased AI. The Turing machine, as it is now called, is abstract in the sense that its description defines all possible operations though not all may be realizable in practice. Although the notion in its original form is clumsy, it encapsulates the essentials of modern digital computers.

The Turing machine can be visualized as an indefinitely long tape of squares on which are numbers, or a square may be blank. The machine reads one square at a time, and it can move the tape to read other squares, forwards or backwards. It can print new symbols, or erase symbols. Turing showed that his very simple machine (which had as its ancestor Charles*Babbage's 'analytical engine' of the 1830s) can specify the steps required for the solution of any problem that can be solved by instructions, explicitly stated rules, or procedures.

Turing considered whether a human being, or rather the human mind, can be described by analogy with such a machine, or can be simulated by one with appropriate programs. The essential idea, which he was among the first to see clearly, is that the physical construction of the machine is unimportant. Turing pointed out that Babbage's computer was mechanical, and though in the twentieth century electricity could be used, as faster and more reliable, it mattered nothing whether a computer was mechanical, electrical, or worked in any other way provided it could carry out the necessary instructions. It is a short step from this to saying that the biological material of the brain, protoplasm, or the way in which the brain is constructed, is not particularly important for intelligence or perhaps for anything else. If we were constructed differently we would in some ways be different; but we might still be intelligent, perceiving, conscious beings.

Turing suggested how we could recognize whether a simulation of the human mind had succeeded or failed. His paper, 'Computing machinery and intelligence' (1950) remains the clearest short account of the philosophy of artificial intelligence, as it came to be called, and 'Turing's test' for judging the adequacy of a simulation of mind remains the best criterion for recognizing intelligence in a machine. The 'test' is the Imitation Game, which Turing describes in these words: 'It is played with three people, a man (*A*), a woman (*B*), and an interrogator (*C*), who may be of either sex. The interrogator stays in a room apart from the other two. The object of the game for the interrogator is to determine which of the other two is the man and which the woman.' The interrogator is allowed to put questions to *A* and *B*, though not of physical characteristics such as length of hair, and he is not allowed to hear their voices. He is allowed to experience or question only *mental* attributes. The next step of the game is to substitute a machine for one of the humans. The machine communicates with a teletype. The question is whether the interrogator can distinguish the remaining human from the machine. Turing points out that for some questions, such as problems in arithmetic, the humans would show up revealingly poorly, and that this is perhaps an objection to the test; but it seems as good a test as any so far suggested for distinguishing between man and intelligent machines. It is of course behaviouristic; but, as Turing says, we cannot 'get inside' another human being, to know directly whether he or she has conscious experience, such as sensations of colour and emotional state. He leaves it open whether we should assume that the machine which passes the test of the Imitation Game is conscious.

Alan Turing was the master code breaker who succeeded in reading the German highestlevel secret codes during the Second World War. This was not revealed until thirty years after the war, when his true importance as the originator of the first practical programmed computer—the Colossus (electronic cryptanalytic machine)—

which, with human intelligence and a good deal of luck, broke the German codes and showed just how powerful informationhandling machines can be. He died tragically at the height of his remarkable powers, as mathematician, biologist, and supreme creative philosopher of computing by machine and brain.

Page 785

U

UNCONSCIOUS, THE. According to Sigmund*Freud a large part of the mind is unconscious—though essentially similar to the conscious mind in having wishes and fears and so on. This Freudian theory is very different from the notion which forms a part of many, more recent psychological theories, that the brain processes accept and analyse information unconsciously, as one might expect of a computer—lack of*consciousness is not the same as the unconscious.

Opinion is probably moving away from the Freudian view, to something closer to this*artificial intelligence notion that unconscious processing is basic to behaviour.

This view, however, is not that of extreme*behaviourism, which claims that there is no consciousness whatever.

The notion of unconscious inference was developed by Hermann von*Helmholtz, when he considered perception as given by inferences ('Unconscious Inferences') from features of the world as signalled by the senses. This gave rise to a very complex historical controversy, with Helmholtz and Freud as major figures, which even now has not been resolved in detail. At the time, the Helmholtz view was highly unpopular, as it was considered that inference requires consciousness, and this argument was associated with the moral position that consciousness is required for ethical judgement. So the notion

of unconscious inference threatened morality and justification of praise, blame, and punishment.

See CONSCIOUSNESS AND CAUSALITY.

R.L.G.

UNIVERSALS. We experience particulars but not universals. Thus we *see* a *particular* triangle, but geometry depends upon generalized concepts of

'triangularity'—which is never seen by the senses. Universals are mental constructs based on inductive inference or hypotheses from the experience of particulars. They are essential for explanation.

UTILITARIANISM. See BENTHAM, JEREMY; MILL, JOHN STUART.

VERSTEHEN. This German term means 'to understand'. A *Verstehen* approach to the study of human beings is any which assumes that the enquiry cannot be modelled on natural science: any 'nonscientistic' approach, to use another term in common employment. Nineteenth-century German opponents of scientism often expressed their claim in the assertion that making sense of human beings was a matter of *Verstehen*, that making sense of natural things was one of *Erklären*, and that the two operations were fundamentally distinct.

The *Verstehen* tradition is often traced to the work of the Italian thinker Giambattista Vico (1668–1744). He countered Descartes's emphasis on the certainty available in the natural sciences with his *verum factum* principle, according to which the true—what we can know for certain—is coextensive with the made—what we have ourselves created. The idea was that we are in a better position to understand human actions, artefacts, and institutions, the products of the mind, than we are to grasp material phenomena that are not of our making. Whether or not through Vico's influence, this idea was an important component in the German Romantic movement at the beginning of the nineteenth century, and was taken up in the thought of Wilhelm Dilthey (1833–1911), the influential philosopher of history. Through Dilthey it passed on to the sociologist Max Weber (1864–1920) and since his time it has been a staple discussion topic among practitioners and philosophers of social science.

In the twentieth century the dominant expression of the scientistic approach to the study of human beings has been logical positivism. Positivist methodology, which derives from the work of the Vienna Circle in the 1920s, lays great stress on the unity of method across respectable cognitive disciplines, and it insists that so far as the understanding of people is respectable, the method followed must be the same as in natural science. *Verstehen* theorists have had to argue against this

that the positivist characterization of explanation does not apply in the human case, and in particular that it does not fit explanations of action. Positivists have been prepared to concede that in thinking up explanations for action we can rely on clues not available in the nonhuman case, and the issue has been whether we also have some special aids at our disposal for corroborating those explanations (see Abel, 1948).

Putting aside the lineaments of the antipositivist debate, and also the details of the earlier tradition, we can say that there are two claims which distinguish any *Verstehen* position. The first, a thesis as often assumed as it is argued, says that our common fashion of explaining what we each say and do is an indispensable explanatory practice. More exactly, the idea is that the working conception of agents which guides us in our interpretation of one another's actions cannot be displaced by a different approach. The conception is identified by its essentially mentalistic concepts, such as those of intention, desire, decision, perception, judgement, and belief. What is supposed is that such concepts cannot be discarded without emasculating the understanding of human beings.

This indispensability thesis is not an easy one to defend. Perhaps the most natural line for the *Verstehen* theorist to argue is that our working conception of agents is tied to the interactive attitude which we adopt *visà-vis* one another, and that it is as entrenched as that attitude. (For other lines, see MacDonald and Pettit, 1981, ch.

2.) The tie to the interactive attitude is easy enough to argue: when we interact we project the responses of the other person, through assuming that he forms mental states on much the pattern that we do, through assuming that he takes us to form mental states on the same pattern, and so on through an indefinite series of mutual replications. It is arguable that such accommodation towards one another is essentially linked with the application of the loose conception of agents embodied in our everyday explanatory practice (see Pettit, 1978, part 2).

But if we grant this link, we still have to argue that the interactive attitude is indispensable; otherwise the indispensability of the associated conception will not have been established. Could we think of giving up this attitude in favour of something like the interventionist disposition that we normally adopt towards natural systems? Some have argued that we could not, short of contemplating a total transformation of our sensibility, and a morally repugnant transformation at that (see Strawson, 1962).

Others have argued a similar line from the following sort of consideration. Suppose that we are playing chess with a computer. We are in a position to give up treating the computer in the ordinary halfinteractive way, wondering what it is up to and what it thinks that we are up to; if we wish, we may adopt the viewpoint of the electronics engineer and attempt to predict its every move for certain. The situation is much as it might

be with a human being, if we could have recourse to a thorough neurophysiology (or even behaviouristic theory) which would allow us to predict every action of a colleague (see Dennett, 1973). With the computer we would not normally give up the interactive stance, at least so long as our interest was in the game of chess, and the suggested moral is that even if there were a theory available which permitted an interventionist attitude towards human beings, in most instances this would not

displace the regular interactive disposition. The reason is that just as the interventionist attitude towards the computer would make chess impossible, so it would undermine important interpersonal exchanges if we adopted it towards people (see Habermas, 1972, appendix).

The second claim, which anyone espousing a *Verstehen* position must embrace, is a distinctiveness thesis: a claim to the effect that our working conception of agents is not only indispensable but distinctive. Specifically, the thesis is that the conception is distinguished by the fact of not allowing the sort of amendment and development which characterizes scientific theory. Unless such a proposition is written into the *Verstehen* charter, the position will be indiscernible from that of enthusiasts for decision theory and game theory, who acknowledge that their preferred approach derives from our everyday conception of agents, but who think that this startingpoint will soon be a distant memory.

There are many ways in which the distinctiveness thesis may be argued, and they make for different versions of the *Verstehen* view. One, and it is the most traditional, is to say that people have a special noninferential access to the human mind, whether in introspection or empathy, and that this intuitive base gives our working conception of agents the required distinctiveness (see Outhwaite, 1974). Another, deriving mainly from the later work of Ludwig*Wittgenstein, says that applying the everyday conception in explaining what agents do and say is not a matter of hypothesizing mental causes, but one of redescribing the actions in a manner which makes them unproblematic, and that a descriptive conceptual framework is naturally less malleable than an explanatory scientific theory (see Melden, 1961). Recent developments in hermeneutics and semantics have generated further arguments for the distinctiveness of our working conception of agents. On the hermeneutic side it has been argued that in explaining human action we cannot rely on theoryindependent data for arguing our preferred interpretation, and that this looseness makes our conception of agents immune to the ordinary pressures of theory refinement (see Taylor, 1971). On the semantic side it has been claimed that such immunity comes from the necessity of assuming a minimum of rationality in accounting for what is taken to be properly human action; the assumption of such rationality, it is said, militates against the possibility that our conception of agents could be radically transformed (see MacDonald and Pettit, 1981, ch. 2).

Any of these arguments, if successful, would suggest that the corroboration of action explanation is different from the corroboration available in the explanation of the natural event: this is the point which *Verstehen* theorists sought to establish against positivism. More generally, any would combine with the argument for the indispensability of our working conception of agents and return us to the point of view of something like Vico's *verum factum* principle. It would leave us secure in the humanistic assumption that where the material world has readily submitted itself to the yoke of scientific theory, the mental will prove in some respects to be resistant and recalcitrant. Whether this assumption is reasonable depends on whether any of the arguments is valid, and this question will be with us for some time.

VISION: THE EARLY WARNING SYSTEM. It is only recently that demands on sophisticated electronics and computing systems have become as severe as those with which our sensory systems must cope. It is interesting to see whether, say, our visual processes and radar systems evolved in similar ways. Radar engineers a generation or so ago became aware that the requirements of early warning of approaching targets are very different from their detailed identification and tracking at close range. The first demanded the rapid detection of many targets appearing simultaneously in a vast space, rather than pinpointing. The second demanded the ability to zoom in on a selected target with great precision and follow it continuously. So it is with the visual system. There are two distinct processes involved: a preattentive one for the almost instantaneous detection of textural changes in our environment that indicate the occurrence of objects, and an attentive, serial one that can shift focal attention to any of the objects detected by the preattentive process. The preattentive process can detect textural changes in a brief flash (less than 150

milliseconds) throughout

inspected with focal attention.

Limits of global (statistical) processing in texture discrimination. Discriminable texture pairs in real life seem to differ both in their local elements and in their global properties. Figs. 1a and 1b show discriminable texture pairs that differ in their local elements: in Fig. 1a the elements are of different sizes, whereas in Fig. 1b the orientation differs. Moreover, one can also demonstrate texture discrimination in their global properties: in Fig. 1a the firstorder statistics are different in the two textures, whereas in Fig. 1b the firstorder statistics agree but the secondorder statistics are different.

What do we mean by first and secondorder statistics? If we randomly throw confetti on a texture of different colours and count the frequencies with which the dots fall on certain colours (black, grey, white, red, etc.), a firstorder statistic is obtained. If we randomly throw needles (their endpoints having certain length and orientation) and count the frequencies that they fall on certain colour combinations (for example, both on black, or one on white, the other on black, etc.), we obtain a secondorder statistic. If a triangle is randomly thrown on a texture, and we count the frequencies that the three vertices of this triangle fall on certain colour combinations, a thirdorder statistic is obtained. Of course, all possible triangles in all possible orientations have to be tried in order to obtain the full thirdorder statistic. Finally, the throwing of n gons at random on a texture, and summing the frequencies that the n vertices of the n gons land on certain colours, yields the n thorder statistic. Thus the firstorder (confetti) statistics differ for the two textures in Fig. 1a, while for the two textures in Fig. 1b their firstorder statistics are identical, though their secondorder (needle) statistics differ.

These examples are typical of naturally occurring textures. Since the discriminable texture pairs differ globally in their first or secondorder statistics, it is impossible to assess the role played by *local* differences in element features, as opposed to that played by *global* differences in their statistics. In order to separate local from global influences, a research paradigm was proposed in 1962 to generate and study texture pairs with identical second(hence also first) order statistics, but different third

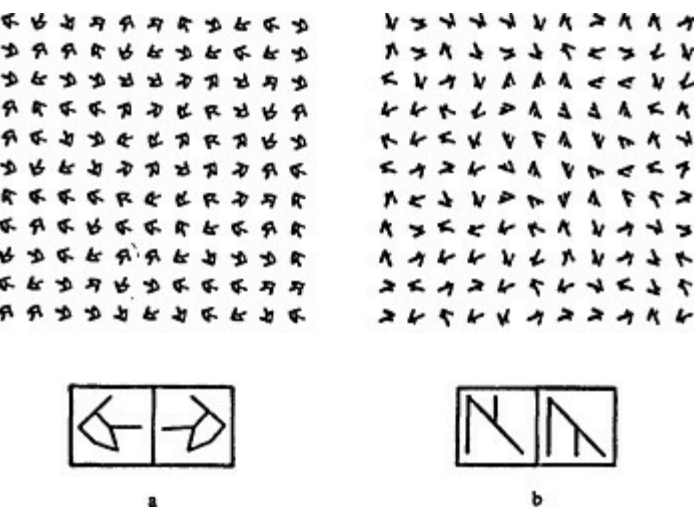

and higherorder statistics (Julesz, 1962). In the years since then, many such isosecondorder texture classes have been discovered, and many of these texture pairs are indistinguishable, in spite of the fact that their elements in isolation are easily told apart. A typical indistinguishable texture pair with identical secondorder statistics is shown in Fig. 2a, generated by a method of Julesz et al. (1973).

The texture pair in Fig. 2a is presented outside the region of foveal attention (such that the boundaries between the texture pair are 12 degrees of arc outside of fixation) for a brief flash (under 150 milliseconds, to prevent scanning eyemovements) followed by an erasing field (to prevent shifting focal attention to various areas of an afterimage). The texture pair appears indistinguishable, but a squareshaped area in Fig. 2a is composed of R s while its neighbourhood is composed of mirrorimage R s. Any texture pair composed of randomly thrown identical micropatterns (in all possible orientations and without overlap) has the same secondorder, but different third or higherorder statistics as a texture generated in similar ways, though without throwing the mirrorimage of the original micropattern.

Another almost indistinguishable texture pair with identical second but different third and higher order statistics is shown in Fig. 2b. This texture pair appears indistinguishable in spite of the fact that the elements by themselves look very different. When they are presented a few degrees of arc left and right from the centre of fixation point, for 150 milliseconds with erasure, they can easily be told apart. These experiments, and many others that yield indistinguishable isosecond order textures, clear

Fig. 1.

Preattentively distinguishable texture pairs (a) with different first order statistics and difference in element size; (b) with different second order statistics and different element orientation.

Page 789

Fig. 2.

Preattentively indistinguishable texture pairs with identical second order statistics but different third and higher order statistics:

(a) composed of randomly thrown and not overlapping similar micropatterns and their mirrorimages, respectively; (b) composed of dual micropatterns that have the same line segment length and width; the number of their terminators (endpoints) also agrees.

ly suggest that preattentive texture discrimination cannot utilize third and higher order statistical parameters. So, if discriminable textures with identical second order statistics are to be found, their discrimination can be based not on global processing but rather on the local processing of some conspicuous local features. We will call these conspicuous local features 'textons', and will show that they are limited to only a few, perhaps only three, kinds (Julesz, 1980).

Textons, the basic units of texture perception. In 1978 several isosecondorder texture classes were found that yielded strong discrimination (Caelli and Julesz, 1978; Caelli et al., 1978; Julesz et al., 1978). In Figs. 3a and 3b two such examples are demonstrated. In Fig. 3a the fourdot micropatterns in one texture are quasicollinear, whereas their fourdot partners in the other texture are not. The texture pair of Fig. 3a is strongly discriminable, so the local conspicuous feature of quasicollinear structures—and *elongated blobs* in general—prove to be of a texton class. In Fig. 3b the left and right areas

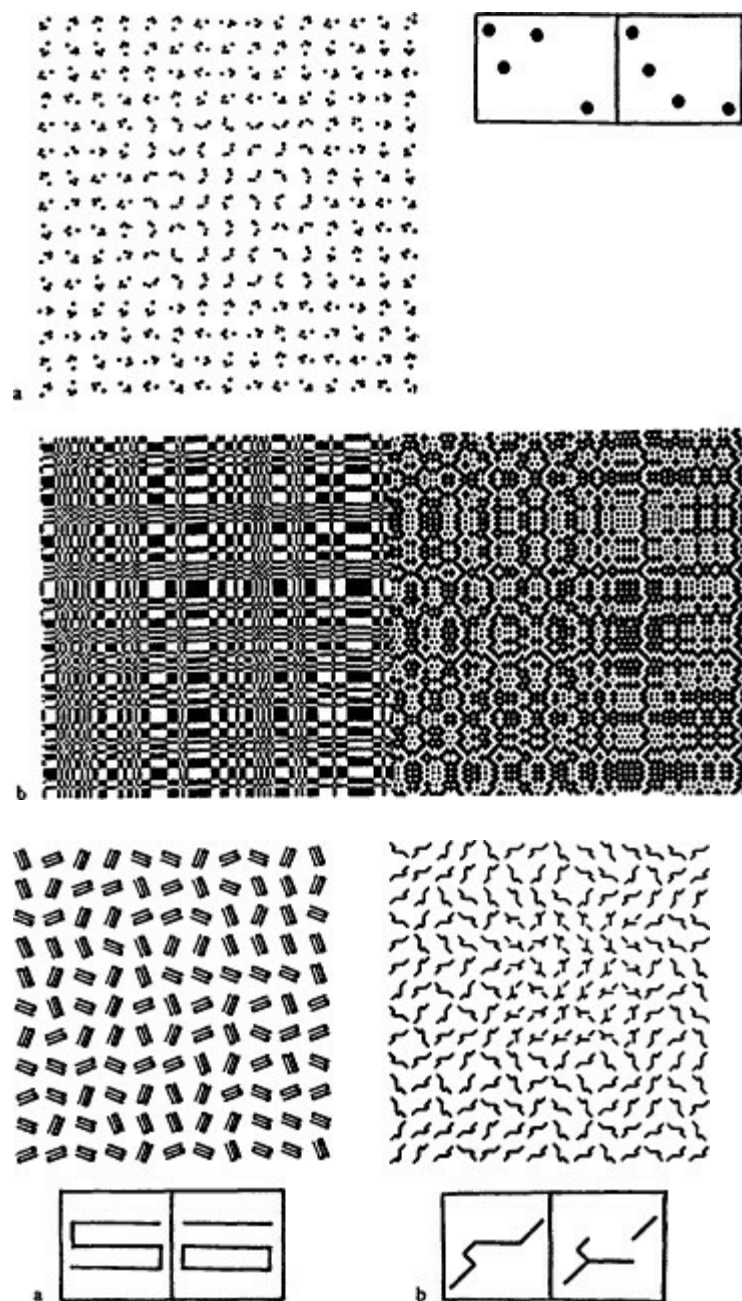

have identical thirdorder statistics (hence identical second and firstorder statistics), and strong discrimination is again due to elongated blob textons that have different width and orientation in the two textures.

It was believed for a while that corner, closure, and connectivity might also be different texton classes. However, as shown by Julesz (1980), if one generates texture pairs in which the dual elements are either connected open line segments, or disconnected closed ones (Fig. 4a, inserts), the texture pair formed by these elements is indistinguishable. It seems that if the elongated blobs (line segments) agree and the *terminators* (*endpoints*) of these elongated blobs (line segments) total the same number, as in Fig. 4a, no texture discrimination can be experienced. That the difference in number of terminators is a crucial parameter is shown in the strongly discriminable texture pair of Fig. 4b, where one of the texture elements contains two terminators while its dual contains five, and this terminator difference of three yields strong texture discrimination. This contrasts with Fig. 2b, where the dual elements have the same number of terminators, and these isosecondorder textures are indistinguishable.

In addition to elongated blobs (particularly line segments) of given colour, width, orientation, and length and their terminators, the third texton class is their crossings.

Whether some additional textons will be found remains to be seen.

Only the firstorder statistics of textons are used in texture perception. So long as the number of terminals remains identical, whether the small line segments in Fig. 4a form an Sshaped or 10shaped micropattern passes unnoticed in preattentive texture perception. Thus it seems that only the differences between firstorder statistics of textons (perhaps only their density gradients) are computed by the textural system; the preattentive process is unable to compute even secondorder statistical parameters (Julesz, 1981)—a conclusion that can be derived from Fig. 5a. Here the top image shows a 4×4 micropattern of eight black and eight white dots, repeated periodically at eightdot intervals both horizontally and vertically. The gaps between these periodic patterns are filled with grey (a chequerboard screen) in the left bottom array, and the whole is flanked by randomdot regions. In the right array, the gaps in the same

Page 790

Fig. 3.

Preattentively distinguishable texture pairs based on local conspicuous features of (a) elongated blobs (here quasicollinear discs) that are absent in the isosecondorder dual texture; (b) elongated blobs of different width, length, and orientation, in spite of the fact that both halffields have identical thirdorder (and hence identical second and firstorder) statistics.

Fig. 4.

Demonstration of the importance of the second texton class, the

terminators (endpoints) of elongated blobs (line segments).

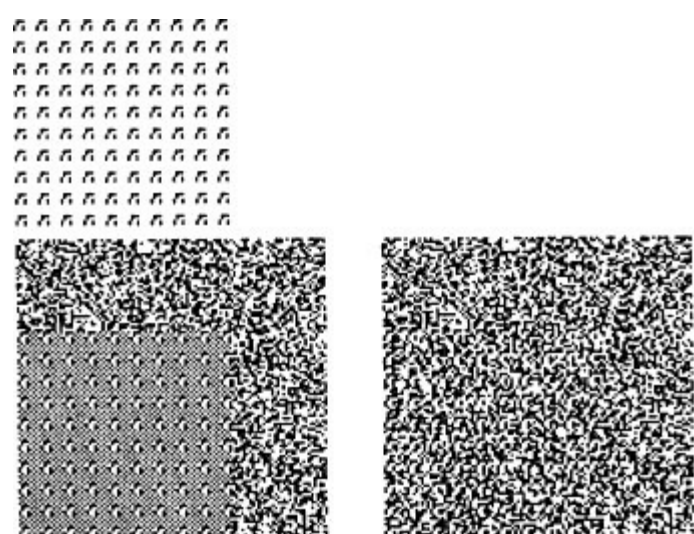

a. Since the number of terminators (two) is the same in each texture,

the textures are indistinguishable, in spite of the fact that one

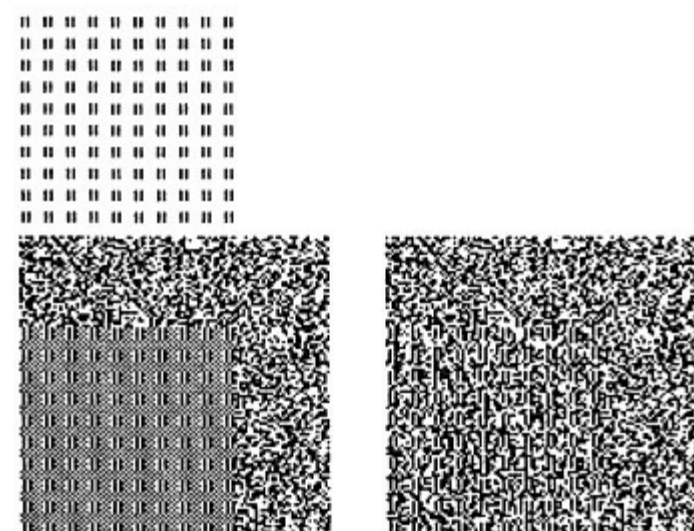

contains openconnected and the other closedunconnected elements.

b. In this pair of identical secondorder statistics, the number of

terminators differs, and hence the textures are strongly discriminable.

a

b

globally differences in secondorder statistics, and only first

order statistical differences in textons yield texture discrimination.

a. Periodically repeated 4×4 dot micropattern that does not contain

textons, flanked by randomly dotted areas. The blank fourdotwide

columns and rows between the periodic micropatterns are filled in

by a chequerboard screen in the lower left half, and by random dots

in the right half. No texture discrimination is obtained. b. Similar to

a except that the 4×4 repeated micropatterns are textonrich.

Texture discrimination is now strong. The autocorrelation difference

is the same between the periodic areas and their random neighbours

in a and b; therefore the textural system cannot detect differences

in autocorrelation (a secondorder statistical parameter), only

differences in the density of textons.

periodic region are filled with randomly selected black and white dots, rendering the periodicity invisible. Although the autocorrelation (a secondorder statistical parameter that for black and white patterns is the secondorder statistics) has periodic peaks at eightdot intervals in the periodic array, while no such periodicity exists in the flanking random regions, the two regions appear equally random. One could argue that perhaps the difference in autocorrelation is too slight for detection.

Page 792

However, in Fig. 5b the same procedure is repeated, except that the periodic 4×4 micropattern is not textonfree, but contains vertical bars and thus is rich in textons. In the right image of Fig. Co the periodic area is distinctly different from its random neighbourhood, although the maximum autocorrelation difference is the same as in Fig. 5a. It is the density difference between textons that yields texture discrimination, and differences in secondorder statistical parameters are not perceived.

The two visual processes. So we have two visual processes. The first, the preattentive process, can inspect a complex texture all over the visual field in parallel, and can detect changes in the kind and density of textons. Only if such changes occur in certain regions does it summon up the attentive, serial process to scrutinize one of these regions by focal pinpointing. Thus the preattentive process acts as an early warning system; for itself it cannot evaluate positional shifts in textons (as long as these shifts do not change the terminator density or yield crossings), although it can look for texton

changes throughout the entire visual field during very brief glimpses. If there is an equilibrium of textons—called ideal camouflage—(as in Figs. 2a, 2b, and 4a), then it is most unlikely that focal attention would notice that certain areas contain elements very different from the rest. Very different texture elements can yield camouflaged textures, as long as the density of their constituent textons agrees.

Work on the texton theory since 1981 has produced further refinements. It has become clear that preattentive texture discrimination operates only if the texture elements are dense, such that the distance between these elements is within about twice the distance of the average element size. The essence of serial scrutiny has also been clarified by presenting patterns very briefly, followed by a masker. It was found that observers could shift a small aperture of focal attention in steps of 2050

milliseconds (almost an order of magnitude faster than scanning eyemovements). Only in this 'searchlight of attention' would the observers know 'what' the textons were and be able to connect them together into shapes. Outside the aperture of focal attention, the preattentive system could only tell 'where' texton gradients occurred but could not connect them. It is this independence between textons that permits them to act as the fundamental elements of the preattentive system.

The preattentive/attentive dichotomy exists only when the texton gradients are high, and the entire visual field can be inspected in parallel. With reduced texton gradients, observers are forced to reduce their visual field to one that can be inspected in parallel in size, hence increasing the coupling between the textons more and more (Bergen and Julesz, 1983). So, there is a continuum between scrutinyfree vision when the textons are independent elements and vision with scrutiny when the textons become more and more connected together, ultimately forming shapes (Gestalten). Obviously when shapes are formed, no perceptual elements exist, and the enigmatic problems of form recognition are encountered.

The texton theory shows many similarities with the trigger features found in the visual cortex of monkeys by neurophysiologists, particularly Hubel and Wiesel (1968).

The preattentive/attentive dichotomy also resembles some theories posed by cognitive psychologists, particularly Anne Treisman (Treisman and Gelade, 1980), and the 'primal sketch' of David Mart (1982), who did his research in the framework of artificial intelligence.

In summary, it was shown that prior to form recognition an important, early visual system exists that can effortlessly locate some conspicuous local feature differences (texton gradients), and in turn can direct the searchlight of attention to these locations. This is in essence how the 'ground' state is segmented into the 'figure' one, if not the fundamental problem of perception.

The second visual process is to inspect regions where the density of textons is different. In so doing, it can perform the prodigious feats of human form recognition.

Whether the fundamental elements of form recognition are some complex combination of textons, or whether they are based on some entirely different constituents, remains to be seen. However, the

finding that preattentive texture perception can be explained by elongated blobs, particularly line segments, their terminators, and their crossings—which in turn are probably the simple and complex cortical units of the neurophysiologist—and that these units are not coupled (only differences in their histograms are taken), might be the first step toward understanding human vision.

VISUAL ADAPTATION. Photographers know that to get a good picture they must have the right light intensity. If the light is too dim the picture will be

'underexposed', a dark scene with only the brightest parts showing detail. If the light is too bright, on the other hand, the picture will be 'overexposed', and detail will again be lacking, swallowed, this time, in a kind of luminous fog. Modern cameras often have an automatic device to regulate the light so that the film receives about the right average light intensity. This is usually achieved by automatic adjustment of the iris stop which controls the intake of light.

It is common experience that our eyes act in the same general way. Without any conscious effort we find that we can appreciate detail over a very great range of light intensities, and indeed the (blue or brown) iris stop of our eyes may be seen to shut down in bright light, leaving the small black entrance pupil of only 2 mm diameter, or in twilight of 10 mm. This mechanism of the iris stop can cause a change in pupil area of 25 times; but since the change in illumination over which the eye can operate well exceeds 10,000 times, it contributes rather little towards it.

Birds that are active by day and go to roost at sundown have a retina very different from night birds. Those that use bright daylight to detect tiny insects and attack ripe, red fruit among green leaves possess good *visual acuity* and colour vision, a faculty often displayed by their coloured plumage. Night birds on the other hand are mainly concerned with distinguishing something from nothing, for at night there is not enough light entering the eye to afford detailed information. The human retina has two types of lightsensitive cells: *cones* that function best in bright light and are essential for acute vision, and *rods* that are necessary for seeing in dim light. (See COLOUR VISION.)

It may be wondered how the eyecamera can manage to handle two types of film at the same time, since a single picture is all that we perceive. The analogy is faulty, of course, for the eye is more like a TV camera. The retinal image is not 'snapped' and fixed as a permanent picture; the living scene is encoded in a moving pattern of nerve signals which are transmitted to the brain for further processing.

Human retinas consist of a mosaic of rods and cones, each receptor having its separate nerve. The assemblage of rod nerves encodes the twilight picture, the cone nerves encode the daylight picture. Rod messages and cone messages coexist all the time and are combined in varying degrees to form one picture whose composition depends upon the level of adaptation. The brighter the light, the more detailed the picture. Thus the dependence of perception upon the level of illumination and the way that contrast is preserved over such an enormous luminance range is chiefly achieved by the

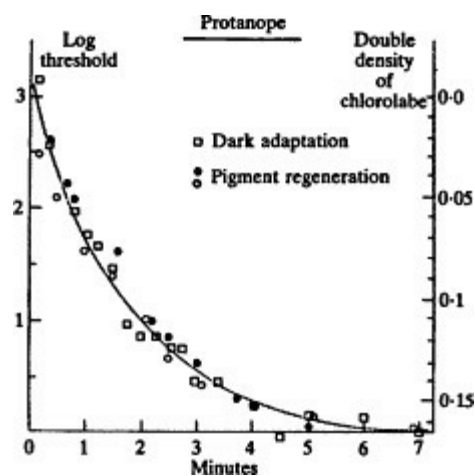

processing of these nerve signals.

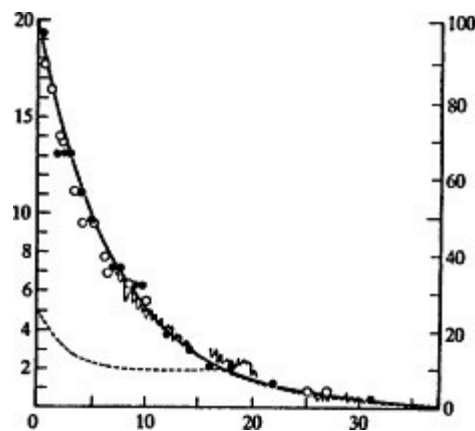

The exact way that this is done, of course, is exceedingly complex. Nerve fibres from the million cones and the hundred million rods of each human retina converge upon about one million fibres of the optic nerve. As Lord*Adrian has said, the 'copy' furnished by these hundredandone million reporters is severely edited and condensed, and only the more dramatic features are telegraphed in code from the retina to the central offices in the brain.

To get a good picture with a photographic camera it is necessary to control the amount of light actually falling on the film. With a TV camera or eye, however, a more flexible control is possible, namely the 'scaling' of the encoded signals. Radio sets possess an *automatic gain control* (AGC) that keeps the sound output at a constant level despite changes in radio input. The AGC in the eye likewise adjusts the encoded signals to about the same average size whatever the brightness of the scene. The retinal image is encoded in terms of contrast (i.e. the brightness of each part compared with the average brightness), a code which has the advantage of being independent of the constantly changing overall brightness level in nature. This intelligible and purposeful adaptation is very different from the way that eyes seem to be temporarily blinded by exposure to a very bright light. The recovery from this state is called *dark adaptation*.

Dark adaptation happens when we go from bright sunlight into a darkened lectureroom or cinema, or leave a brilliantly lit room to walk a dark lane. At first the eye is so insensitive that we can hardly see anything, though improvement rapidly begins. It takes half an hour, however, to reach full darkadapted sensitivity. What is going on that takes all this time for its accomplishment? Are not the nerves very slow in reorganizing themselves? It is chemicals, not nerves, that are responsible for the delay. The sensitive pigments of our retinal film are bleached away by strong light; and we cannot regain full sensitivity until they have been restored by the eye's chemical regenerative process.

The course of recovery in the dark may be measured and displayed as in the curve of Fig. 1. In this experiment the subject looked directly at a

Page 794

Fig. 1.

Foveal dark adaptation curve from a protanope. The subject had only greensensitive cones on the central retinal region where the test flash fell. These had their pigment bleached away by a strong light that was extinguished at zero minutes. At various subsequent times the strength of the test flash, so weak as to be only just visible, was measured. Its logarithm is plotted (scale on the left) by the squares. Black and white circles (two runs) show the amount of green cone pigment present during regeneration (scale on right).

The fact that all the 'points' lie on the same curve means that recovery of sensitivity waits upon the regeneration of pigment.

very bright light, which after a short time was extinguished, and then, in darkness, he transferred his gaze to a repeatedly flashing, weak test light of adjustable intensity.

This was reduced so that the flash was only just perceptible, and the logarithm of this threshold intensity was noted (ordinate in Fig. I with scale to the left); the time since the adapting light was extinguished is plotted horizontally.

The results shown by the squares refer to the recovery of cones, since there are no rods at the fovea, the central fixation point of the retina, where the test flash fell. It is seen that immediately after this strong light adaptation the threshold was 103 (= a thousand times) as high as the fully darkadapted level, reached seven minutes later. By our reflection densitometer it is possible to measure at each moment the amount of visual pigment in the cones. It is plotted by the black and white circles (two

sets of measurements) read by the scale on the right. The adapting light was so strong that initially all the cone pigment had been bleached away. But in the dark it immediately began to be regenerated and returned along the curve that fits the return of the visual threshold. This means that at every moment during recovery the visual threshold was raised above the fully dark value by an amount proportional to the amount of pigment still in the bleached state.

The subject of this experiment was 'colourblind' and possessed only greensensitive cones on the fovea. So these results are uncomplicated. But just the same results occur with normal subjects when the adapting light is white and bleaches red and greensensitive cones equally.

Fig. 2 shows the dark adaptation curve in a subject defective in all types of cone, so her threshold depended entirely upon the rods of twilight vision. The irregular line is an automatic plot of visual threshold by a device which made the series of light flashes get continually brighter when a switch was up, and continually dimmer when down. When the subject could see the flashing test she depressed the switch and when the flashes consequently became too faint to see she lifted the switch. There is no irregular line before seven minutes, because until then she saw no flash though it was a million times above the final dark threshold (log scale on the left).

The dotted curve in Fig. 2 shows the threshold in a normal eye when the test flash falls offcentre upon a place where both rods and cones are present. The cones recover much faster, and the dotted curve, like the cone curve in Fig. 1, recovers completely in seven minutes. But when the continually falling rod curve reaches this cone level, the dotted curve is seen to join it. For after this point it is the rods that are the more sensitive, and consequently they define the threshold for vision.

The black circles of Fig. 2 show the pigment content of the rods throughout regeneration. The scale on the right gives the proportion of pigment in the bleached state, and we see again that this is

Fig. 2.

Rod dark adaptation curve from a subject nearly devoid of cones.

Irregular line plots the log intensity of a threshold flash at

various times after extinction of bleaching light (scale on left: horizontal

timescale in minutes). Black circles: time course of regeneration

of rod pigment in this subject (scale on right shows fraction of

pigment in the bleached state). White circles: regeneration in a

normal subject whose visual threshold is indicated by the dotted

curves, cones to the left, rods where this meets the heavy curve.

proportional to the rise in visual threshold over the millionfold range where this can be measured. The white circles plot the pigment regeneration of a normal eye, to show that our subject who lacked cones had nothing abnormal with her rod pigment.

It may be asked, 'Why is the rod threshold raised ten to one hundred times (12 log units) when the rods still contain 90 per cent of their pigment?' This seems a crippling loss of performance from so small a loss of pigment. We have no very clear answer to this but it must lie along the following lines.

If a bright light is observed for a short time with steady gaze it leaves a persistent*afterimage. For instance, the bars of a window seen against the sky may be observed floating across the ceiling with the drift of the observer's eye. Against the white ceiling the bright sky image appears black, and the bars white in contrast (negative afterimage). The contrast is reversed if the eyes are now shut or the gaze shifted to some black background (positive afterimage).

H. B. Barlow and J. M. B. Sparrock in an elegant experiment compared the positive afterimage of a flash with the brightness of a real light held fixed (stabilized) upon a neighbouring retinal region. They found that when the stabilized light was made equal to the afterimage in brightness, it was also equal in raising the threshold of a superposed test flash. Now the threshold rise of a test flash when it falls upon the afterimage of a bright light is identical to what is plotted in the dark adaptation curve, following bleaching by the bright light. Thus a rather small pigment loss causes a large threshold rise because it generates a strong and persistent afterimage that forms a bright background against which weak lights will be quite invisible.

Visual adaptation is one of the most marvellous features of that marvellous organ, the eye. In common usage it automatically sets the sensitivity so as to extract the best contrast from the retinal picture over a millionfold range of illumination. But when a dazzlingly bright bleaching light throws the normal mechanism out of adjustment, the receptor activity is prolonged and gives rise to the afterimage. The eye adapts to this situation as though it was a real light flooding the scene, and the normal retinal picture fades into darkness by contrast.

VISUAL ILLUSIONS. See ILLUSIONS.

VISUAL INFORMATION RATE. Let us first estimate the information capacity of the visual system, then see how much of this capacity is used in a decision based solely on visual information, and finally discuss what are the factors that determine the capacity. Accurate data are available only for the central region of the retina (a circle whose diameter is 2° in the visual field) and this area is

considered below. The total information capacity of the visual system is about 10 times that of this central circle, known as the fovea.

The number of points that can be resolved within the central 2° circle is about 104. When the eye is working near the limit of resolution, contrast discrimination is poor.

Jacobson (1951) assumed that, at the limit of resolution, a person could distinguish black from white but not discriminate any intermediate shades of grey. He thus associated one bit of information with each small area surrounding one of the resolved points. (One bit is the amount of information required to decide between two equally probable alternatives: see BIT; INFORMATION THEORY.) For the central region the flickerfusion frequency is about 50 cycles per second, so that the information capacity is $50 \times 104 = 5 \times 10^5$ bits per second.

Ditchburn and Drysdale (1973) calculated the information capacity from measurements of the variation of contrast sensitivity with number of lines per degree of visual angle for targets which were sinusoidal grating. This calculation also yields a value of 5×10^5 bits per second, though their method includes capacity in terms of targets with different shades of grey. Neither of these estimates includes colour information, but it is unlikely that the additional information due to colour is more than about 20

per cent, making 6×10^5 bits per second in all.

Jacobson estimated the capacity for the ear at about 104 bits per second. Thus the central region of the retina has about 50 times the capacity of the ear and the whole visual system has about 500 or 600 times the aural capacity.

Vernier acuity judgements are probably the most precise decisions based on visual information. FoleyFisher (1972) found that 4 to 5 bits of visual information were used in this judgement. For other visual tasks, values of 3 and less have been found (Crossman, 1969). Experiments on rates of response have yielded values of up to 50 bits per second (Klemmer, 1957). Some allowance must be made for unutilized spare capacity—for instance, when a subject makes a vernier acuity judgement on whether two lines are correctly aligned he could simultaneously make judgements on the width, length, and colour of the lines. When considerations like this are taken into account, the information used may rise to between 10 and 20 bits in a single judgement and the rate to about 200 bits per second, but even these values are very small compared with a capacity of 104 bits for a single judgement or 6×10^5 bits per second for the rate.

Ditchburn and Drysdale calculated that, for the lower illuminances at which foveal vision operates, nearly one bit of information was obtained for every photon absorbed by the conedectors. This was true both for steady illumination and for brief flashes of light. At higher luminances the efficiency (measured in bits per photon absorbed) fell so that at daylight level about 104 photons must be absorbed to yield one bit. Thus at the lower

luminances purely physical considerations determine the efficiency, but at higher levels it is

determined by properties of the visual system. The relevant properties are (i) the aperture and quality of the lens of the eye, (ii) the number, and hence the spacing, of the photodetectors, (iii) the number of associated nerve fibres, and (iv) the neural processes by which information is transformed so that it is most readily appreciated by the higher centres of the brain.

The first three of these properties are matched in such a way that each by itself would give a limit of about 10^4 resolved points in the central 2° . The neural processes include an edgesharpening device (lateral inhibition), an arrangement by which an object appears to be about the same size over a range of distances (size constancy scaling), and many similar manipulations of the basic information. Some loss of information in these processes is inevitable, but the system is very economical and the loss may only be about 20 per cent.

In the situation involved in the evolution of the higher animals, decisions vital to survival had to be made mainly or solely on visual information. A wide variety of situations was encountered, so a vast information capacity was needed. Yet the amount used in making a decision had to be limited to the minimum required for a correct decision. This limited amount had to be processed to yield an action as rapidly as possible. If too little information was processed so that there was a considerable chance of a wrong decision, or if too much was processed so that the decision came too late, the animal did not survive. Those species which did survive usually had a large visual information capacity but were able to select a small number of bits for processing towards an action decision.

The amount of information actually used in a decision is determined by limitations of short-term memory and other aspects of brain processing which are not strictly part of the visual system.

VISUAL SPACE. The space that appears to us visually at any moment was defined by Ewald-Hering as *visual space*. It is a manifold of three dimensions in which objects are located in an ordered fashion. What metrical properties it has do not make it a space of constant curvature, because free movability of objects, an important characteristic of such a space, does not occur in visual space: sun and moon vary in apparent size with elevation. Nor is visual space unbounded like infinite Euclidean space: the sky forms a dome.

An individual's concept of spatial relationships is not an exact replica of the 'outside world'. Physical transduction in the eye and neural transformation of impulses arising in retinal receptors shape sensory signals in genetically preprogrammed ways that match preprogrammed neural response

patterns (for example, eye movements); visual*illusions have their origin in many ambiguities and mismatches.

By abstractions, and by logical deductions from moment to moment sensory input and from memory traces, a concept of spatial relationships is built up, transcending immediate visual space and containing fewer contradictions: perceptual processes are now involved that are described by laws such as size constancy, i.e. distances are estimated by the size (and relative sizes) of known objects.

The physicist takes these abstractions and logical deductions from experience (he calls them theories based on experiments) many steps further, and constructs edifices like*Newton's absolute space or the more esoteric spaces of modern views of the universe (see MACH.). But, as*Poincaré pointed out, the geometry of the physicist's space is a part of his theory, it being a matter of convention what are regarded as the laws of physics and what are the properties of the space within which they operate.

In contrast to visual space, a product of the individual's sensory processes, the mathematician's formal spaces are analytical structures of relationships developed from axioms and merely need to satisfy the condition of not containing internal contradictions. Attempts to express the properties of visual space in formal mathematical terms (for example, postulating a hyperbolic, metric for visual space) have generally not met with success. The many restrictive conditions which are built in during the formulation of a mathematical space cannot immediately be assumed to apply to visual space, which may, for example, be nonArchimidean and often features internal contradictions—witness the logicodeductive process necessary to detect illusions of the type found in the graphic works of M. C. Escher.

VISUAL SYSTEM: ENVIRONMENTAL INFLUENCES. Experience in early life influences the organization of the visual system. That is, a specific set of environmental conditions seems to modify the properties of the visual system in a way that reflects these conditions. The best known example of this is the changes produced by 'monocular deprivation'. If in infancy the input to one eye is selectively impaired, either due to a severe refractive error or squint (see EYE DEFECTS

AND THEIR CORRECTION), there is a loss of visual capability in the affected eye, which persists in adult life even after the original disorder has been corrected.

This is a type of 'amblyopia' and it has been investigated experimentally by rearing animals (cats or monkeys) from eye opening time with one eye sutured closed. If after a period of three

Page 797

months or more of this monocular deprivation, the eye is opened, it looks perfectly normal, but the animal appears to be behaviourally blind in it. Examination of the visual cortex of animals reared in this way reveals dramatic changes in the distribution of ocular dominance columns (see VISUAL

SYSTEM: ORGANIZATION).

Instead of the normal bands of alternating left and righteye ocular dominance columns, virtually all the cells outside layer IV are driven only by the nondeprived eye.

Within layer IV, the number of cells receiving an input from the deprived eye is greatly reduced, and the number receiving an input from the normal eye greatly increased. In other words, in layer IV the deprivedeye ocular dominance columns appear to shrink, and the nondeprived (normal) columns expand. Moreover, the cells still receiving an input from the deprived eye in layer IV seem to lose the capability to drive the cells in the other layers of the cortex.

Critical period and binocular competition. In animals, the marked changes in cortical organization following monocular deprivation are seen only if the deprivation occurs during the first three months of life. After that age, even extended periods of deprivation seem to have little effect. There is thus a critical period in early life in which the visual system is particularly susceptible to environmental influences. Moreover, within this critical period it is possible to reverse the effects of monocular deprivation. For example, even one week of monocular deprivation can result in the changes described above but, if at this stage the deprived eye is opened and the other closed, after another week or so the situation reverses, and the cortex becomes dominated by the initially deprived eye. A competitive interaction between the inputs from the two eyes therefore seems to be an important factor in producing the changes in cortical organization that can occur within the critical period. If both eyes are closed at eyeopening time, so that there is binocular as opposed to monocular deprivation, both eyes retain equal access to the visual cortex although there is a reduction in the number of binocularly driven cells. It appears that only when the input from one eye is selectively decreased, with respect to the other, does it lose the ability to drive cortical cells. This suggests a competition between the excitatory nerve terminals for synaptic sites on cortical cells (see NERVOUS SYSTEM).

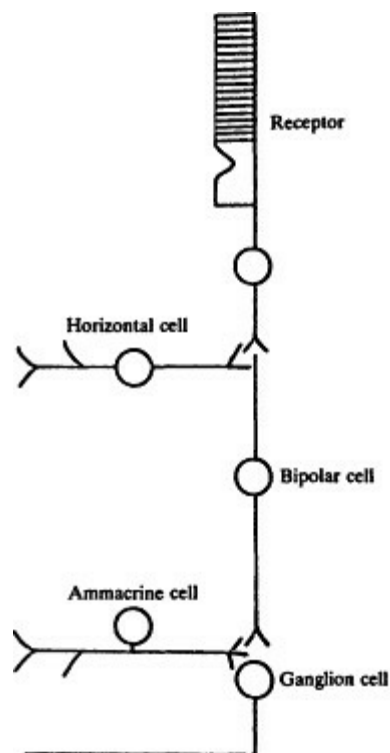

Thus, during monocular deprivation there would be a reorganization of excitatory terminals within the cortex, so that the lateral geniculate neurones and cortical interneurones relaying the input from the nondeprived eye take over the synaptic sites normally occupied by terminals from the deprived eye. However, things are not quite this simple. Recent work has shown that it is possible under some conditions to reveal inputs from the deprived eye in monocularly deprived animals, in a way which suggests that at least some synapses are present but ineffective. The cortical changes occurring during monocular deprivation may thus involve a change in synaptic effectiveness, or some form of synaptic suppression, as well as the redistribution of terminals.

Other factors influenced in the critical period. So far, a large part of the discussion has been concerned with environmental influences on ocular dominance columns in the cortex. However, other aspects of visual cortical organization also seem to be influenced by the environment. The subset of orientation columns crossing the ocular dominance columns appears to be sensitive to the distribution of the orientation of the contours in the visual world in early life. Thus, rearing an animal in an environment where it only 'sees' vertical stripes results in a population of cortical neurones which, instead of representing all orientations, are biased to orientations in the region of the vertical, and not

to others. Precisely organized binocular inputs to cortical cells render them sensitive to retinal image disparity, and form the basis of normal*stereoscopic vision. This is a more subtle level of organization than that seen in the gross distribution of ocular dominance columns, and it is very sensitive to abnormal environments. Even relatively mild squints seem to be able to upset the formation of these connections, and possibly result in loss of binocular connection altogether.

Significance of the critical period. Taken as a whole, it seems that the visual system is set up during early life to match the visual environment. A 'normal' set of connections appears only if the environment is normal. There has been considerable debate as to whether the normal cortical organization is innately determined, but can be distorted by abnormal experience in the critical period, or whether it is mainly experience which determines connections in a system that is 'designed' simply to match the environment. Present evidence suggests that genetic constraints predispose the cortex to a certain pattern of development, whilst the environment determines whether this is fully realized or not. One important reason for the plasticity in binocular connections may be the need to match these to the changing pattern of input as the separation of the eyes increases in the growing head.

This is an exciting area of brain research with a number of important implications. There are many questions to follow up. For example, are other aspects of brain function so dependent on experience in early life? (See, for instance, SPATIAL COORDINATION OF THE SENSES.) Why is the brain only susceptible in this particular way to its environment in the critical period? Indeed, what factors determine the critical period? Recent evidence has raised the possibility that nonspecific inputs to the cortex from the cholinergic and noradrenergic 'neuromodulatory systems' may play an important role in the plasticity seen in the critical period. If this is so, it may be possible to use some type of pharmacological manipulation to regenerate

plasticity in the adult brain. The potential clinical implications of this are considerable. We have here an example of how scientific study of fundamental neurobiological problems can produce wide-reaching conclusions of pragmatic value, which strongly influence the way we understand our own development.

VISUAL SYSTEM: ORGANIZATION. At the most simple level the visual system may be considered as comprising the eyes and a long chain of neural connections extending from the retinal receptors at the back of the eye through the visual pathway to the cerebral cortex. The optics of the eye produce an image of the external world on the retina. This results in a patterned excitation of retinal receptors which is then processed by the neuronal machinery of the visual system to form a representation of the external world in our brain. The representation does not seem to be formed in any one region but in a series of interacting regions that process different aspects of the input in parallel.

Retina. The retinal receptors convert the pattern of light that is the visual image, into a neural signal. This is then processed by the neuronal network of the retina and transmitted to the brain by the axons of the 'retinal ganglion cells'. The retinal receptors make synaptic contact with bipolar cells, which in turn make synaptic contact with the retinal ganglion cells—these are serial connections. At the same time, two other groups of cells, the horizontal cells and amacrine cells, make laterally directed connections that control the transfer of information through the serial connections (see Sterling et al., 1986). The neural organization of the retina is summarized in Fig. 1.

Retinal receptors fall into two groups: the cones, which are associated with daylight vision and colour vision, and the rods, which are associated with night vision.

The cones can be subdivided into three types each responding best to light from a different part of the visible spectrum. These are essential to normal colour vision and a loss or deficiency in the operation of one of the three categories leads to a corresponding deficiency in colour vision. People referred to

as 'protanopes'

Fig. 1.

Interconnections between cells in the retina.

The receptors respond to changes in the level

of the light falling on them, and synaptically

activate bipolar cells which in turn activate

the retinal ganglion cells. Lateral connections

are made by horizontal cells and amacrine cells.

These modify the transmission of information

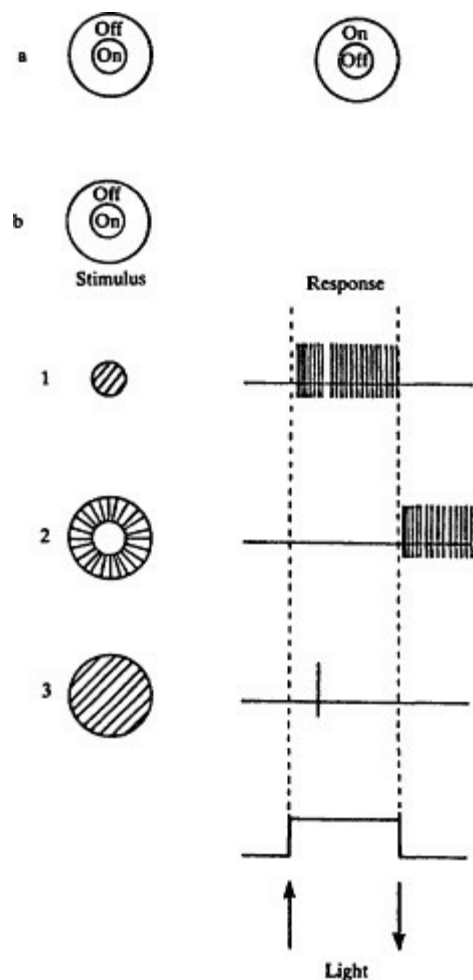

from receptor to ganglion cells and result in the

ganglion cell response being influenced in a complex

way by the activity of a large number of receptors.

lack the cones sensitive to the red end of the spectrum, 'deuteranopes' those to the green portion, and 'tritanopes' those sensitive to the blue end of the spectrum.

Retinal activity. Whilst it is commonly accepted that most nerve cells in the brain generate action potentials (see NERVOUS SYSTEM), this is not the case in the retina. Only the retinal ganglion cells generate action potentials; the other cells in the retina and the retinal receptors exhibit graded shifts in membrane potential, in response to changing levels of illumination without developing a propagating action potential. If one views an action potential as a mechanism for transmitting information over *long* nerve axons, this is not surprising. The retina is a thin structure, with correspondingly short connections, and the electrotonic spread of potential change is adequate for the length of the neural processes involved. When a retinal receptor is exposed to light the membrane of the receptor

Page 799

'hyperpolarizes', and the amount of neurotransmitter released by the synaptic process of the receptor goes down. Receptors depolarize and release more neurotransmitter when the level of light decreases. The potential changes in the receptor are mediated by the action of light on the photopigment contained in the outer segment, and involve a series of chemical interactions leading to a reduction in the level of cyclic GMP, and a consequent decrease in the sodium conductance of the membrane (Lamb, 1986). The transmitter released by the retinal receptors produces potential changes in bipolar cells; these can be subdivided into two groups—one is hyperpolarized by the transmitter and the other depolarized. This difference in the response of bipolar cells leads in turn to two categories of retinal ganglion cells.

Responses of retinal ganglion cells. The various synaptic interactions occurring in the neural circuits of the retina determine the response of retinal ganglion cells to visual stimuli. Since the retinal ganglion cells provide the output from the eyes to the brain, how they respond to visual stimuli tells us something of the nature of the message the brain is receiving. The visual response properties of retinal ganglion cells can be demonstrated in a very simple experiment. An electrode is implanted into the optic nerve of an eye, which is focused on a projector screen. The electrode records the activity (action potentials) of the axons of retinal ganglion cells in the optic nerve. A spot of light is then shone on to the screen and moved over it. As the image of this spot in turn moves over the retina, a point is reached at which the light excites the receptors providing the input to the ganglion cell under study. This induces an action potential discharge in the ganglion cell, which is detected by the

electrode recording from its axon. The area over which responses can be elicited from the ganglion cell constitutes its receptive field. Although these receptive field properties can appear quite complex, they can be simply understood if one considers the 'problem' they have to deal with. The retinal image consists of a set of variations in light intensity above and below the background illumination level (this ignores colour vision). Following from the bipolar cells, retinal ganglion cells exhibit two types of receptive field. In one, the cell is excited by an *increase in* light intensity above background level and, in the other, it is excited by a *decrease in* light intensity below the background level. The receptive fields consist of a concentrically organized centre and surround region. Broadly speaking, in each cell's receptive field the amount of light falling on the centre is compared with that falling on the surround, by lateral synaptic interactions, mediated by the horizontal and amacrine cells. For one type of cell, a relative increment in the amount of light falling on the receptive field centre, with respect to the surround, causes an increase in firing, whilst the converse applies to the other type of cell. Obviously, the relative amount of light falling on the centre, with respect to the surround, can be varied by changes in the absolute light level on either centre or surround. The comparison of

Fig. 2.

a. 'On' and 'off' centre retinal ganglion cells. b. Responses of 'on'

centre retinal ganglion cell to: 1. Spot of light illuminating centre of

the receptive field only. 2. Annulus of light illuminating receptive

field surround. 3. Large spot of light illuminating both receptive field

centre and surround. In each case the light is briefly flashed on and

then off as indicated at the bottom of the records. The records show

the spikes elicited by each of the three stimuli. In 1 the spot of

light elicits a response while it is *on*; in 2 the annulus produces no

apparent response while it is on, but a vigorous response when it

goes *off*. Illumination of both centre and surround as in 3 produces

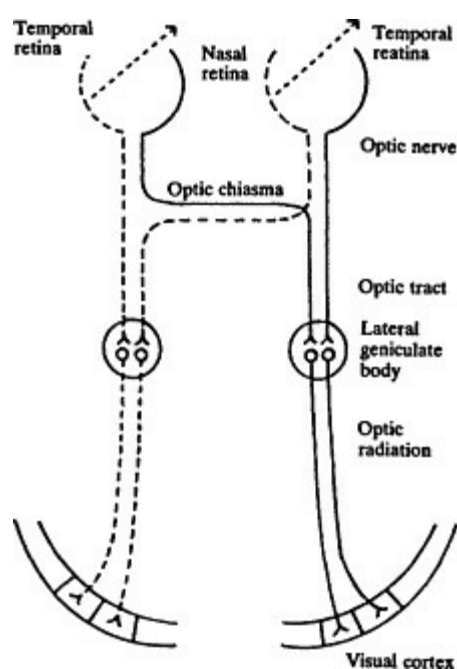

very little response either while the illumination is on or when it goes

off, thus demonstrating the mutual antagonism between the centre

and the surround. See also RECEPTIVE FIELD, Fig. 2, for a simplified

view of the neuronal connections that may form the inhibitory

surround of the concentric receptive field.

Page 800

illumination levels on the receptive field of centre and surround is important to maintaining optimal sensitivity to change in illumination over a wide range of background illumination levels. For a discussion of the process of adaptation and dark adaptation, see VISUAL ADAPTATION.

In one type of retinal ganglion cell, an increment in the relative amount of light falling on the centre (light 'on') causes an increased discharge, whilst in the other a decrement (light 'off') causes a discharge; thus, neurophysiologists describe the two types of cell as 'on' and 'off' centre cells. Because the cells actually compare the light falling on the centre and surround, changes in the surround illumination of the opposite polarity to that exciting the centre, cause an increased response; hence 'on'

centre cells are said to have 'off' surrounds, and 'off' centre cells have 'on' surrounds. Contrast in the retinal image is not only defined by luminance but also by colour.

Thus, the retinal circuitry also processes the input from the three types of cone in a way which allows different classes of retinal ganglion cell to transmit details of the chromatic properties of the image. In some ways, the receptive field properties of retinal ganglion cells, transmitting information about colour contrast, follow a similar logic to that outlined above for luminance contrast.

Types of retinal ganglion cell. Retinal ganglion cells fall into a range of different types. In addition to the 'on' and 'off' centre cells already mentioned, there are further subdivisions in terms of the chromatic sensitivity of the cells and the type of spatial summation shown in the receptive field. With respect to spatial summation, some cells show a linear summation of the components of a distribution of varying luminance across their receptive field, others a nonlinear summation (EnrothCugell and Robson, 1966). These are referred to as X and Y cells respectively, and show distinctions in a range of other properties, including receptive field size, sensitivity to stimulus velocity, and spatial

frequency (see PSYCHOPHYSICS) (Sherman, 1985). In particular, X cells can resolve finer visual patterns (higher spatial frequencies) than Y cells. They are also distinguished on anatomical grounds; the Y cells correspond to the alpha retinal ganglion cells distinguished by anatomists; they are larger and have thicker axons than the beta cells which correspond to X cells. One important point to note is that the Y cells have faster conducting axons than X

cells. These distinctions cut across the broad subdivision into 'on' and 'off' centre types.

The visual pathway. The axons of the retinal ganglion cells travel in the optic nerve to the brain. Each retina can be considered as subdivided into two halves in the vertical plane—a nasal half and a temporal half. The axons from the nasal half of each retina, after travelling in the optic nerve, cross over to the other side of the brain in the optic chiasma. They join fibres, from the temporal half

Fig. 3.

Schematic diagram of the visual pathway as seen by looking down

from above the head. Note that, because of the crossing in the

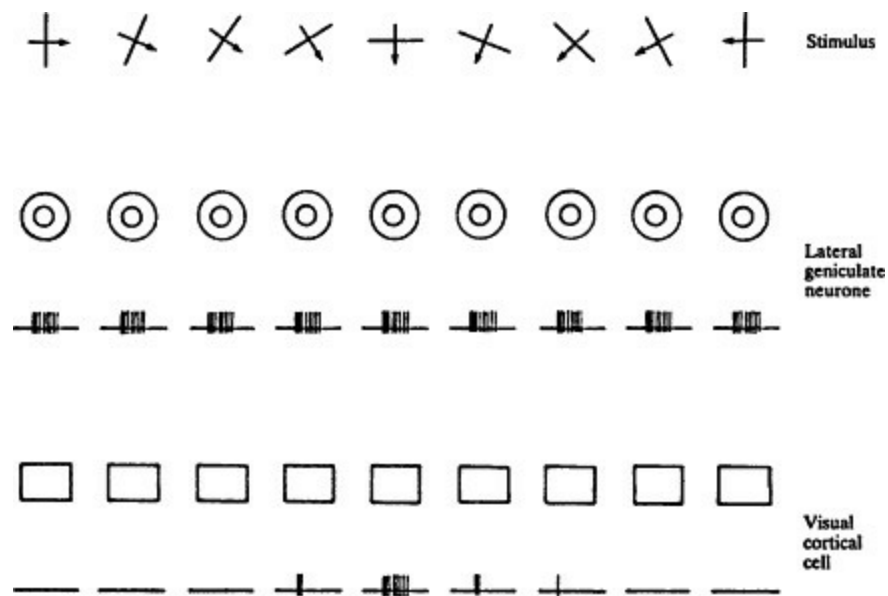

optic chiasma, the right side of the brain 'sees' the left side of the

visual world, and vice versa.

of the other retina, which encompass the same half of the visual field, and pass with these to the lateral geniculate body (a group of cells in the thalamus). The lateral geniculate body is a laminated structure with six separate layers, four parvocellular and two magnocellular. The inputs from the two eyes synapse in separate layers.

The axons of the lateral geniculate cells project via the optic radiation to the visual cortex. One can view the visual cortex as a folded 'slab' of grey matter containing nerve cells, with an underlying layer of white matter formed by the nerve fibres entering and leaving the grey matter. The grey matter of the cortex is commonly subdivided into six layers. The projection from the lateral geniculate body terminates most densely in the vicinity of layer IV of the visual cortex. In this layer, the input from the two eyes is kept separate (or approximately so). There are thus alternating bands in layer IV of cells dominated respectively by the ipsilateral (sameside) and contralateral (oppositeside) eyes. This forms the basis of the so-called 'ocular dominance' columns in the cortex. In the cortical layers above and below layer IV, there are laterally spreading connections which result in binocularly driven cells. The crossing in the optic chiasma thus ultimately enables the retinal inputs relating to the two views of the same part of the visual world to be brought together.

In the visual projection there is an orderly map of each half retina on the lateral geniculate body,

Page 801

and then again in the cortex. Each retinal ganglion cell 'looks' at a particular part of the retinal image, and hence a point in visual space, and its neighbour at an adjacent or overlapping point, and so on. This sequence of sampling of visual space is reflected in the projection to the lateral geniculate nucleus, and from there to the cortex.

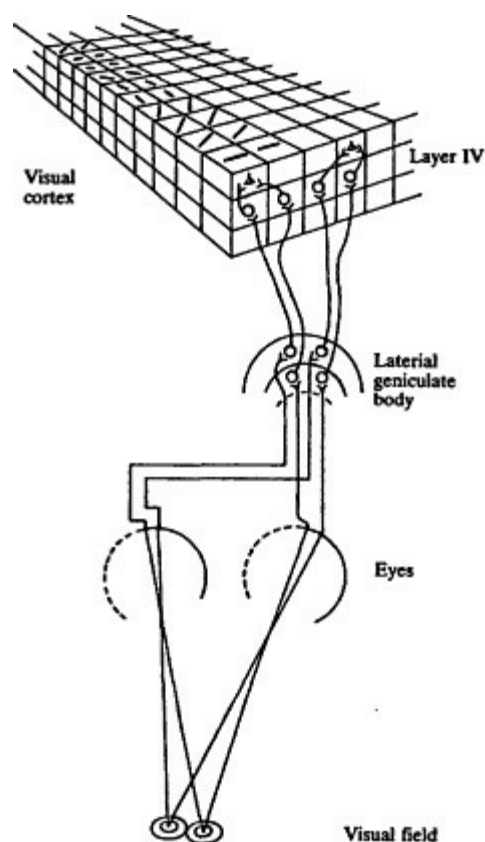

The inputs from the two half retinae are in register; thus there is a double mapping of the same view of the visual world, firstly in the separate geniculate layers, and then again through the ocular dominance columns in the visual cortex. The 'slab' of grey matter forming the left visual cortex is thus a 'map' of the right visual world as seen from two slightly different viewpoints. Moreover, the various categories of retinal ganglion cell all sample the visual field more or less uniformly. They convey different types of information to the central visual system, and the patterns of termination of the inputs relaying this information are distinctive. The input to the visual cortex, thus, not only reflects the visual world seen from two slightly different viewpoints, but also the visual world sampled several times over by elements with differing sensitivity to the properties of the retinal image.

Receptor density and the central visual map. The density of retinal receptors is not uniform over the retina, but is highest in the fovea and falls off towards the periphery of the retina. The higher the density of receptors, the smaller their size and the greater the visual acuity. Broadly, one can equate receptor size with the grain size in a photographic emulsion. The proportion of the map in the central visual system devoted to each retinal area reflects the density of receptors, rather than the dimensions of the area. Thus, in terms of the area of the visual field, the visual cortical representation of the fovea is much larger than that for peripheral parts of the retina.

Processing of the visual input. Our knowledge of the way in which the visual input is first processed within the brain owes a great deal to the work of Hubel and Wiesel. They studied the response properties of cells in the lateral geniculate nucleus and visual cortex, utilizing the same overall technique as that described for the analysis of retinal ganglion cell response properties. The eyes of an anaesthetized animal were focused on a projector screen and the activity of cells in the lateral geniculate nucleus and visual cortex recorded. Because of the orderly visual projection, as an image

moves over the projector screen and hence over the retina, it also moves in a similar fashion over the map of the retina in the lateral geniculate nucleus and visual cortex. When examined this way, cells in the lateral geniculate nucleus were found to have receptive fields that were very similar to those seen in retinal ganglion cells. They were well activated by flashing spots of light, and fell into the same broad categories (e.g. 'on' and 'off' centre X and Y cells). Conversely, the majority of cells in the visual cortex were not best activated by flashing Fig. 4.

Comparison of the response of a lateral geniculate neurone and a visual cortical cell to a bar of light moving over their receptive field. The lateral geniculate neurone responds to the bar at all orientations. The visual cortical cell is very selective to the orientation of the stimulus. As visual cortical cells get their excitatory input from lateral geniculate neurones, this implies that there is some specific organization of inhibitory and excitatory interconnections within the cortex generating this orientation selectivity.

spots of light, but by an elongated stimulus moving over their receptive field at a particular orientation. This selectivity to the orientation of the 'contour' of a stimulus is a characteristic feature

of visual cortical cells (Hubel, 1963). A retinal ganglion cell, or a cell in the lateral geniculate nucleus, responds to a bar of light moving over its receptive field at all orientations. In the light of this evidence, Hubel and Wiesel proposed that visual cortical cells were concerned with the detection of specific features of the visual environment. The selectivity to stimulus orientation appears to be an important component of the way in which nervous systems throughout the animal kingdom encode the visual input; it is seen, for example, in the higher visual centres of mammals, cephalopods, and birds. Although selectivity to stimulus orientation seems to be a particularly important facet of the neuronal machinery, in the visual cortex, cells exhibit selectivity to a range of other properties of the visual input. This includes direction of stimulus motion, the colour, the length, and the depth in visual space. The latter property underlies stereopsis (see STEREOSCOPIC

VISION) and involves cells that are driven by both eyes, but are sensitive to the disparity of the image location on the two retinae.

Columnar organization of visual cortex. One of the major discoveries made by Hubel and Wiesel was that the visual cortex is divided into a sequence of columns or sheets of neurones, with common functional properties. The ocular dominance columns have been described elsewhere (see HUBEL AND WIESEL: JOINT

WORK). These run from the surface of the cortex to the white matter, and are themselves subdivided into a further subset of columns, which appear to be concerned with stimulus orientation. These are the 'orientation columns', containing cells with common orientation selectivity. Adjacent orientation columns are sensitive to slightly different orientations and this process repeats as a series of approximately 10° steps from one column to the next. The portion of an ocular dominance column, representing one location in visual space, contains a series of orientation columns that, on average, cover an entire 180° range. Each location in visual space is thus represented by two ocular dominance columns (for the right and left eye), and their subsets of orientation columns. The orientation and ocular dominance columns can be envisaged as crossing each other at right angles as shown in Fig. 5. However, the true situation is not as orderly as this and it is possibly better to envisage the two sets of columns as intersecting in a pseudorandom fashion, but one which broadly ensures that each location in visual space is represented by a full complement of orientation columns.

Laminar organization of the visual cortex. There is a difference between the input and output connections of the cells in each layer of the visual cortex.

Consequently, in addition to the columnar

Fig. 5.

Detailed view of the organization of the visual perception

through the lateral geniculate body to the visual cortex. This

shows the projection of two adjacent regions in the visual field

on to adjacent groups of neurones in the lateral geniculate body and visual cortex. Note that the input relating to the corresponding points in the two eyes ends on separate layers in the lateral geniculate body and on separate bands (ocular dominance columns) of neurones in layer IV of the cortex. However there is binocular convergence on to single neurones in the cortex, mainly outside layer IV.

organization, there is a differentiation of function in the vertical domain, i.e. within an orientation column. In their early work on this matter, Hubel and Wiesel proposed three types of cell in a column—simple cells, complex cells, and hypercomplex cells. The term 'simple' was applied to the cells in layer IV receiving their input directly from the lateral geniculate body. Orientation selectivity was thought to be set up in this layer by the organization of the geniculate cell connections to simple cells. Each simple cell was conjectured to receive an excitatory input from several geniculate cells, with their receptive fields extending in a row through visual space (see RECEPTIVE FIELD, Fig. 2). Only a bar of the appropriate orientation would simultaneously activate all the input cells, and Page 803

hence produce a maximal response in the simple cell. A group of simple cells were then thought to provide the drive out of layer IV to complex cells, and complex cells, in turn, to provide a drive to hypercomplex cells. Each of these cell types was considered to have a receptive field organization elaborating successively more complex features of the visual environment.

The strictly hierarchical view of the organization of cells in a column has not been supported by subsequent findings. Present evidence emphasizes parallel processing of different facets of the visual input in the cortex, utilizing a circuitry that is much more complex than originally envisaged (Sherman, 1985, Rose and Dobson, 1985, Martin, 1984). Extensive excitatory and inhibitory connections mediate lateral interactions in the visual cortex, which generate many aspects of the stimulus selectivity of the cells. Indeed, experiments inducing a localized blockade of intracortical inhibitory processes have demonstrated that inhibitory connections play a critical role in the generation of some receptive field properties; these include sensitivity to the direction of stimulus motion and, for some cells, stimulus orientation (Sillito, 1984). The direct comparison here is with the retina, where horizontal and amacrine cell connections generate the concentric receptive field of ganglion cells, not just the direct connections from the receptors via the bipolar cells. However, in the central visual system, the heavy reciprocal interconnections between each level in the system suggest that any analysis of its function must take note of the fact that the levels constitute interacting components of a circuit, rather than just a stage in a sequence. For example, the projection from the visual cortex to the lateral geniculate nucleus is as dense, or even denser, than that from the retina, and yet, remarkably, the function of the former is largely ignored. Obviously the cortex is potentially capable of exerting a powerful control over the response of geniculate cells, and yet at the same time the cortical activity is dependent on the geniculate input. Similar comments apply to the interactions

between the cortical laminae and the different cortical areas.

Further progress in our understanding, at this level of analysis, requires a hypothesis regarding visual system function that needs the synaptic complexity we now know to exist.

' Blobs' and colour processing in the visual cortex. Recent evidence in the Primate has shown that, in addition to the columnar organization of the visual cortex, there is a sequence of regularly repeated bloblike structures. These can be distinguished anatomically by virtue of the fact that they stain very densely for the mitochondrial enzyme, cytochrome oxidase. They are most conspicuous in layers H and III of the cortex, and are notable in a functional sense because they contain cells that seem to be primarily concerned with processing colour information, and they lack cells sensitive to stimulus orientation. The blobs show a regular distribution in the tangential plane, in relation to the ocular dominance columns, in a way which suggests that there is a blob for each location in visual space as well as a full complement of orientation columns. The pattern of the output from the blobs, and columnar regions of the primary visual cortex, suggests that colour information and orientation are processed in parallel through separate channels.

Cortical pathways processing the visual Input. The processing of the visual input, after the primary visual cortex, appears to proceed through distinct, although interlinked, groups of cortical areas. The regions of cortex most strongly dominated by the visual input are often labelled in sequence as V1 (primary visual cortex or area 17), through V2, up to V5. There seem to be two major channels of processing. One passes from V1 to V2, from there to V4, and eventually to the inferotemporal cortex. This seems to be involved in object recognition and colour. The other channel passes from V1 to V2, and from V2 to V5 (V5 is also referred to as 'MT'), and the inferior parietal cortex; it seems to be involved in object location and movement in visual space. Within these broad channels, various aspects of the input are likely to be processed in parallel for all, or part, of the sequence of connections, as for example for colour and orientation, in the sequence of connections passing to V4. Neurones in the inferotemporal cortical region can have highly selective response properties, some for example seem to respond only to faces.

However, it is far from clear that this represents a general case for the sequential elaboration of more and more complex fields dealing with specialized elements of our environment. Many would suggest that in general this level of representation involves ensemble encoding in a matrix of interacting neurones. The presence of facespecific neurones in Primates may have more to do with the biological importance of faces than the general rules underlying visual processing.

VOLLEY THEORY. The transmission of sound by the ear to the brain presents a special problem, because sound frequencies greatly exceed the maximum frequency of action potentials in a nerve fibre. The volley theory, based on electrical recordings of action potentials in auditory nerves, states that for frequencies up to perhaps 500 hertz each cycle of a sound wave produces a single neural spike (actually at the zero energy crossover of the wave), but, at frequencies beyond those that a nerve can follow, other nerve fibres are recruited to code higher frequencies by combinations of spikes from cooperating nerves.

For still higher frequencies, the cochlea analyses the various frequencies into different positions along the basilar membrane, so that different hair cells are activated, and different neural channels employed, to transmit each frequency. There are thus three ways, depending on frequency, in which sounds are represented and transmitted by the ear.

During the 1920s and 1930s his work included quantum theory, mathematical logic, ergodic theory, continuous geometry, and abstract algebra; his interest then turned to theoretical hydrodynamics. He became well known as a member of the Atomic Energy Commission, having been professor in the school of mathematics at the Institute for Advanced Study at Princeton from 1933 until 1954.

Von Neumann first became known internationally for his work in developing the digital computer. It was at the Moore School of Electrical Engineering in Philadelphia in 1946 that he led a team that completed ENIAC, the first digital computer. His work gave publicity to the subject under the title *The Theory and Techniques of Electronic Digital Computers*, and set out the design principles that in essentials remain unchanged today. Then, immediately the ENIAC was complete, the design was set out for a smaller and much more powerful computer, with a store of 1,000 words each of ten decimal digits—fifty times that of ENIAC. New storage methods were designed and new programming techniques suggested, leading to the present digital computer with a store capacity for millions of words. The work fitted in with that of Alan* Turing. Von Neumann worked primarily from the standpoint of the engineer and was concerned with the hardware realization, while Turing worked on the algorithmic approach to define what was computable. The first four generations of computers are now called Von Neumann machines since they all followed the essential features of Von Neumann's earliest design; as a result nearly all the computer languages in existence are essentially Von Neumann languages.

The most famous of his many contributions to mathematics was embodied in *The Theory of Games and Economic Behavior* (1944; revised edn. 1953), which he wrote in collaboration with the American economist Oskar Morgenstern. It was concerned to develop a general theory of the rational behaviour of two or more people in what are basically conflicting or competing situations, although coalitions are also considered. First he developed the theory of twoperson, zerosum games, in which one player's gain is the other player's loss; he then suggested the concept of equilibrium, known as the *minimax* solution, in which one player minimizes the maximum loss the other player can impose on him. The solution of a game depended on the players using mixed strategies where the actual moves are chosen at random. Later, games for many players were devised, not necessarily zerosum; here coalitions were possible, and a number of solution concepts were developed.

The special case of 'the prisoner's dilemma' was made explicit, where neither player would wish to change his move given the strategy of the other—a pair of strategies that is worse for both players

than any alternative. The development of the theory of games since Von Neumann has been considerable and involves decision making (especially under conditions of uncertainty), games against nature, and the very important interpretation of the theory known as linear programming.

Von Neumann's next major work was *Probabilistic Logics* (1952). In this he was primarily concerned with the role of error in logical nets, which Page 805

are particular examples of finite automata and designed to be abstract models of the central nervous system. He was interested in the technique of *multiplexing*, which is multiplication of neural connections between neural type elements, so that if a certain number of fibres fail, the system is still operable. The basic element of the Von Neumann automata, unlike the usual use of conjunction and negation, was the Sheller stroke element. This element fires when either of its two input elements fire, but not when both do, for if they fire together they inhibit the element and stop an output firing. The orelement, andelement, and notelement are then defined in terms of the Sheller stroke. This in turn leads to the majority organ whose output fires if and only if the majority of the inputs fire. The multiple line trick was used to provide the needed multiplexing. This is done by setting a fiducial level k to the number of lines of the bundle to be stimulated; then, for $0 < k < \frac{1}{2}$ at least $(lk)N$ lines being stimulated is said to be in a positive state—and conversely, when no more than kN are stimulated, it implies a negative state. Building on this multiplexing method, Von Neumann examined in detail the notion of error.

The final phase of Von Neumann's work was represented by the Silliman lectures which he was to have given at Yale in 1956 and which were embodied in his posthumous *The Computer and the Brain* (1958). His terminal illness made the lectures impossible but the book made clear the form they would have taken. The work was that of the mathematician operating in the field of brain studies and emphasized the differences and similarities between brains and computers. The nerve impulse is primarily electrical, apparently digital, and has time characteristics not unlike the pulses in a computer. Overall, computer speeds then were slower at performing the range of functions performed by the brain—a state of affairs that has gradually changed. The languages of the brain involve mathematical, logical, and statistical methods, and Yon Neumann foresaw that in describing the brain and the nervous system new forms of mathematics would be developed. This has occurred in the forms of uncertainty logics and empirical logics. The precision of brain operation he thought of as logical, its computational working as arithmetic, and the functional description as statistical.

F. H. G.

VYGOTSKY, LEO (Lev Semionovich, 1896-1934). The most outstanding Soviet psychologist, and founder of the most influential school of Soviet psychology, Vygotsky was born in Orsha (Belorussia), and began his work in psychology after leaving Moscow University (faculty of letters) in 1919. As a young man he wrote the subsequently wellknown pieces that were included in the *Psychology of Art* (1965; Eng. trans. 1971). Psychological analysis of the personality of Hamlet, as well as studies in

the psychology of fables, were central to the work of this outstanding young scholar. After a few years in Gomel (Belorussia), where he taught psychology and wrote *Pedagogical Psychology* (1926; in Russian), he moved to Moscow, where his most important work began. He soon became a leading figure of the Institute there, and the central figure in a group of young scholars (including A. N. Leontiev and A. R. Luria) who became his first coworkers and followers.

At the time of his early studies, psychology was in a state of crisis. It was split into two independent sciences. The first was the *explanatory or physiological psychology* of Wundt and Ebbinghaus, who tried to explain complex psychological phenomena by reducing them to elementary physiological components. They refused to deal scientifically with the highest, specifically human forms of conscious behaviour—motives, abstract thinking, active memorizing, voluntary actions, etc.

The second school attempted a *descriptive psychology* which did consider the highest forms of conscious experiences, treating them as spiritual forms of mental life, and supposing that these phenomena may be described in phenomenological terms but not explained scientifically.

Vygotsky assumed that the basic goal of scientific psychology was to overcome this division, and to try to explain scientifically not only the elementary but also the highest forms of psychological processes. This—he thought—could be done by reducing the complex psychological phenomena not to physiological 'elements', but rather to more complex psychological 'units', which would preserve all the properties of the complex forms of conscious behaviour and which could serve as its models, making the more complicated forms of mental life accessible for scientific analysis.

Supposing the highest forms of mental life and conscious behaviour to be not of a spiritual nature but a product of social development, Vygotsky saw toolusing and signusing ('significant') behaviour as essential for all higher forms of psychological processes. He also considered forms of signusing behaviour, its rules, and the stages of its development. Studies in signusing, as a model of complex active memory, were his first attempt to approach experimentally the most complicated psychological processes. (The results of these studies were published by A. N. Leontiev.)

His work on simple 'units' of tool and signusing behaviour led Vygotsky to investigate the role that language (the most universal system of signs) plays in human behaviour, and to a careful analysis of its development during the life of the individual. The main purpose was to describe the semantic structure of words. His famous experiments with artificial words (the Vygotsky-Sakharov technique) were published later by Hanfman and Kasanin and became known as the Vygotsky-Hanfman

Kasanin tests.

These investigations led Vygotsky to one of his

Page 806

main discoveries that the meaning of words undergoes a complex development, and that words starting as emotional soon become concrete designations of objects later to acquire abstract meaning. (See LANGUAGE: LEARNING WORD MEANINGS.) This conclusion was followed by the statement

that the whole of mental development can be understood as a profound change of psychological systems which mediate the basic forms of activities; and that with each new stage the leading function changes. So, Vygotsky supposed, the child is thinking by memorizing, whereas the adult is memorizing by thinking. This systemic approach to complex psychological functions was one of the most important steps in contemporary psychology.

The idea that the higher psychological processes have a social origin brought Vygotsky to a new approach in the evaluation of the child's mental development, and to the assumption that not only the actual 'mental age' of the child has to be measured, but also its potential capacities—what he called 'the zone of potential development'. This can be done by comparing how the child solves certain problems by itself with a second indicator: how it can solve similar tasks with the help of the teacher—representing here the ability to acquire social prompting. The principles proposed by Vygotsky were of the highest importance for practical educational and clinical psychology.

During his short life in science (he died at the age of 37 from tuberculosis, and worked actively in experimental psychology only for about ten years), Vygotsky was active in many fields of scientific psychology: general psychological problems, child psychology, the problems of retarded and deaf children, the psychological analysis of local brain injuries, and a series of related fields. Although his career was very brief, his influence on Soviet and world psychology has become more and more significant with the passing years. In addition to the two works mentioned, his most important books are *Thought and Language* (1937; Eng. trans. 1962); *Selected Psychological Studies* (1956; in Russian); and *Development of the Higher, Mental Processes* (1960; in Russian).

W

WALLACE, ALFRED RUSSEL (1823-1913). British naturalist, born at Usk, Monmouthshire. He made extensive natural history collections in the Amazon basin (though a large part of these were lost when the ship he was on caught fire) and later in the Malay Archipelago.

Independently of Charles*Darwin (and, like him, to some extent inspired by reading*Malthus's *Essay on Population*), he conceived the notion of evolution by survival of the fittest. On 18 June 1848 Darwin received a letter from Wallace which expressed the key concept that he had been working on for over twenty years. Darwin wrote to Charles Lyell:

Your words have come true with a vengeance—that I should be forestalled. You said this, when I explained to you here very briefly my views on 'Natural Selection'

depending on the struggle for existence. I never saw a more striking coincidence; if Wallace had my MS. sketch written out in 1842, he could not have made a better short abstract! Even his terms now stand as heads of my chapters.

The problem of priority was solved by the two of them in the most gentlemanly fashion with a joint paper presented to the Linnean Society on 1 July 1858.

Nevertheless, Wallace's letter prompted Darwin into writing *The Origin of Species*, which was finished on 19 March 1859.

Though unfortunate in being anticipated by Darwin and overshadowed by him, Wallace was an excellent naturalist and a careful, original thinker. In later life, however, he became an advocate of spiritualism. He was elected Fellow of the Royal Society in 1893 and appointed to the Order of Merit in 1910.

Among Wallace's main works are *Contributions to the Theory of Natural Selection* (1870); *The Malay Archipelago* (1869); *Darwinism* (1889); *On Miracles and Modern Spiritualism* (1881); and, for solid scientific work, *Geographical Distribution of Animals* (1876) and *Island Life* (1880). See also *Man's Place in the Universe* (1903) and *My Life, an Autobiography*, 2 vols. (1905).

WALTER, WILLIAM GREY (1910-1976), Anglo-American physiologist, was born in Kansas City and educated at Westminster School, London, and at Cambridge.

As a postgraduate student with E. D. Adrian, he worked on muscle contraction before joining Frederick Lucien Goll at the Maudsley Hospital in London in 1935, to start his work on the electrical activity of the brain by recording the electroencephalogram (the EEG) that was to continue for the next forty years. In 1939 he moved with Goll to Bristol, to open a research laboratory and clinic called the Burden Neurological Institute. In addition to his work on the EEG, Grey Walter was much concerned with the development and use of electroconvulsive therapy (ECT), and the first shock treatment on patients in Britain was done at the Institute, with apparatus he designed and constructed.

In about 1940 Grey Walter started work on two aspects of the EEG that were to occupy his efforts for many years—frequency analysis, and mental attributes such as imagery (see IMAGING). Then came a period of several years when he turned to the construction of electromechanical models to simulate brain function behaviour. This was the time of the birth of cybernetics. The publicity that these fascinating models received tended to distract attention from their scientific value. The famous electromechanical tortoise (*M. speculatrix*) was designed to see how many sensory systems had to interact before complex behaviour patterns were produced. This turned out to require very few active elements, with only two control systems (one light-sensitive and the other touch-sensitive). The simplicity of the model was the mark of its value: a fact that many imitators did not appreciate, and thus they merely produced elaborate toys. Grey Walter was the first to show that simple control devices could produce lifelike behaviour, with learning.

While all this was going on, the 22-channel toposcope was being made to examine aspects of the rhythmic electrical activity of the brain that the frequency analyser was unable to achieve. The helical scan 'Topsy' was useful for measurement and display of frequency and phase relationships on a short timescale at many electrode sites.

Then, at about this time, two events occurred at the Institute that were to change the course of the work. First was the use of implanted electrodes for investigation of epilepsy and treatment of psychiatric illness, which allowed recording from local brain regions in conscious humans; and second was the development of a 2channel evoked potential averager. This gave Grey the chance he had been waiting for—the opportunity of studying the functioning brain in its complexity, particularly interactions between associated stimuli. He had attempted these conditioning experiments on several occasions since the 1930s, probably stimulated in the early days by meeting Ivan Parlor. In 1962 a study was undertaken of a group of autistic children, using scalp electrodes, and it was during this work that Grey Walter first

noticed a negative shift between the associated stimuli. The contingent negative variation (CNV)—brain activity occurring just before a decision—was made public at a meeting of the EEG Society in 1964.

His highly productive work on evoked potentials for the rest of that decade was tragically halted in 1970 by a severe head injury from which he never fully recovered.

Grey Walter was a pioneer and an intellectual leader of world renown; but he was never fully accepted by the British scientific establishment. He wrote some 200

research papers and a uniquely stimulating book: *The Living Brain* (1953), which attracted many students to follow in his footsteps.

R.C.

WARD, JAMES (1843-1925), English philosopher, educated at Cambridge and later at the universities of Göttingen and Berlin. While in Germany, he acquired considerable understanding of both physiology and psychophysics, and after his return to Cambridge published an article on Fechner's law in the first volume of the neurological journal *Brain*.

Ward's major interest in later life lay almost wholly in philosophy, but this did not deter him from writing a celebrated article on psychology for the ninth edition of the *Encyclopaedia Britannica* in 1886, which he expanded and largely rewrote for the eleventh edition in 1911. His other major contribution to psychology was an impressive, if difficult, treatise on *Psychological Principles* (1918). Although he did not contribute further to experimental psychology, he did much to foster its development in Cambridge through the activities of such men as W. H. R. Rivers, C. S. Myers, and F. C. Bartlett.

A bibliography of Ward's writings by E. B. Titchener and W. S. Foster was published in the *American Journal of Psychology*, 23, 457-60 and reprinted in 1926, with some extensions to the date of Ward's death, in the *Monist*, 36, 170-6.

O. L. Z.

WATSON, JOHN BROADUS (1878-1958) was the founder of the American school of psychology

known as behaviourism. The movement was launched in 1913

with his paper 'Psychology as the Behaviorist Views It', and was bolstered by many subsequent papers and popular articles, as well as by his four influential books: *Behavior: an introduction to comparative psychology* (1914), *Psychology from the Standpoint of a Behaviorist* (1919), *Behaviorism* (1924), and *The Psychological Care of Infant and Child* (1928). Reacting against the influential introspective psychology of his day, which even he had practised early in his career, Watson declared that behaviour should be the only subjectmatter of psychology. Though psychology had long been concerned with the study of mind, Watson believed that such an endeavour had proved fruitless. Psychology could become a productive science like other natural sciences only by being objective and dealing with the observable; the study of mind could never be accomplished objectively, but the study of behaviour could. The goal of psychology would become the prediction and control of behaviour. Consciousness, mind, and mental states were to be ignored.

Soon after Pavlov's reflexology became prominent in America, Watson adopted the reflex as the basic unit by which all behaviour was to be explained. He believed that all complex human behaviour was the sum of simple conditioned reflexes. So powerful did he see the conditioning process that he eventually promoted a staunch environmentalism, a philosophical belief that all behaviour is learned. In advocating this position, Watson made many extreme statements about the power of conditioning. The best known is:

Give me a dozen healthy infants... and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchantchief and, yes, even beggarman and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors.

Though Watson qualified this statement and others like it, his qualifying statements have often been overlooked and his views simplified. For example, he is usually credited with the simplistic notion that thinking is merely subvocal speech or laryngeal movement, though he repudiated such a view on several occasions (for example, in *The Battle of Behaviorism*, published in 1928 with William McDougall).

Watson's work had an immeasurable impact on American psychology. The tenets of behaviourism dominated the field until perhaps the 1950s, and psychology is still often known as the science of 'behaviour' rather than the science of 'mind'. It was Watson's behaviourism that inspired B. F. Skinner's early work in psychology, though Skinner, in developing the modern version of behaviourism, abandoned Watson's environmentalism and his aversion to a consideration of mind (see BEHAVIOURISM: SKINNER ON).

Though his impact was longlasting, Watson only remained active in academic psychology until 1920, when, as a result of a personal scandal, he was forced to resign from his position at Johns Hopkins University. His subsequent successful career was in advertising.

WEBER, ERNST HEINRICH (1795-1878). German physiologist, born at Wittenberg; professor of anatomy and later of physiology at Leipzig. He is Page 809

celebrated for developing methods of measuring the sensitivity of the skin which, together with the work of Gustav*Fechner, resulted in the Weber-Fechner law ($I/I_0 =$

constant), where I is the intensity of the sensation and the constant is known as Weber's constant. The constant is different for each sense (for intensity of light, sound, etc.) and tends to increase with ageing, as sensory discrimination becomes impaired. (See AGEING: SENSORY AND PERCEPTUAL CHANGES.) It represents the smallest stimulus intensity difference that can be distinguished, and is a constant proportion (generally about 3 per cent) of the stimulus. This logarithmic relation is basic to almost all sensory discrimination, so that larger differences are required for greater intensities. (For a detailed account of the psychophysics that is the basis of experimental psychology and is still rooted in the work of Weber and Fechner, see PSYCHOPHYSICS; see also SIZE-WEIGHT ILLUSION.) **WERNICKE**, CARL (1848-1905), German neurologist and psychiatrist, qualified at the University of Breslau and returned to it many years later as a professor after spending several years in Berlin. He trained under the distinguished neuropathologist Theodor Meynert, who had great influence on Sigmund*Freud. Indeed Freud's early work in neurology betrays an outlook which had much in common with that of Wernicke and he likewise wrote a monograph on*aphasia.

At the early age of 26, Wernicke published the monograph that won him lasting fame. Its title was *Der Aphasische Symptomencomplex* (The Aphasic Syndrome) and it appeared in 1874. The syndrome described by Wernicke was quite different from—and in many ways much more interesting than—that described a few years earlier by Paul*Broca and which had become known as *motor aphasia*. Whereas the latter involved essentially a loss or defect in the expression of speech, the form of aphasia described by Wernicke was marked by a severe defect in the understanding of speech, and correspondingly became known as *sensory aphasia*. This term, however, is by no means totally appropriate as expressive disorders undoubtedly occur in Wernicke's aphasia, but they are disorders in word usage and word choice rather than disorders in the articulation or expression of speech. In severe cases, indeed, the patient's speech approximates to incomprehensible jargon. In such cases, it is the phonemic structure of language rather than its formulation and expression that is at fault.

Wernicke was further able to demonstrate that there are important differences between these two

forms of aphasia, not only in clinical features but also in the site of the responsible lesions; whereas in Broca's aphasia the lesion as a rule involves the posterior portion of the left frontal lobe, Wernicke's aphasia is typically localized in the left temporal lobe, though bilateral lesions are not uncommon in cases in which the receptive loss is severe.

Wernicke's interest in aphasia was far from limited to its phenomenology and localization. He made a most creditable attempt to tie together anatomical and functional findings in order to produce a general theory of language and its disorders. This approach was well represented in the fact that his monograph bore the subtitle: 'A psychological study on an anatomical basis'. By bringing together the cortical localizations of the two major speech areas, namely those of Broca and himself, Wernicke evolved what we should no doubt today describe as a flow diagram for language in the brain, and his theory provided a major stimulus to the discovery and understanding of new syndromes, for example his pupil Hugo Liepmann's work on apraxia and its relation to lesions of the corpus callosum.

Although the type of thinking exemplified by Wernicke and his pupils, with its strong emphasis on brain centres and the connections between them, went out of fashion between the two world wars, in modified form it has once again become a foundation stone in the work of many presentday investigators. (See also LANGUAGE

AREAS OF THE BRAIN; LANGUAGE: NEUROPSYCHOLOGY.)

Apart from his papers on aphasia, Wernicke wrote on a variety of neurological issues, and is still remembered for his description of a form of encephalopathy resulting from thiamine deficiency (common among alcoholics), which bears his name. He also wrote a textbook entitled *Foundations of Psychiatry*, which he himself regarded as his most important work, though it failed to achieve the popularity of Emil*Kraepelin's textbook.

Wernicke, C. (1895). *Gesammelte Aufsätze und Kritische Referate zur Pathologie des Nervensystems*. Berlin.

WERTHEIMER, MAX (1880-1943). Born in Prague, Wertheimer is conventionally regarded as the founder of*Gestalt psychology. Working under F. Schumann at the University of Frankfurt, he carried out an important study on apparent visual motion, published in 1912 (see KORTE'S LAWS). His colleagues at that time included Wolfgang*Köhler and Kurt*Koffka, who acted as subjects in his experiments. Wertheimer's report of this work was a seminal paper in the evolution of Gestalt theory: 'Experimentelle Studien über Sehen von Bewegung', *Zeitschrift für Psychologie*, 61, (1912), 161-265.

Wertheimer later transferred to Berlin and subsequently emigrated to the United States, where he later reported original experimental work on learning, described in a book entitled *Productive Thinking* (1945; enlarged edition 1959).

WHITEHEAD, ALFRED NORTH (1861-1947). Born in London and educated at Sherborne and Trinity College, Cambridge, Whitehead was both a

mathematician and philosopher. He was coauthor, with Bertrand Russell, of *Principia Mathematica* (1910-13), yet he differed greatly from Russell in his philosophy, as he was an idealist. His main works are: *Process and Reality* (1929); *Adventures of Ideas* (1933); and *Modes of Thought* (1938). He was elected Fellow of the Royal Society in 1903 and appointed to the Order of Merit in 1945.

WIENER, NORBERT (1894-1964), American mathematician of international stature, born at Cambridge, Massachusetts. He joined the faculty of the Massachusetts Institute of Technology at the age of 25, and worked extensively on problems in the mathematics of electrical engineering, and especially on nonlinear problems. Much of this work was later published in *Nonlinear Problems in Random Theory* (1958). His exceptional talents as a mathematician were evident very early; he graduated from Tufts University at the age of 14 and won his doctorate from Harvard at 18. His range of activities included work on assemblages, functions of a real variable, mathematical logic, relativity, quantum theory, and the Fourier integral and many of its applications. Late in the 1930s he became increasingly interested in biological and social problems, and formed a group with Arturo Rosenblueth, who was then at the Harvard Medical School. The group included philosophers, anthropologists, sociologists, psychologists, physiologists, mathematicians, and electrical engineers. Their meetings were concerned with scientific method and the unification of science; they continued until 1944, when Rosenblueth went to Mexico, and from them came the concept of cybernetics. This dates from 1942 but was not named 'cybernetics' until 1947. It was defined generally as 'the science of control and communication in the animal and the machine', but the clear idea was that 'animal' included human being.

The idea of cybernetics arose not only from the integration of science to include all aspects of scientific activities; it was inspired also by the development of the computer which was taking place at the same time under the influence of Von Neumann, Turing, and others. It was affected too by the development of information theory, work on which had emanated from the Bell Telephone Company under the influence of C. E. Shannon and W. Weaver. This work described the principles involved in communication between any 'source' and 'sink'. Meaning was irrelevant to the measurement of information encoded, transmitted, and decoded, in a possibly noisy channel. Channel capacity and optimum coding procedures were all considered, and the whole development was incorporated into the cybernetic mode of thought.

Wiener himself made use of time series and other statistical techniques, also involving Gibbsian theory. Information and its processing, in all its aspects, was seen to apply to a wide range of phenomena both organic and inorganic, including human speech, genetics, the nervous system, and the muscular system. Philosophical issues were involved in cybernetics, since vitalism was brought into the cybernetic view and its world was thought of as one of Bergsonian time rather than Newtonian.

Mathematically, Wiener brought group theory and statistical mechanics into the picture and made it a

part of the bulwark of what was primarily an attempt to show that man was a complex 'machine'. The language of the computer (originally binary code) was likened to the language of the nervous system and gave rise to the development of automata known as logical nets. This was carried out by two other members of the cybernetic group, Warren*McCulloch and Walter Pitts.

Yet another component of the cybernetic viewpoint was that of servosystems. It was recognized that*feedback was essential to learning, and that the sort of adaptive control typified by a thermostat must operate in all animals, and especially human beings. It was recognized too that there were higherlevel feedbacks which, as it were, adjusted the thermostat settings. The idea of man being a 'machine' had existed for years before Wiener's cybernetics. Democritus in early Greek times, Diderot,*Helvetius,*La Mettrie, and many others, including Mark Twain, had thought the same, but Wiener was the first person to give genuine evidence to support such a view. He saw human beings as encompassed by the same basic principles as other animals, and this included selforganization and selfreproduction.

Wiener pointed out some of the social dangers of cybernetics in *The Human Use of Human Beings* (1950); and it is now well known that science and technology have contributed, as he foresaw, to unemployment and to the need to reconstruct our society to allow for social evolution. He spent his last years working on the applications of cybernetics to human thinking, notably in areas where the detail was immensely complicated. Not only did he see the need for economic and social change, but he worked in more immediately practical fields, particularly in artificial limbs, thus showing the enormous range of cybernetics. This range of application, from the abstract to the particular, led to fragmentations such as biocybernetics, engineering cybernetics, neurocybernetics, and sociocybernetics.

Wiener also wrote a number of articles, with Rosenblueth and Julian Bigelow, on the philosophical aspects of cybernetics. The most controversial of these dealt with teleology as purposiveness, and attempts to justify a relatively simple feedback control system as necessary to scientific explanation. That teleological explanation is now widely accepted, as part of scientific explanation, is due mainly to him, even if the precise detail of such a form of explanation is still controversial and goes beyond what he originally envisaged. There are now new subdivisions of cybernetics in which automata theory is more

Page 811

developed mathematically, though the dose association with philosophy is maintained. The central core of Wiener's cybernetics has been developed under the label*'artificial intelligence'. This has taken over the concept of 'man as a machine' and, with it, extensive theories of*sensation,*perception,*learning,*thinking,*problemsolving, and language, have been built up, all in mathematical and 'machinelike' terms. Wiener's most famous book, *Cybernetics* (1947; revised edn. 1961), started a scientific revolution which has, as he would have wished, evolved and grown, and yet retains the central idea that human beings, however highly complex and sophisticated they might be, are 'machines' in that they can, in principle, be built in the laboratory.

WIESEL, TORSTEN NILS (1924), Swedishborn physiologist. See HUBEL AND WIESEL: JOINT WORK.

WILLED ACTION. See FREE WILL for references.

WINNICOTT, DONALD (18961971), British paediatrician, child psychiatrist and psychoanalyst. See FREUDIANISM: LATER DEVELOPMENTS.

WITTGENSTEIN, LUDWIG JOSEF JOHANN (18891951). Born in Vienna, the son of h wealthy engineer, he studied engineering at Berlin and at Manchester (190811), where he designed a propeller. Here he became interested in mathematics and logic, which he studied under Bertrand*Russell at Cambridge from 1912 to 1913. He served in the Austrian artillery during the First World War, was captured, and ended the war in a prisoneroftwar camp near Monte Cassino, where he wrote the *Tractatus LogicoPhilosophicus* (Leipzig, 1921; published with parallel EnglishGerman text in 1922 with an introduction by Russell). Wittgenstein taught in a village school in Austria from 1920 to 1926, worked in a monastery garden, and then, after designing a house for his sister, returned to philosophy at Cambridge.

He was a Fellow of Trinity College from 1930 to 1936, and professor from 1939 to 1947. For part of this time he did war service as a porter in Guy's Hospital, London. He became a naturalized British subject in 1938.

He lived austerey in his college rooms. It is said that he only dined once in the college hall, finding the conversation dull. His room was furnished with deckchairs for his students and a fireproof safe for his papers. After a lengthy illness, during much of which he lived in Ireland, he died in Cambridge on 29 April 1951.

Wittgenstein's main works are: *Notebooks 191416* (repr. 1961); *Tractatus LogicoPhilosophicus* (1922); *Philosophical Remarks* (1930; repr. 1975);

Philosophical Grammar (1974; completed in 1933); *The Blue and Brown Books* (1958; compiled from lecture notes of the period 19335); *Remarks on the Foundations of Mathematics* (1956; compiled from notes of the period 193744); *Philosophical Investigations* (1953).

WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE. The philosophy of language gives a general account of the nature and function of language. The central question that it tries to answer is, 'What is meaning?' It is closely connected with the philosophy of mind, because language expresses things that are in the mind, such as thoughts and intentions. More generally, whatever the functions of language, their performance depends on constancy of meaning, and the preservation of this constancy is an intellectual achievement.

*Wittgenstein's philosophy developed in two stages. His first theory of language is set out in *Tractatus LogicoPhilosophicus*, and his second in *Philosophical Investigations*. The first theory is mainly concerned with statements of fact, while the second is equally concerned with other uses of language. The first theory gives a very abstract account of factual discourse and says little about what goes on in the minds of its producers, whereas the second presents language, in all its uses, as part of human life, so that questions about meaning lead inevitably to questions about what goes on in people's minds.

It may seem surprising that Wittgenstein focused his first study on to factual discourse, because he certainly did not regard religion and morality as unimportant, or their statements as meaningless. The explanation is that his interest in the philosophy of language began when he was working on the foundations of logic and mathematics (see WITTGENSTEIN'S PHILOSOPHY OF LOGIC AND MATHEMATICS). For anyone who wants to understand how logical formulae achieve necessary truth must first understand how ordinary statements achieve contingent truth. The work already done by Gottlob Frege and Bertrand Russell on the foundations of logic and mathematics had made that very clear. Now factual statements are the most perspicuous kind, because the conditions under which they achieve truth are most easily understood. So given Wittgenstein's approach, it was natural for him to concentrate on them. He treated them in a very abstract way, because that is what logicians always do to language.

Factual discourse is also the dominant kind, and we tend to construe other kinds of discourse by reference to it, making either an assimilation or a contrast. According to the *Tractatus*, it mirrors the actual world by presenting it as it is, and alternative possible worlds by presenting them as they might be. Since it expresses everything that can be said, it sets a limit to what can be imagined or conceived. Beyond that limit there is nothing—i.e. nothing of the same kind, only better. There are facts and possibilities, and, beyond them, nothing.

This seems to imply that all nonfactual discourse is meaningless. But Wittgenstein distinguished two ways of understanding. In order to understand a factual statement, you have to know its sense, i.e. the possibility which, if it were actualized, would make it true. Other kinds of statement lack sense, but they are not, therefore, meaningless, like jumbled factual messages. They achieve meaning by revealing certain features of the world and human life. This is the mystical element in Wittgenstein's early philosophy.

His reconciliation of the competing claims of scientific understanding and other modes of

apprehension is *Kantian in spirit. The novelty is that it is presented as part of a theory of language. Factual discourse stretches to the extreme limit of what we can understand, but only on one level. There is also another, deeper level of discourse, which can be construed only by contrast with factual discourse, because assimilation would render it meaningless. For example, religious statements must not be construed as factual statements of a special kind.

The distinguishing mark of a factual statement is, according to the *Tractatus*, its pictorial character. The words that make up the statement are correlated with things in the world, just as the points on a map are correlated with points on the ground. The arrangement of the words reveals how the things are arranged, if the statement is true, and the statement says that they are so arranged, truly, if they are. The analogy with the kind of picture that is used to convey factual information is obvious. But Wittgenstein generalized the obvious analogy, because he did not think that the words and their arrangement have to be *like* the things and their arrangement. All that he thought necessary is that the statement should have the same form as the fact that it reports. The shared form is spatial in the case of a map, but it need not be spatial, because it could be purely logical. So the analogy between factual statements and informative pictures is a very abstract one.

This theory differs from Frege's, because Wittgenstein takes assertion to be an essential part of a statement, which possesses sense only because it is a shot at the truth. It also differs from Russell's theory, which treated logical forms as things with which we are acquainted, albeit in a Platonic way. The central point of Wittgenstein's theory is that logical form can neither be named nor described. It is inherent in reality, and it can only be revealed in language. So his mysticism touches the centre of his theory of factual discourse.

His later philosophy of language is very different. It does not draw a single line dividing factual discourse from the rest. Language is now presented as something multiply variegated, the nature of each variety being determined by its function. There is no longer any attempt to impose a system on the phenomena. All theorizing is avoided and its place taken by careful description of different uses of language ('language games'). Although the description is untheoretical, it is not undirected, because it is designed to check our endemic tendency to misunderstand the logic of our language. That had been one of the aims of the *Tractatus* too. What is new is the method, which is not to seek a profound, abstract theory, but, rather, to sift the details that lie open to view on the surface of language. So *Philosophical Investigations* is a contribution to *Geisteswissenschaft*. The enquiry traverses some of the territory of psychology, and even sociology, but the purpose is philosophical, viz. to understand how we mean what we mean by what we say.

When language is examined in its natural setting, as a part of human life, questions about meaning lead inevitably to questions about what goes on in people's minds.

What does someone else mean by those words? How do you know what he means? How do you even know what you yourself meant by a particular word in the past? These questions all lead into the subject that dominates Wittgenstein's later philosophy of language, the preservation of constancy of meaning by individuals and by cultures.

The early account of factual language relied on correlations between words and things. But how were the correlations to be maintained? A natural answer is that the speaker must follow a rule. However, Wittgenstein makes the important point that a rule is not like the mechanism of a clock, which forces the hands to move as they do. You may have internalized a rule governing the use of a particular word, but the internalized rule still needs to be interpreted, and any interpretation will be verbal and so will need to be interpreted in its turn. Perhaps it looks as if we could cut out all problems of interpretation by going straight to your actual applications of the word. But many of them lie in the future, and Wittgenstein argues that nothing that is in your mind now determines exactly how you will apply the word in the future.

What you have internalized is not a programme of the kind that can be inserted in a machine.

What is in your mind now does not rigidly predetermine your use of the word, the same will be true of other people too. But this seems to threaten communication.

For how can you be sure that what is in the mind of someone who claims to understand you is the same as what was in your mind when you spoke? Would not improvisation make all communication impossible?

Wittgenstein rejects the theory on which these questions are based. If the meaning of a word, as used by you, had to conform to a kind of template in your mind, communication would indeed be impossible. For when you were using the word, the difference between fidelity and improvisation could not be detected by others.

Even you could not be sure of it, because the template might have

Page 813

changed without your noticing the change. So he suggests, instead, that two people agree about the meaning of a word when they agree, and see that they agree, in their applications of it. This may sound like behaviourism, but in fact there is no repudiation of mental events and processes. The point is only that the contact that keeps the meaning of a word the same for different people is public and part of the life that they live together.

It follows that communication about what occurs in people's minds is possible only if they already share a language for describing what occurs outside their minds. For a vocabulary with the first of these two functions necessarily depends on a vocabulary with the second one (see WITTGENSTEIN'S PHILOSOPHY OF MIND).

This argument against the possibility of a 'private language'—i.e. a completely independent language for describing the contents of the mind—is the key to Wittgenstein's later theory of meaning.

D. F. P.

WITTGENSTEIN'S PHILOSOPHY OF LOGIC AND MATHEMATICS. Both logic and

mathematics are concerned with connections of thought—for example, the connection between the information that there are two heaps of walnuts on the table, each containing twelve nuts, and the conclusion that there are twentyfour nuts on the table. This is a necessary connection. It is, perhaps, discovered by experience, but it certainly is not vulnerable to experience. Anyone who claimed to have found that it broke down in certain cases would be told that he did not understand arithmetic. The necessity of a mathematical equation, such as $12 +$

$12 = 24$, is quite different from the universal truth of the contingent statement that no walnut weighs a pound. The same is true of the necessities of logic. Experience could never upset the hypothetical statement that, if no walnut weighs a pound, and if you have chosen a walnut, then what you have chosen does not weigh a pound.

If a discipline invokes special ideas, or things of a special kind, its philosophy must explain them. Logic and mathematics evidently do introduce new kinds of things, such as numbers and the logical forms of sentences. But the most fundamental idea that is peculiar to these two disciplines is the idea of necessity. What is the nature of the necessity of a mathematical equation or a logical formula? And how do we know about it? Wittgenstein's philosophy of logic and mathematics is mainly a search for answers to these two questions.

Like his other philosophy, it divides into two stages. His first account of logic and mathematics is given in the *Tractatus LogicoPhilosophicus*, and his later ideas are developed in *Philosophical Remarks*, *Philosophical Grammar*, and *Remarks on the Foundations of Mathematics*. The most striking feature of both accounts is his preoccupation with applied logic and mathematics. In the examples used above, a mathematical equation enabled us to answer the question, how many nuts there were on the table, without combining the two heaps and counting again, and a logical formula enabled us to answer the question, whether a particular nut weighed a pound, without actually weighing it. Wittgenstein always kept this kind of application in the centre of the picture. In fact, it is arguable that he did not pay enough attention to pure mathematics or pure logic.

His preoccupation with applied logic and mathematics is most conspicuous in his later work, which treats language as part of human life and investigates it in its natural setting (see WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE). But though his early work is more abstract, and, therefore, less concerned with the actual uses of language, one of its leading ideas already points towards the later developments. Logicians often assume that their job is to prove the formulae that are used in everyday life, but in the *Tractatus* Wittgenstein argues that such proofs achieve nothing, and, anyway, are not needed. This is directed against Gottlob Frege and Bertrand*Russell, who both assumed that applied logic relies on pure logic to ratify its formulae by deducing them from the smallest possible set of axioms.

First, consider what, if anything, such proofs achieve. Suppose that the candidate to be proved is the logical formula used above, viz. 'If no A is B, and if this is an A, then this is not B'. You choose a set of axioms, and, using them as premisses, you set out to prove this particular formula. But even if you are successful, Wittgenstein points out that your achievement will be limited. You will know that, if your axioms are necessary truths, then this formula too is a necessary truth. But how will you know

whether your axioms are necessarily true? It is no good saying that they are selfevident, as Russell did. For we have no criterion of selfevidence, and, if we are going to rely on it in the end, we might as well appeal to it immediately and say that the formula itself is selfevident.

Wittgenstein's second thesis, that in any case such proofs are not needed, is based on the idea that the necessary connection between premisses and conclusion in an ordinary valid argument, like the one set out above, is guaranteed by their structures. They simply fit together, like the pieces of a jigsaw puzzle, and there is no need for any formula, or instruction for fitting them together, still less for a proof of the formula itself. Such devices seem to be needed only because ordinary language is not perspicuous and does not reveal the structures of the thoughts that it expresses. Consequently, we feel unable to do the jigsaw puzzle without more apparatus. But Wittgenstein regards this as an illusion. If we had a perspicuous language, we would see that 'logic takes care of itself'. If q follows from p , this can be read off from the structures of the two sentences, once they have been made perspicuous.

The idea of a perfectly perspicuous language is one that Wittgenstein borrows from Frege and Russell and uses against them. He also rejects their Page 814

theory that mathematics is an extension of logic, involving no new ideas and dealing with no new kinds of things (the theory known as 'logicism'). He thinks that mathematics too takes care of itself. For the necessary connection expressed by an equation is guaranteed by the structures of the expressions flanking the sign for equality.

This assignment of an autonomous status to mathematics is another feature that points towards later developments. His hostility to logicism continued, and he came to see mathematics itself as a group of separate, autonomous disciplines, or, to use his word for it, 'a motley'. The new view was a consequence of the general reorientation of his philosophy. He gave up the idea that philosophers should seek systematic theories, and came to think that their task is to describe our modes of thought, or 'language games', in all their variety. In each of them it is possible to distinguish correct from incorrect performances, but the appeal is always to a criterion that is internal to the practice, and never to one that is fixed independently of it.

The new conception of the philosophy of logic and mathematics led to changes that are difficult to assess. His emphasis on application is increased, but there seems to be a complete change in his account of necessity. His early theory was that necessity depends on structure, and we give a sentence its structure by determining its truthconditions, i.e. the contingencies that would make it true. The early theory was that, when we have fixed the semantics of sentences in this way, we have already determined whether they are necessarily connected with one another or not, and there is nothing more that we can do about it. His later view seems to be that there is something more that we can do about it: we can ratify, or refuse to ratify, the connection as a necessary one.

If we really do have this option, proof is not what it seems to be. In the argument about the weight of the nut it seems to trace a necessary connection that is predetermined by the semantics of three sentences. This is, of course, a proof in the application of logic (or of mathematics in the other example). But proofs in the pure disciplines seem to run on equally predetermined lines. However,

Wittgenstein appears to be denying predetermination in both kinds of case. If he meant the denial literally, he would be making logic and mathematics completely unsystematic. Every move would be autonomous, and the theory would be extreme conventionalism.

It is difficult to divine the precise meaning of his new, paradoxical view of necessity. This is partly because we try to relate it to other contemporary theories, such as intuitionism or strict finitism. But the chief reason is that he is making a profound suggestion, which is designed to change our whole conception of language and thought, without changing the ways in which we actually speak and think. His suggestion is that the concept of following a rule, which is fundamental in the philosophy of language, is not what it seems to be. It seems that there is something in the mind of a person who is following a rule which determines what will count as following it in the future. But Wittgenstein regards this as an illusion. If he is right, we were wrong in thinking that, when we fix the semantics of a sentence, we predetermine everything. On the contrary, there will still be options left open. So the later development of Wittgenstein's philosophy of language is the key to his new philosophy of logic and mathematics. Some problems of interpretation still remain baffling, but it does open many doors.

D. F. P.

WITTGENSTEIN'S PHILOSOPHY OF MIND. Psychology occupies a central position among the sciences, because everything about which we know anything is filtered through the mind. For the same reason the philosophy of mind stands at the centre of all philosophy. The difference between psychology and the philosophy of mind is that the latter is not concerned with scientific questions but concentrates on questions of the utmost generality. For example, the question why people are aggressive is for psychologists to answer, but the philosopher asks, 'What is a motive?' and, 'What sort of thing is an unconscious motive?' For his interest is in the general nature of mental phenomena. He also asks how we know what goes on in people's minds, and the history of*behaviourism shows that the two questions are, at least, connected.

Given the central position of the philosophy of mind, it is surprising how little discussion it gets in*Wittgenstein's early works (*Notebooks 1914/16*, and *Tractatus LogicoPhilosophicus*). This is because they are concerned mainly with the philosophy of language, approached through logic and mathematics (see WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE and WITTGENSTEIN'S PHILOSOPHY OF LOGIC AND MATHEMATICS). In them Wittgenstein developed a theory of meaning based on an analogy between sentences and pictures. These things mirror the world, but he said very little about what goes on in the minds of people who use them. He believed that their unspoken thoughts must have the same structure as their sentences, but he made no attempt to explain what a thought is. Such details, he supposed, could be left to psychologists. The philosopher only had to produce an abstract model of language and logic, without bothering about the way in which the model is exemplified in real life.

After he had published the *Tractatus* his view of philosophy changed. He came to think that it is impossible to understand the nature of language or of logical necessity without going down into the marketplace and finding out about people who use sentences and arguments. How do they endow them with meaning? And how do they succeed in understanding what is going on in each other's minds? His

later work (*Philosophical Remarks*, *Philosophical Grammar*, *The Blue and Brown Books*, and *Philosophical Investigations*) is mainly an attempt to find answers to these questions.

Page 815

This may seem surprising, because the questions appear to be for psychologists rather than philosophers. Surely if you want to know what goes on in the minds of people who use language, you should construct a scientific theory about it and test it against the empirical evidence. So how does the philosopher come into it? The short answer, already given, is that he is concerned with very general problems about mental phenomena. But though this is true, it does not tell us about the specific character of Wittgenstein's philosophy of mind. It is equally true of the philosophy of mind of Spinoza, whose procedure was to define the mental and its various forms.

Wittgenstein's method is completely different. One of the dominant themes of his later philosophy is the futility of definitions. He accepted the fact that the philosopher's interest in mental phenomena is general, but he did not draw the conclusion that his results should be general too. A philosopher who starts investigating meaning or understanding should not expect to be able to pack up his discoveries in neat definitions. On the contrary, he will find the answers to his general questions in individual cases. What he discovers will not be new facts, because he is not a scientist, but, rather, the significance of familiar facts. He will find the essence in its particular exemplifications, like an artist.

This method is well adapted to the philosophy of mind. For the distinctive characteristic of the mental is its infinitely subtle variegation. How else could it hold up a mirror to the world? If someone asks, 'How do people endow sentences with meaning and succeed in understanding one another?' the reaction might well be, 'It depends on what they are talking about'. This simple reaction is a natural one, because there is no reason to expect the same answer when they are talking about objects in their environment and when they are talking about their feelings. The aim of Wittgenstein's new method is to put us back in touch with familiar things in this case, with the familiar facts of our mental lives—from which we are so often alienated by false analogies.

This introduces two more themes which dominate his later philosophy. One is the variety of different modes of meaning, and the other is the therapeutic character of philosophy, which frees us from the grip of false analogies.

The second theme is especially important in the philosophy of mind. Take, for example, his treatment of the phenomenon of understanding. It is only too easy to be misled by the following piece of analogical reasoning. If A uses an ordinary word like 'blue', and B understands it, his understanding must be a mental process because it is not a physical one. Now we can often explain a physical process by pointing to some physical event that produces it. So in order to explain understanding, we should look for an introspectible mental event. The most likely candidate is the occurrence of an image of the colour in B's mind. So we are led to conclude that understanding essentially involves mental images.

Wittgenstein's therapeutic treatment of this case starts from the familiar fact, forgotten by this theory,

that quite often B has no mental image. Then he argues that, even when B has one, its occurrence does not explain his understanding. For in order to get the right image and know that he has got it, B must already understand the word 'blue', unless, of course, he got the right image by luck. But in that case he might have taken the word 'blue' to mean 'coloured' or anything under the sun.

More generally, Wittgenstein claims that understanding is not really a mental process at all. If you silently run through the dates of the kings of England, that is a mental process. But often there is nothing introspectible to mark the achievement of understanding. What counts is B's ability to operate with the word 'blue'. The idea that at the moment of understanding there must be mental events too quick to be introspected is a myth. It is the false analogy with physical phenomena that generates the myth, and the cure is to remind ourselves of the familiar facts of our mental lives, from which the analogy has alienated us. This is not behaviourism. Wittgenstein's point is not that there are no mental events or processes, but rather that we exaggerate their frequency, because we credit them with more explanatory power than they actually possess.

If philosophy is a kind of therapy designed to free us from bewitchment by false analogies, it will help us to recognize the variety of different modes of meaning, which was the first of the two themes mentioned just now. For we should be misled if we construed sentences about emotions or sensations on the analogy with sentences about physical phenomena. Wittgenstein's explanation of the differences between these two types of sentences is his main contribution to the philosophy of mind.

It begins, characteristically, with a thesis about meaning (see WITTGENSTEIN'S PHILOSOPHY OF LANGUAGE). Meaning must be kept constant, not only in order that A should be able to communicate with B, but also in order that A should be able to communicate with himself across an interval of time—for example, in his diary. But A's use of the word 'blue' cannot be kept constant by reference to anything fixed in his mind, because there are no reliable mental templates. If A's template were a mental image of the colour, it could change without his noticing any change. Even if it did not change, it would not rigidly predetermine his applications of the word 'blue' to other things. It is really the other way round: his public applications of the word to physical objects determine the character of the images that he accepts as 'blue'. So even if he did rely on a private image when he applied the word to a physical object, his appeal to it would not be final, because there would always be the further question, whether he had appealed to the right

Page 816

image, viz. to a blue one, rather than to one that he was inclined, rightly or wrongly, to call 'blue'.

If the meaning of the word 'blue' is kept constant by its public applications, B's understanding of A's meaning is no longer the unverifiable miracle that it would be on the theory of private mental templates. But what about words like 'pain' and 'anger', which, unlike the word 'blue', are applied exclusively to mental phenomena?

Wittgenstein argues that here too constancy of meaning is preserved by public criteria. But in these cases, which are typical cases of mental phenomena, there is a complication. The words 'pain' and

'anger' are not used to *describe* their public criteria, and yet it is the meanings of *these* words that their public criteria keep constant. Much of Wittgenstein's philosophy of mind is devoted to explaining how this feat is achieved.

D. F. P.

WOODWORTH, ROBERT SESSIONS (1869-1962). American psychologist, born in Belcher Town, Massachusetts, and educated at Amherst College, where he graduated in philosophy. He proceeded to Harvard for his graduate studies, where he worked with William*James, Josiah Royce, and George Santayana, and completed his doctoral thesis *On the Accuracy of Voluntary Movement*. After working for a time as assistant in physiology at Harvard, Woodworth worked briefly in SharpeySchäfer's laboratory in Edinburgh and returned to England two years later as a senior demonstrator in physiology and as an assistant to C. S.*Sherrington at Liverpool, where he published a paper on 'The Electrical Conductivity of Mammalian Nerve'.

On his final return to America, Woodworth was appointed to an instructorship in psychology under James McKeen*Cattell at Columbia University, where he collaborated with E. L.*Thorndike, who shared his interest in the measurement of individual differences. He became professor of psychology in 1909 and was elected president of the American Psychological Association in 1914.

Apart from his work on individual differences and his attempt during the First World War to devise objective tests of emotional stability, Woodworth's contributions to research were somewhat meagre. He was, however, a prolific writer, his *Dynamic Psychology* appearing in 1918 and his massive *Experimental Psychology* in 1938 (revised edition 1954). His popular, though thoughtful, *Contemporary Schools of Psychology* was first published in 1931 and went into several editions.

Woodworth edited a monograph series from Columbia entitled *Archives of Psychology* from 1906 to 1948. He published one book in French, *Le Mouvement*, in 1903.

WORDBLINDNESS. See ALEXIA.

WUNDT, WILHELM MAX (1832-1920). Wilhelm Wundt, the 'father' of experimental psychology, was born at Neckerau in Baden and educated at Tübingen and Heidelberg. He studied physiology at Berlin with Johannes*Müller and Du BoisReymond before qualifying in medicine at Heidelberg, where he became a *docent* in physiology shortly before Hermann von*Helmholtz's arrival as professor and head of the physiology department. Although Wundt held Helmholtz in high esteem, it seems probable that the two men were never close. Whereas Helmholtz did not regard himself explicitly as a psychologist, Wundt became increasingly preoccupied with philosophical and psychological issues and for many years held lectures on psychology directed primarily at students of philosophy.

Wundt's most important book is *Grundzüge der Physiologische Psychologie*, which was first published in 1873 and went into six editions. It presented psychology as an independent scientific discipline complementary to anatomy and physiology though in no sense reducible to them. The first

and largest part of the fifth edition was translated into English by his former doctoral student and great admirer, Edward**Titchener*, under the title of *Principles of Physiological Psychology*.

Although it has been said that, in this book, anatomy and physiology were only marginally related to psychology, the book none the less established the principle that experimental psychology will find its future in close alliance with the anatomy and physiology of the central nervous system.

Wundt was appointed professor of physiology at Leipzig in 1875 and, in the same year, established the first laboratory in the world expressly dedicated to the advancement of experimental psychology: the Institute for Experimental Psychology. This laboratory very soon became a focus for those who held a serious interest in psychology, at first mainly for those who had studied philosophy and psychology in other German universities, but soon for graduates of several American and a few British universities. All subsequent psychological laboratories were closely modelled in their early years on the Wundt model.

Understandably, the activities of Wundt's laboratory closely reflected both the physiological background and the more recent philosophical preoccupations of its founder. On the more philosophical side, these were represented by the study of attention and what, following J. F.**Herbart*, was termed**apperception*; on the more psychological side, one might specify the study of sensory processes, psychophysics, and the measurement of reaction times.

In this approach to experiment in psychology, Wundt's subjects were invariably adults who had undergone an intensive training in the technique of introspection (as it was understood by Wundt) in order that the facts of immediately apprehended conscious experience should not be contaminated by previous knowledge or anticipation. Even though this alleged purity of introspective report

Page 817

was taken to extremes, bordering on the ridiculous, there is no doubt that it did provide a genuine training in precise and consistent subjective observation that contrasted strongly with the often haphazard and poorly controlled observations that had characterized much earlier work on sensory thresholds and**psychophysics*.

Whether, however, such an approach to scientific psychology is truly applicable to the investigation of human personality and its development, or to abnormal states of mind, is an altogether different and far more controversial affair. None the less, it is important to bear in mind that Wundt did not himself believe that experimental method is applicable to all aspects of human psychology. In particular, he had no doubt that our understanding of language and its development must be sought through our understanding of history and culture rather than through experimental analysis. Wundt himself wrote voluminously on such issues in his later years, though very little of this work has appeared in English. It is, however, clear that the 'founder of experimental psychology' was neither a reductionist nor a dualist and that he believed that the field of application of experiment in psychology was distinctly limited.

Wundt's autobiography, *Erlebtes und Erkanntes* (1920), gives a straightforward account of his life and career and describes in some detail the establishment of his Institute for Experimental Psychology. This narrative outlines in a most interesting way Wundt's relations with a number of his contemporaries, not least E. H.*Weber and G. T.*Fechner, both of whom resided in Leipzig and both of whom he came to know well, despite the fact that Weber was a very old man at the time when Wundt first made his acquaintance. Fechner, on the other hand, was still active and directly inspired some of the experimental work in psychophysics that Wundt set in train in his new laboratory.

O. L. Z.

For a reassessment of Wundt seen through modern eyes, see A. L. Blumenthal, 'A ReAppraisal of Wilhelm Wundt', *American Psychologist* (1975), pp. 1,0818.

Also relevant is R. W. Rieber (ed.) *Wilhelm Wundt and the Making of Modern Psychology* (1980), of particular interest is K. Danziger's chapter in this volume on

'Wundt's Theory of Behaviour and Volition'. An older, if possibly unduly fulsome, account of Wundt's psychological system and the work of his laboratory is to be found in E. G. Boring, *History of Experimental Psychology*, 1st edn. (1925), ch. 15.

Page 818

Y

YELLOW appears to be a primary or simple colour; but in fact it is signalled at the retina by a mixture of red and greensensitive (cone) receptors having overlapping spectral sensitivity. This is a warning that it is not possible to infer the simplicity of physiological mechanisms from the simplicity or apparent complexity of experience. It shows indeed the fallibility of introspection for understanding functions of the nervous system, if not of the mind.

See COLOUR VISION; YOUNG.

YOUNG, THOMAS (17731829), British physician, physicist, and Egyptologist. Born at Milverton in Somerset he was, as the plaque to his memory in Westminster Abbey says, 'a man alike eminent in almost every branch of human learning, endowed with the faculty of intuitive perception, who, bringing an equal mastery to the most abstruse investigations of letters and science, first established the undulatory theory of light, and first penetrated the obscurity which had veiled for ages the hieroglyphics of Egypt'. This last he accomplished by studying the Rosetta stone in the British Museum.

Young suggested that*colour vision, as we might put it, is given by neural mixture from three retinal channels, tuned to different but overlapping spectral bands. The notion was developed by*Helmholtz into the YoungHelmholtz trichromatic theory of colour vision, which is now generally accepted as an account of the first stage of colour analysis. Young also was the first to measure (on his own eyes) astigmatism, which he (wrongly) accounted for by supposing the eye's lens to be tilted. He showed by

experiments (correctly) that accommodation to different distances is given by changing curvature of the anterior surface of the lens, and not by changes of curvature of the cornea.

He studied medicine at London, Edinburgh, Göttingen, and Cambridge, and he practised in London; but his main work was in research at the newly founded Royal Institution, where he became professor of natural philosophy in 1801. His optical experiments set the wave theory of light and phenomena of interference on a sound experimental and theoretical basis.

Young's classic paper 'On the Theory of Light and Colours' was delivered to the Royal Society, as the Bakerian lecture, on 12 November 1801, and printed in 1802

(*Philosophical Transactions*, 92, 12). His argument for only a few (three) primary colours is based on the consideration that visual acuity is almost normal in coloured light:

Now, as it is almost impossible to conceive each sensitive point of the retina to contain an infinite number of particles, each capable of vibrating in perfect unison with every possible undulation, it becomes necessary to suppose the number limited, for instance, to the three principal colours, red, yellow, and blue, of which the undulations are related in magnitude nearly as the numbers 8, 7, and 6; and that each of the particles is capable of being put in motion less or more forcibly, by undulations differing less or more from a perfect unison; for instance, the undulations of green light being nearly in the ratio of $6\frac{1}{2}$, will affect equally the particles in unison with yellow and blue, and produce the same effect as a light composed of those two species: and each sensitive filament of the nerve may consist of three portions, one for each principal colour.

In later papers, Young changed his 'principal' colours to red, green, and violet. The concept of 'principal' or 'primary' colours is a treacherous one, and he never fully grasped its multiple ambiguities. He was not, however, ensnared by one common error, that of supposing that the retinal receptors must have their greatest sensitivities at wavelengths which subjectively appear to us as 'pure' or 'unmixed' hues; but he did fall into a second common error, that of supposing that the three spectral regions that are conveniently used as primaries in colourmixing experiments are those which produce maximal activity in the three kinds of receptor. We now know that the cone receptors have their peak absorbances in the violet, the green, and the yellowgreen parts of the spectrum (see COLOUR VISION). A light that looks red is not a light that optimally excites the last of these three types of cone; rather it is a light that produces the maximum *ratio* of absorptions in the last two of these types, and such a light lies at a wavelength much longer than the wavelength of peak sensitivity of either of them. This realization did not come until the second half of the nineteenth century, and to this day the term 'primary colour' continues to obstruct the proper understanding of colour among nonspecialists.

Young's *A Course of Lectures on Natural Philosophy and the Mechanical Arts* (1807); new edition edited by Kelland in two volumes in 1845 is a useful source.

His complete papers were edited in three volumes in 1854 by Peacock and Leitch: *Miscellaneous Works of Dr. Thomas Young*.

Z

ZENO OF ELEA (5th century BC). Greek philosopher, celebrated for his Paradoxes of motion. These are: Achilles and the tortoise, the Flying Arrow, the Stadium, and the Row of Solids. They are well described by J. Burnet in *Early Greek Philosophy* (4th edn., 1930).

Zeno introduced the philosophical technique of trying to establish characteristics of reality—or at least of what cannot be real—from paradoxes.

The basis of the Paradoxes is that if a distance between A and B can be subdivided an infinite number of times, and an object travels from A to B by crossing successive points (subdivisions), then it must cross an infinite number of points—which would take an infinite time. Therefore, motion is impossible! The Paradoxes derive from the manner of expressing the problem. This is itself interesting, indicating the extreme importance of finding appropriate mathematical and logical kinds of description, as well as appropriate conceptual models for describing or explaining the physical world and mind.
